Preface

We live in a world powered by light, but much of the understanding of light was developed around the time of the French Revolution. Before the 1950s, optics technology was viewed as well established and there was little expectation of growth either in scientific understanding or in technological exploitation. The end of the Second World War brought about huge growth in scientific exploration, and the field of optics benefited from that growth. The key event was the discovery of methods for producing a source of coherent radiation, with the key milestone being the demonstration of the first laser by Ted Maiman in 1960. Other lasers, nonlinear optical phenomena, and technologies such as holography and optical signal processing, followed in the early 1960s. In the 1970s the foundations of fiber optical communications were laid, with the development of low-loss glass fibers and sources that operated in the wavelength region of low loss. The 1980s saw the most significant technological accomplishment: the development of efficient optical systems and resulting useful devices. Now, some forty years after the demonstration of the first coherent light source, we find that optics has become the enabling technology in areas such as:

- information technology and telecommunications;
- health care and the life sciences;
- sensing, lighting, and energy;
- manufacturing;
- national defense;
- manufacturing of precision optical components and systems; and
- optics research and education.

We find ourselves depending on CDs for data storage, on digital cameras and printers to produce our family photographs, on high speed internet connections based on optical fibers, on optical based DNA sequencing systems; our physicians are making use of new therapies and diagnostic techniques founded on optics.

To contribute to such a wide range of applications requires a truly multidisciplinary effort drawing together knowledge spanning many of the traditional academic boundaries. To exploit the accomplishments of the past forty years and to enable a revolution in world fiber-optic communications, new modalities in the practice of medicine, a more effective national defense, exploration of the frontiers of science, and much more, a resource to provide access to the foundations of this field is needed. The purpose of this Encyclopedia is to provide a resource for introducing optical fundamentals and technologies to the general technical audience for whom optics is a key capability in exploring their field of interest.

Some 25 internationally recognized scientists and engineers served as editors. They helped in selecting the topical coverage and choosing the over 260 authors who prepared the individual articles. The authors form an international group who are expert in their discipline and come from every part of the technological community spanning academia, government and industry. The editors and authors of this Encyclopedia hope that the reader finds in these pages the information needed to provide guidance in exploring and utilizing optics.

As Editor-in-Chief I would like to thank all of the topical editors, authors and the staff of Elsevier for each of their contributions. Special thanks should go Dr Martin Ruck of Elsevier who provided not only organizational skills but also technological knowledge which allowed all of the numerous loose ends to be tied.

Introduction

The breakthrough of optical amplification, combined with the techniques of wavelength division multiplexing (WDM) and dispersion management, have made it possible to exploit a sizeable fraction of the optical fiber bandwidth (several terahertz). Systems based on 10 Gbit/s per channel bit-rate and showing capacities of several terabit/s, with transmission capabilities of hundreds or even thousands of kilometers, have reached the commercial area.

While greater capacities and spectral efficiencies are likely to be reached with current technologies, there is potential economic interest in reducing the number of wavelength channels by increasing the channel rate (e.g., 40 Gbit/s). However, such fourfold increase in the channel bit-rate clearly results in a significant increase in propagation impairments, stemming from the combined effects of noise accumulation, fiber dispersion, fiber nonlinearities, and inter-channel interactions and contributing to two main forms of signal degradation. The first one is related to the amplitude domain; power levels of marks and spaces can suffer from random deviations arising from interaction between signal and amplified spontaneous emission (ASE) noise or with signals from other channels through cross-phase modulation (XPM) from distortions induced by chromatic dispersion. The second type of signal degradations occurs in the time domain; time position of pulses can also suffer from random deviations arising from interactions between signal and ASE noise through fiber dispersion. Preservation of high power contrast between '1' and '0', and of both amplitude fluctuations and timing jitter below some acceptable levels, are mandatory for high transmission quality, evaluated through bit-error-rate (BER) measurements or estimated by Q-factors. Moreover, in future optical networks, it appears mandatory to ensure similar but high optical signal quality at the output of whatever nodes in the networks, as to enable successful transmission of the data over arbitrary distance.

Among possible solutions to overcome such systems limitations is the implementation of Optical Signal Regeneration, either in-line for long-haul transmission applications or at the output of network nodes. Such Signal Regeneration performs, or should be able to perform, three basic signal-processing functions that are Re-amplifying, Re-shaping, and Re-timing, hence the generic acronym '3R' (**Figure 1**). When Re-timing is absent, one usually refers to the regenerator as '2R' device, which has only re-amplifying and re-shaping capabilities. Thus, full 3R regeneration with retiming capability requires clock extraction.

Given system impairments after some transmission distance, two solutions remain for extending the actual reach of an optical transmission system or the scalability of an optical network. The first consists in segmenting the system into independent trunks, with full electronic repeater/transceivers at interfaces (we shall refer to this as 'opto-electronic regeneration' or O/E Regeneration forthwith). The second solution, i.e., all-optical Regeneration, is not the optical version of the first which would have higher bandwidth capability but still performs the same signal-restoring functions with far reduced complexity. At this point, it should be noted that Optical 3R techniques are not necessarily void of any electronic functions (e.g., when using electronic clock recovery and O/E modulation), but the main feature is that these electronic functions are narrowband (as opposed to broadband in the case of electronic regeneration).

Some key issues have to be considered when comparing such Signal Regeneration approaches. The first is that today's and future optical transmission systems or/and networks are WDM networks.

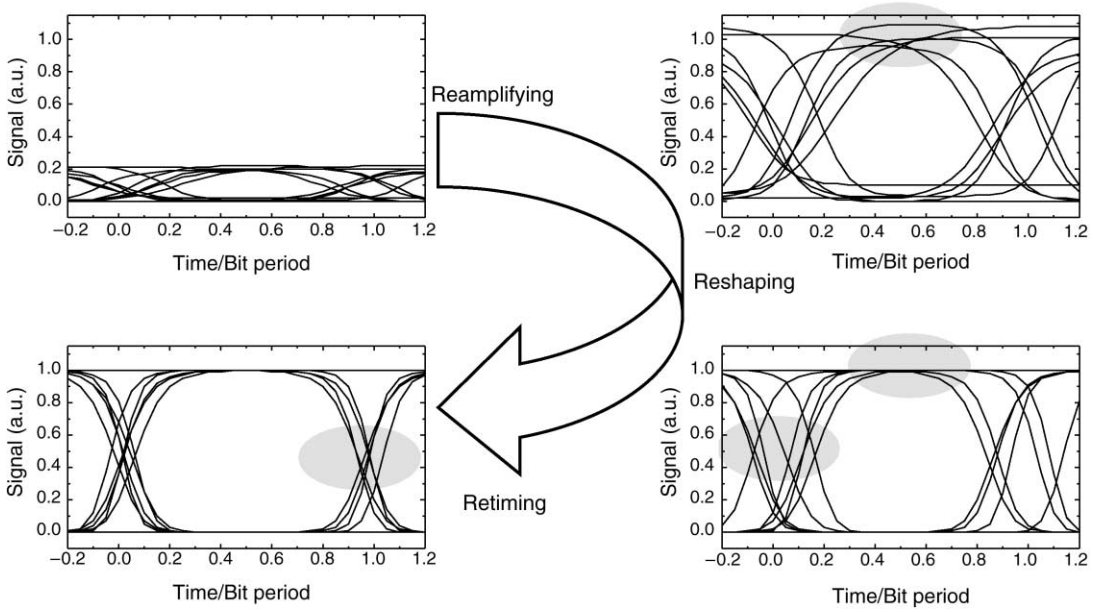

Figure 1 Principle of 3R regeneration, as applied to NRZ signals. (a) Re-Amplifying; (b) Re-Shaping; (c) Re-Timing. NB: Such eye diagrams can be either optical or electrical eye diagrams.

Under this condition, the WDM compatibility – or the fact that any Regeneration solution can simultaneously process several WDM channels – represents a key advantage. The maturity of the technology – either purely optical or opto-electronic – also plays an important role in the potential (pre-)development of such solutions. But the main parameter that will decide the actual technology (and also technique) relies on the tradeoff between actual performance of the regeneration solutions and their costs (device and implementation), depending on the targeted applications (long-haul system, medium haul transport, wide area optical network, etc.).

In this article, we review the current alternatives for all-optical Signal Regeneration, considering both theoretical and experimental performance and practical implementation issues. Key advantages and possible drawbacks of each solutions are discussed, to sketch the picture in this field. However, first we must focus on some generalities about Signal Regeneration and the way to define (and qualify) such regenerator performance. In a second part, we will detail the currently-investigated optical solutions for Signal Regeneration with a specific highlight for semiconductor-based solutions using either semiconductor optical amplifiers (SOA) technology or newly-developed saturable absorbers. Optical Regeneration techniques based on synchronous modulation will also be discussed in a third section. The conclusion will summarize the key features of each solution, so as to underline the demanding challenge optical components are facing in this application.

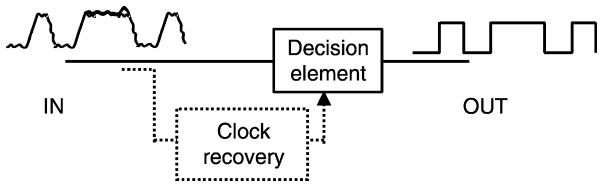

Figure 2 Generic structure of Signal 2R/3R Regenerator based on Decision Element (2R) and Decision Element and Clock Recovery (3R).

Generalities on Signal Regeneration

Principles

In the general case, Signal Regeneration is performed using a decision element exhibiting a nonlinear transfer function. Provided with a threshold level and when associated with an amplifier, such an element then performs the actual Re-shaping of the incoming data (either in the electrical or optical domain) and completes a 2R Signal Regenerator. Figure 2 shows the generic structure of such a Signal Regenerator in the general case as applied to non return to zero (NRZ) data. A clock recovery block can be added (dotted lines) to provide the decision element with time reference and hence perform the third R (Re-timing) of full Signal 3R Regeneration. At this point, it should be mentioned that the decision

element can operate either on electrical signals (standard electrical DFF) provided that optical → electrical and electrical → optical signal conversion stages are added or directed onto optical signals using the different techniques described below. The clock signal can be of an electrical nature, as for electrical decision element in O/E regenerator – or either an electrical or a purely optical signal in all-optical regenerators.

Prior to reviewing and describing the various current technology alternatives for such Optical Signal Regeneration, the issue of the actual characterization of regenerator performance needs to be explained and clarified. As previously mentioned, the core element of any Signal Regenerator is the decision element showing a nonlinear transfer function that can be of varying steepness. As will be seen in Figure 3, the actual regenerative performance of the regenerator will indeed depend upon the degree of nonlinearity of the decision element transfer function.

Figure 3 shows the principle of operation of a regenerator incorporating a decision element with two steepnesses of the nonlinear transfer function. In any case, the '1' and '0' symbols amplitude probability densities (PD) are squeezed after passing through the decision element. However, depending upon the addition of a clock reference for triggering the decision element, the symbol arrival time PD will be also squeezed (clocked decision = 3R regeneration) or enlarged (no clock reference = 2R regeneration) resulting in conversion of amplitude fluctuations to time position fluctuations.

As for system performance – expressed through BER – regenerative capabilities of any regenerator simultaneously depend upon both the output amplitude and arrival time PD of the '1' and '0' symbols. In the unusual case of 2R regeneration (no clocked decision), a tradeoff has then to be derived, considering both the reduction of amplitude PD and the enlarged arrival time PD induced by the regenerator, to ensure sufficient signal improvement. In Figure 3a, we consider a step function for the transfer function of the decision element. In this case, amplitude PD are squeezed to Dirac PD after the decision element, and depending upon addition or not of a clock reference, arrival time PD is reduced (3R) or dramatically enlarged (2R). In Figure 3b, the decision element exhibits a moderately nonlinear transfer function. This results in an asymmetric and less-pronounced squeezing of the amplitude PD compared to the previous case, but in turn results in a significantly less enlarged arrival time PD when no clock reference is added (2R regeneration). Comparison of these two decision element of different nonlinear transfer function indicates that for 3R regeneration applications, the more nonlinear the transfer function of the decision element the better performance, the ideal case being the step function. In the case of 2R regeneration applications, a tradeoff between the actual reduction of the amplitude PD and enlargement of timing PD is to be derived and clearly depends upon the actual shape of the nonlinear transfer function of the decision element.

Qualification of Signal Regenerator Performance

To further illustrate the impact of the actual shape of the nonlinear transfer function of the decision

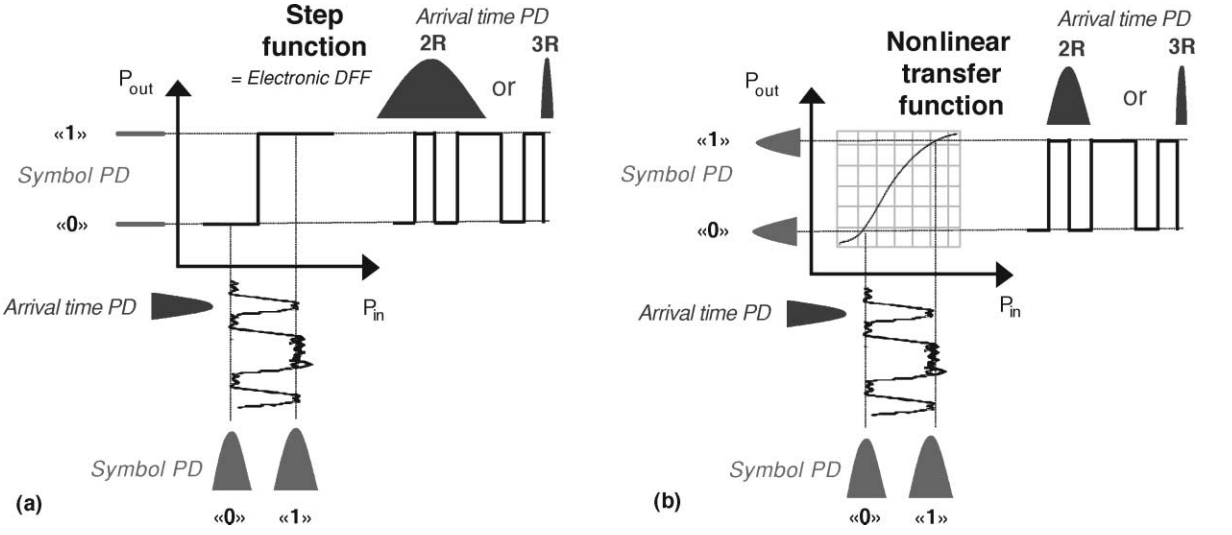

Figure 3 Signal Regeneration process using Nonlinear Gates. (a) Step transfer function (= Electronic DFF); (b) 'moderately' nonlinear transfer function. As an illustration of the Regenerator operation '1' and '0' symbols amplitude probability density (PD) and arrival time probability density (PD) are shown in light gray and dark gray, respectively.

element in 3R application, the theoretical evolution of BER with number of concatenated regenerators have been plotted for regenerators having different nonlinear responses. Figure 4 shows the numerically calculated evolution of the BER of a 10 Gbit/s NRZ signal with fixed optical signal-to-noise ratio (OSNR) at the input of the 3R regenerator, as a function of the cascaded regenerator incorporating nonlinear gates with nonlinear transfer function of different depths. From Figure 4, can be seen different behaviors depending on the nonlinear function shape. As previously stated, the best regeneration performance is obtained with an ideal step function (case a), which is actually the case for O/E regenerator using electronic decision flip-flop (DFF). In that case, BER linearly increase (i.e., more errors) in the cascade. Conversely, when nonlinearity is reduced (cases (b) and (c)), both BER and noise accumulate, until the concatenation of nonlinear functions reach some steady-state pattern, from which BER linearly increases. Concatenation of nonlinear devices thus magnifies shape differences in their nonlinear response, and hence their regenerative capabilities.

Moreover, as can be seen in Figure 4, all curves standing for different regeneration efficiencies pass through a common point defined after the first device. This clearly indicates that it is not possible to qualify the regenerative capability of any regenerator when considering the output signal after only one regenerator. Indeed, the BER is the same for either a 3R regenerator or a mere amplifier if only measured after a single element. This originates from the initial overlap between noise distributions associated with marks and spaces, that cannot be suppressed but only minimized by a single decision element through threshold adjustment.

As a general result, the actual characterization of the regenerative performance of any regenerator should *in fine* be conducted considering a cascade of regenerators. In practice this can easily be done with the experimental implementation of the regenerator under study in a recirculating loop. Moreover, such an investigation tool will also enable access to the regenerator performance with respect to the transmission capabilities of the regenerated signal, which should not be overlooked.

Let us now consider the physical implementation of such all-optical Signal Regenerators, along with the key features offered by the different alternatives.

All-Optical 2R/3R Regeneration Using Optical Nonlinear Gates

Prior to describing the different solutions for all-optical in-line Optical Signal Regeneration, it should be mentioned that since the polarization states of the optical data signals cannot be preserved during propagation, it is required that the regenerator exhibits an extremely low polarization sensitivity. This clearly translates to a careful optimization of all the different optical components making up the 2R/3R regenerator. It should be noted that this also applies to the O/E solutions but is of limited impact, since only the photodiode has to be polarization insensitive.

Figure 5 illustrates the generic principle of operation of an all-optical 3R Regenerator using optical nonlinear gates. Contrary to what occurs in O/E, regenerator where the extracted clock signal drives the electrical decision element, the incoming and distorted optical data signal triggers the nonlinear gate, hence generating a switching window which is

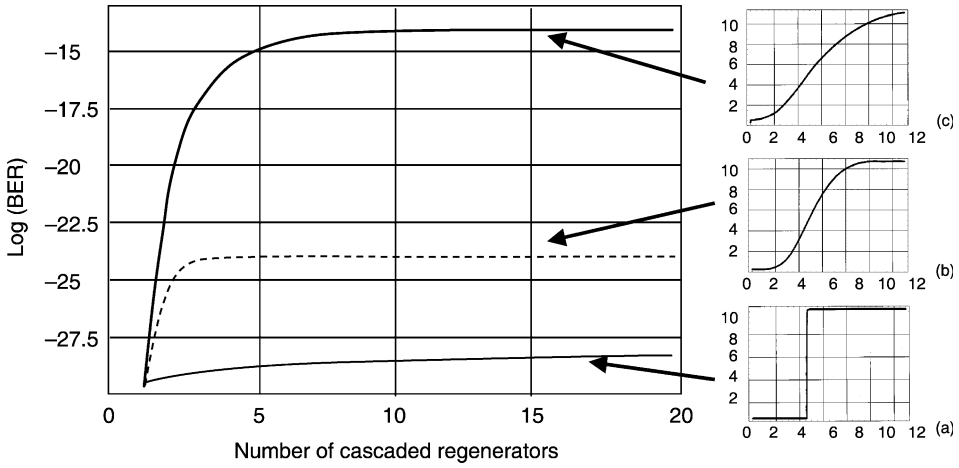

Figure 4 Evolution of the BER with concatenated regenerators for nonlinear gates with nonlinear transfer function of decreasing depths from case (a)–(c) (step function).

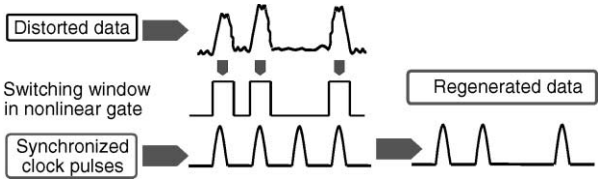

Figure 5 Principle of operation of an all-Optical Signal 3R Regenerator using nonlinear gates.

applied to a newly generated optical clock signal so as to reproduce the initial data stream on the new optical carrier.

In the case of 2R Optical Signal Regeneration, a continuous wave (CW) signal is substituted for the synchronized optical clock pulses. As previously mentioned, the actual regeneration performance of the 2R/3R devices will mainly depend upon the nonlinearity of the transfer function of the decision element but in 3R applications the quality of the optical clock pulses has also to be considered. In the following, we describe current solutions to explain the two main building blocks of all-optical Signal Regenerators: the decision element (i.e., nonlinear gate) and the clock recovery (CR) elements.

Optical Decision Element

In the physical domain, optical decision elements with ideal step response – as for electrical DFF – do not exist. Different nonlinear optical transfer functions, approaching more or less the ideal case, can be realized in various media such as fiber, SOA, electro-absorption modulators (EAM), and lasers. Generally, as described below, the actual response (hence the regenerative properties of the device) of such optical gates directly depends upon the incoming signal instantaneous power. Under these conditions, it appears essential to add an adaptation stage so as to reduce intensity fluctuations (as caused by propagation or crossing routing/switching node) and provide the decision element with fixed power conditions. In practice, this results in the addition of a control circuitry (either optical or electrical) in the Re-amplification block, whose complexity directly depends on actual system environment (ultra-fast power equalization for packet-switching applications and compensation of slow power fluctuations in transmission applications).

As previously described the decision gate performs Re-shaping (and Re-timing when clock pulses are added) of the incoming distorted optical signal, and represent the regenerator's core element. Ideally, it should also act as a transmitter with characteristics ensuring the actual propagation of the regenerated data stream. In that respect, the chirp possibly induced by the optical decision gate onto the regenerated signal – and the initial quality of the optical clock pulses in 3R applications – should be carefully considered (ideally by means of loop transmission) as to adequately match line transmission requirements.

Different solutions for the actual realization of the optical decision element have been proposed and extensively investigated using, for example, cross gain modulation in semiconductor optical amplifier (SOA) devices but the most promising and flexible devices probably are interferometers, for which, descriptions of the generic principle of operation follows. Consider a CW signal (probe) at λ_2 wavelength injected into an optical interferometer, in which one arm incorporates a nonlinear medium in which an input signal carried by λ_1 wavelength (command) is, in turn, injected. Such a signal, at λ_1 wavelength, induces a phase shift through cross-phase modulation (XPM) in this arm of the interferometer, the amount depending upon power level $P_{\text{in},\lambda 1}$. In turn, such phase modulation (PM) induces amplitude modulation (AM) on the signal at λ_2 wavelength when recombined at the output of the interferometer and translates the information carried by wavelength λ_1 onto λ_2. Under these conditions, such optical gates clearly act as wavelength converters (it should be mentioned that Wavelength Conversion is not necessarily equivalent to Regeneration; i.e., a linear transfer function performs suitable Wavelength Conversion but by no means Signal Regeneration).

Optical interferometers can be classified according to the nature of the nonlinearity exploited to achieve a π phase shift. In the case of fiber-based devices, such as the nonlinear optical loop mirror (NOLM), the phase shift is induced through the Kerr effect in an optical fiber. The key advantage of fiber-based devices such as NOLM lies in the near-instantaneous (fs) response of the Kerr nonlinearity, making them very attractive for ultra-high bit-rate operation ($\geq$160 Gbit/s). Polarization-insensitive NOLMs have been realized, although with the same drawbacks concerning integrability. With recent developments in highly nonlinear (HNL) fibers, however, the required NOLM fiber length could be significantly reduced, hence dramatically reducing environmental instability.

A second type of device is the integrated SOA-based Mach-Zehnder interferometers (MZI). In MZIs, the phase shift is due to the effect of photo-induced carrier depletion in the gain saturation regime of one of the SOAs. The control and probe can be launched in counter- or co-directional ways. In the first case, no optical filter is required at the output

of the device for rejecting the signal at λ_1 wavelength but operation of the MZI is limited by its speed. At this point, one should mention that the photo-induced modulation effects in SOAs are intrinsically limited in speed by the gain recovery time, which is a function of the carrier lifetime and the injection current. An approach referred to as differential operation mode (DOM) and illustrated on Figure 6, which takes advantage of the MZI's interferometric properties, makes it possible to artificially increase the operation speed of such 'slow' devices up to 40 Gbit/s.

As discussed earlier, the nonlinear response is a key parameter for regeneration efficiency. Combining two interferometers is a straightforward means to improve the nonlinearity of the decision element transfer function, and hence regeneration efficiency. This approach was validated at 40 Gbit/s using a cascade of two SOA-MZI, (see Figure 7 (**left**)). Such a scheme offers the advantage of restoring data polarity and wavelength, hence making the regenerator inherently transparent. Finally, the second conversion stage can be used as an adaptation interface to the transmission link achieved through chirp tuning in this second device.

Such an Optical 3R Regenerator was upgraded to 40 Gbit/s, using DOM in both SOA-MZIs with validation in a 40 Gbit/s loop RZ transmission. The 40 Gbit/s eye diagram monitored at the regenerator output after 1, 10, and 100 circulations are shown in Figure 7 (**right**) and remain unaltered by distance. With this all-optical regenerator structure, the minimum OSNR tolerated by the regenerator (1 dB sensitivity penalty at 10^{-10} BER) was found to be as low as 25 dB/0.1 nm. Such results clearly illustrate the high performance of this SOA-based regenerator structure for 40 Gbit/s optical data signals.

Such a complex mode of operation for addressing 40 Git/s bit-rates will probably be discarded when we consider the recent demonstration of standard-mode wavelength conversion at 40 Gbit/s, which uses a newly-designed active-passive SOA-MZI incorporating evanescent-coupling SOAs. The device architecture is flexible in the number of SOAs, thus enabling easier operation optimization and reduced power consumption, leading to simplified architectures and operation for 40 Gbit/s optical 3R regeneration.

Based on the same concept of wavelength conversion for Optical 3R Regeneration, it should be noted many devices have been proposed and experimentally validated as wavelength converters at rates up to 84 Gbit/s, but with cascadability issues still to be demonstrated to assess their actual regenerative properties.

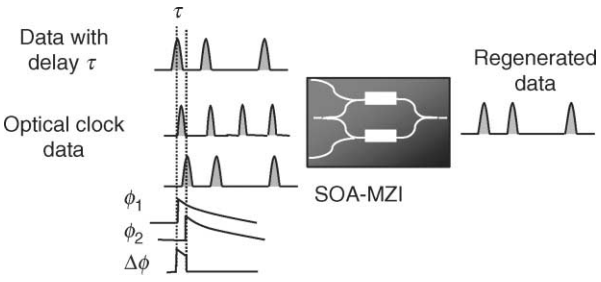

Figure 6 Schematic and principle of operation of SOA-MZI in differential mode.

Optical Clock Recovery (CR)

Next to the decision, the CR is a second key function in 3R regenerators. One possible approach for CR uses electronics while another only uses optics. The former goes with OE conversion by means of a photodiode and subsequent EO conversion through a modulator. This conversion becomes more complex and power-hungry as the data-rate increases. It is clear that the maturity of electronics gives a current advantage to this approach. But considering the pros and cons of electronic CR for cost-effective implementation, the all-optical approach seems more promising, since full regenerator integration is potentially possible with reduced power consumption. In this view, we shall focus here on the optical approach and more specifically on the self-pulsating effect in three-sections distributed feedback (DFB) lasers or more recently in distributed Bragg reflector

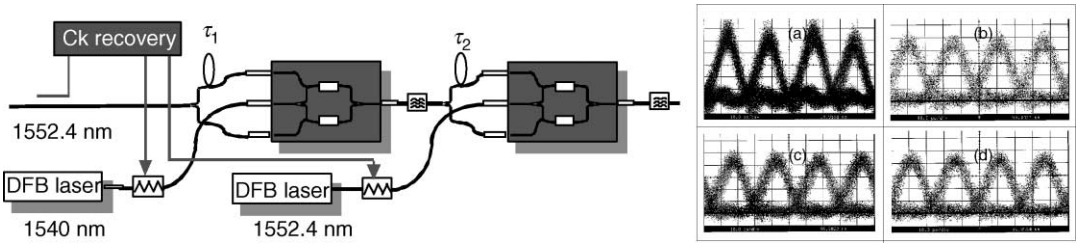

Figure 7 Optimized structure of a 40 Gbit/s SOA-based 3R regenerator. 40 Gbit/s eye diagram evolution: (a) B-to-B; (b) 1 lap; (c) 10 laps; (d) 100 laps.

(DBR) lasers. Recent experimental results illustrate the potentials of such devices for high bit rates (up to 160 Gbit/s), broad dynamic range, broad frequency tuning, polarization insensitivity, and relatively short locking times (1 ns). This last feature makes these devices good candidates for operation in asynchronous-packet regimes.

Optical Regeneration by Saturable Absorbers

We next consider saturable absorbers (SA) as nonlinear elements for optical regeneration. Figure 8 (**left**) shows a typical SA transfer function and illustrates the principle of operation. When illuminated with an optical signal with peak power below some threshold (P_{sat}), the photonic absorption of the SA is high and the device is opaque to the signal (low transmittance). Above P_{sat}, the SA transmittance rapidly increases and asymptotically saturates to transparency (passive loss being overlooked). Such a nonlinear transfer function only applies to 2R optical regeneration.

Different technologies for implementing SAs are available, but the most promising approach uses semiconductors. In this case, SA relies upon the control of carrier dynamics through the material's recombination centers. Parameters such as on–off contrast (ratio of transmittance at high and low incident powers), recovery time (1/e) and saturation energy, are key to device optimization. In the following, we consider a newly-developed ion-irradiated MQW-based device incorporated in a micro-cavity and shown on Figure 8 (**right**). The device operates as a reflection-mode vertical cavity, providing both a high on/off extinction ratio by canceling reflection at low intensity and a low saturation energy of 2 pJ. It is also intrinsically polarization-insensitive. Heavy ion-irradiation of the SA ensures recovery times (at 1/*e*) shorter than 5 ps (hence compatible with bit-rate above 40 Gbit/s), while maintaining a dynamic contrast in excess of 2.5 dB at 40 GHz repetition rate.

The regenerative properties of SA make it possible to reduce cumulated amplified spontaneous emission (ASE) in the '0' bits, resulting in a higher contrast between mark and space, hence increasing system performance. Yet SAs do not suppress intensity noise in the marks, which makes the regenerator incomplete. A solution for this noise suppression is optical filtering with nonlinear (soliton) pulses. The principle is as follows. In absence of chirp, the soliton temporal width scales in the same way as the reciprocal of its spectral width (Fourier-transform limit) times its intensity (fundamental soliton relation). Thus, an increase in pulse intensity corresponds to both time narrowing and spectral broadening. Conversely, a decrease in pulse intensity corresponds to time broadening and spectral narrowing. Thus, the filter causes higher loss when intensity increases, and lower loss when intensity decreases. The filter thus acts as an automatic power control (APC) in feed-forward mode, which causes power stabilization. The resulting 2R regenerator (composed by the SA and the optical filter) is fully passive, which is of high interest for submarine systems where the power consumption must be minimal, but it does not include any control in the time domain (no Re-timing).

System demonstrations of such passive SA-based Optical Regeneration have been reported with a 20 Gbit/s single-channel loop experiment. Implementation of the SA-based 2R Regenerator with 160 km-loop periodicity made it possible to double the error-free distance (Q = 15.6 dB or 10^{-9} BER) of a 20 Gbit/s RZ signal. So as to extend the capability of passive 2R regeneration to 40 Gbit/s systems, an improved configuration was derived from numerical optimization and experimentally demonstrated in a 40 Gbit/s WDM-like, dispersion-managed loop transmission, showing more than a fourfold increase in the WDM transmission distance at 10^{-4} BER (1650 km without the SA-based regenerator and 7600 km when implementing the 2R regenerator with 240 km periodicity).

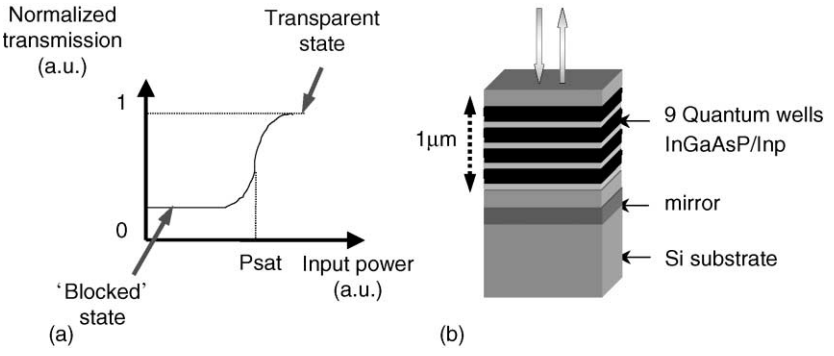

Figure 8 (a) Saturable Absorber (SA) ideal transfer function. (b) Structure of Multi-Quantum Well SA.

Such a result illustrates the potential high interest of such passive optical 2R regeneration in long-haul transmission (typically in noise-limited systems) since the implementation of SA increases the system's robustness to OSNR degradation without any extra power consumption. Reducing both saturation energy and insertion loss along with increasing dynamic contrast represent key future device improvements. Regeneration of WDM signals from the same device, such as one SA chip with multiple fibers implemented between Mux/DMux stages, should also be thoroughly investigated. In this respect, SA wavelength selectivity in quantum dots could possibly be advantageously exploited.

Synchronous Modulation Technique

All-optical 3R regeneration can be also achieved through in-line synchronous modulation (SM) associated with narrowband filtering (NF). Figure 9 shows the basic layout of such an Optical 3R Regenerator. It is composed of an optical filter followed by an Intensity and Phase Modulator (IM/PM) driven by a recovered clock. Periodic insertion of SM-based modulators along the transmission link provides efficient jitter reduction and asymptotically controls ASE noise level, resulting in virtually unlimited transmission distances. Re-shaping and Re-timing provided by IM/PM intrinsically requires nonlinear (soliton) propagation in the trunk fiber following the SM block. Therefore, one can refer to the approach as distributed optical regeneration. This contrasts with lumped regeneration, where 3R is completed within the regenerator (see above with Optical Regeneration using nonlinear gates), and is independent of line transmission characteristics.

However, when using a new approach referred to 'black box' optical regeneration (BBOR), it is possible to make the SM regeneration function and transmission work independently in such a way that any type of RZ signals (soliton or non-soliton) can be transmitted through the system. The BBOR technique includes an adaptation stage for incoming RZ pulses in the SM-based regenerator, which ensures high regeneration efficiency regardless of RZ signal format (linear RZ, DM-soliton, C-RZ, etc.). This is achieved using a local and periodic soliton conversion of RZ pulses by means of launching an adequate power into some length of fiber with anomalous dispersion. The actual experimental demonstration of the BBOR approach and its superiority over the 'classical' SM-based scheme for DM transmission was experimentally investigated in 40 Gbit/s DM loop transmission. Under these conditions, one can then independently exploit dispersion management (DM) techniques for increasing spectral efficiency in long-haul transmission, while ensuring high transmission quality through BBOR.

One of the key properties of the SM-based all-optical Regeneration technique relies on its WDM compatibility. The first (Figure 10, **left**) and straightforward solution to apply Signal Regeneration to WDM channels amounts to allocating a regenerator to each WDM channel. The second consists in sharing a single modulator, thus processing the WDM channels at once in serial fashion. This approach requires WDM synchronicity, meaning that all bits be synchronous with the modulation, that can be achieved either by use of appropriate time-delay lines located within a DMux/Mux apparatus (Figure 10, **upper right**), or by making the WDM channels inherently time-coincident at specific regenerator locations (Figure 10, **bottom right**). Clearly, the serial regeneration scheme is far simpler and cost-effective than the parallel version; however, optimized re-synchronization schemes still remain to be

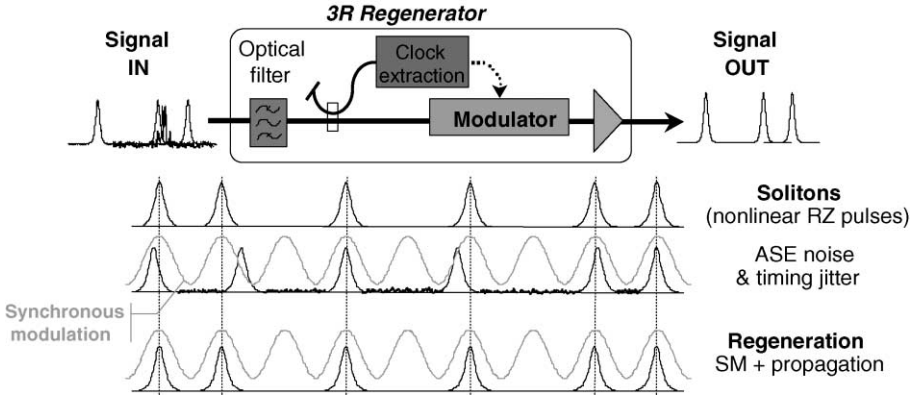

Figure 9 Basic layout of the all-optical Regenerator by Synchronous Modulation and Narrowband Filtering and illustration of the principle of operation.

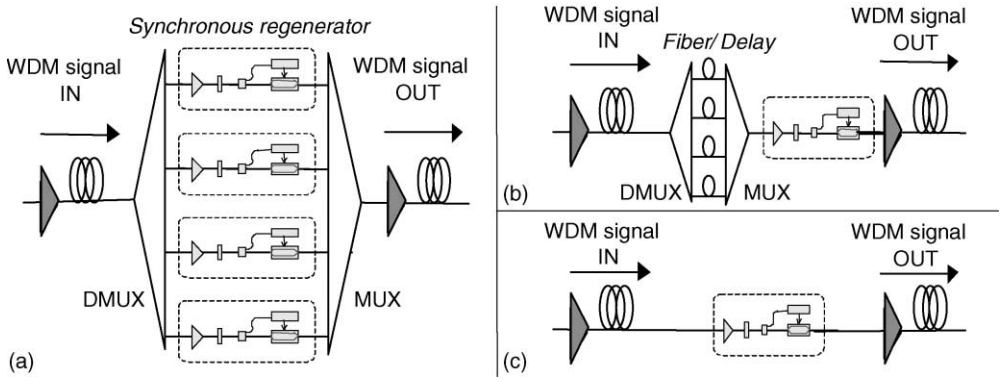

Figure 10 Basic implementation schemes for WDM all-Optical Regeneration. (a) parallel asynchronous; (b) serial re-synchronized; (c) serial self-synchronized.

developed for realistic applications. Experimental demonstration of this concept was assessed by means of a 4×40 Gbit/s dispersion-managed transmission over 10 000 km (BER $< 5.10^{-8}$) in which a single modulator was used for the simultaneous regeneration of the 4 WDM channels.

Considering next all-optical regeneration schemes with ultra-high speed potential, a compact and loss-free 40 Gbit/s Synchronous Modulator, based on optically-controlled SOA-MZI, was proposed and loop-demonstrated at 40 Gbit/s with an error-free transmission distance in excess of 10 000 km. Moreover, potential ultra-high operation of this improved BBOR scheme was recently experimentally demonstrated by means of a 80 GHz clock conversion with appropriate characteristics through the SOA-MZI. One should finally mention all fiber-based devices such as NOLM and NALM for addressing ultra-high speed SM-based Optical Regeneration, although no successful experimental demonstrations have been reported so far in this field.

Conclusion

In summary, optical solutions for Signal Regeneration present many key advantages. These are the only advantages to date to possibly ensure WDM compatibility of the regeneration function (mostly 2R related). Such optical devices clearly exhibits the best 2R regeneration performance (wrt to O/E solutions) as a result of the moderately nonlinear transfer function (which in turn can be considered as a drawback in 3R applications), but the optimum configuration is still to be clearly derived and identified depending upon the system application. Optics also allow to foresee and possibly target ultrafast applications above 40G, for signal regeneration if needed. Among the current drawbacks, one should mention the relative lack of wavelength/formats flexibility of these solutions (compared to O/E solutions). It is complex or difficult to restore the input wavelength or address any C-band wavelength at the output of the device or to successfully regenerate modulation formats other than RZ. In that respect, investigations should be conducted to derive new optical solutions capable of processing more advanced modulation formats at 40G. Finally, the fact that the nonlinear transfer function of the optical is in general triggered by the input signal instantaneous power also turns out to be a drawback since it requires control circuitry. The issue of cost (footprint, power consumption, etc.) of these solutions, compared to O/E ones, is still open. In this respect, purely optical solutions incorporating all-optical clock recovery, the performance of which is still to be technically assessed, are of high interest for reducing costs. Complete integration of an all-optical 2R/3R regenerator or such parallel regenerators onto a single semiconductor chip should also contribute to make all-optical solutions cost-attractive even though acceptable performance of such fully integrated devices is still to be demonstrated.

From today's status concerning the two alternative approaches for in-line regeneration (O/E or all-optical), it is safe to say that the choice between either solution will be primarily dictated by both engineering and economical considerations. It will result from a tradeoff between overall system performance, system complexity and reliability, availability, time-to-market, and rapid returns from the technology investment.

BABINET'S PRINCIPLE

B D Guenther, Duke University, Durham, NC, USA

© 2005, Elsevier Ltd. All Rights Reserved.

In the development of the theory of diffraction, the diffraction field is due to a surface integral, the Fresnel integral, but no restrictions are imposed on the choice of the surface over which the integration must be performed. This fact leads to a very useful property called Babinet's principle, first stated by Jacques Babinet (1794–1872) in 1837 for scalar waves. We will discuss only the scalar Babinet's principle; discussion of the rigorous vector formulation can be found in a number of books on electromagnetic theory.

To introduce Babinet's principle, we label a plane, separating the source, S, and observation point, P, as Σ. If no obstructions are present, a surface integration over Σ yields the light distribution at P. If we place an opaque obstruction in this plane with a clear aperture, Σ_1, then the field at P is given by integrating over only Σ_1; contributions from Σ, outside of Σ_1, are zero since the obstruction is opaque.

We may define an aperture, Σ_2, as complementary to Σ_1 if the obstruction is constructed by replacing the transparent regions of Σ, i.e., Σ_1, by opaque surfaces and the opaque regions of Σ by clear apertures. Figure 1 shows two complementary obstructions, where the shaded region indicates an opaque surface.

The surface integral over Σ generates the field, E, in the absence of any obstruction. If obstruction Σ_1 is present then the diffraction field is E_1, obtained by integrating over Σ_1. According to Babinet's principle, the diffraction field due to obstruction Σ_2, must be

$$\tilde{E}_2 = \tilde{E} - \tilde{E}_1$$

We will look at examples of the application of the principle for both Fraunhofer and Fresnel diffraction.

Fraunhofer Diffraction

The electric field due to Fraunhofer diffraction is given by

$$E_{\mathrm{P}}(\omega_x, \omega_y) = \frac{\mathrm{i}\alpha \mathrm{e}^{-\mathrm{i}kR_0}}{\lambda R_0} \iint_{\Sigma} f(x, y) \mathrm{e}^{-\mathrm{i}(\omega_x x + \omega_y y)} \, \mathrm{d}x \, \mathrm{d}y$$

where α is the amplitude of the incident plane wave and R_0 is the distance from the obstruction to the observation point. We have defined the spatial frequencies, ω_x and ω_y by the equations

$$\omega_x = kL = -\frac{2\pi\xi}{\lambda R_0} \qquad \omega_y = kM = -\frac{2\pi\eta}{\lambda R_0}$$

This surface integral is an approximation of the Hygens–Fresnel integral and can be identified as a Fourier transform of the aperture transmission function, $f(x, y)$ in two dimensions. For our discussion we will consider only one dimension and ignore the parameters in front of the integral.

Assume that $a(x)$ is the amplitude transmission of an aperture in an obstruction, $b(x)$ is the amplitude transmission function of the complementary obstruction and g is the amplitude of the wave when no

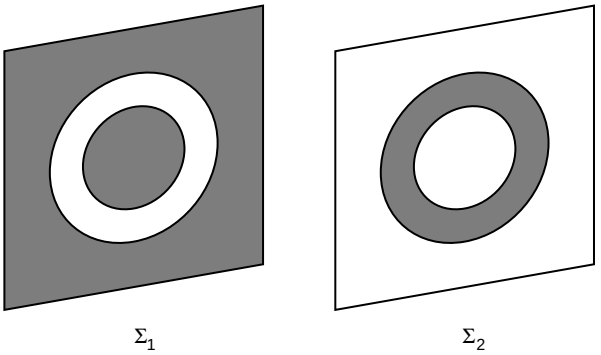

Figure 1 An aperture Σ_1 shown by the unshaded region and its complement Σ_2. Reproduced with permission from Guenther R (1990) *Modern Optics*. New York: Wiley. Copyright © 1990 John Wiley & Sons.

obstruction is present. The Fourier transforms of the one-dimensional amplitude transmission functions of the two apertures are equal to the Fraunhofer diffraction patterns that will be generated by the two apertures

$$A(k) = \int_{-\infty}^{\infty} a(x)\mathrm{e}^{-ikx}\,\mathrm{d}x$$

$$B(k) = \int_{-\infty}^{\infty} b(x)\mathrm{e}^{-ikx}\,\mathrm{d}x$$

With no aperture present, the far field amplitude is

$$G(k) = g\int_{-\infty}^{\infty} \mathrm{e}^{-ikx}\,\mathrm{d}x$$

Babinet's principle states that

$$B(x) = G - A(x)$$

must be the Fraunhofer diffraction field of the complementary aperture. We may rewrite this equation for the diffraction field as

$$B(k) = G\delta(k) + A(k)\mathrm{e}^{i\pi} \qquad [1]$$

The first term on the right of the Fraunhofer diffraction field for the complementary obstruction [1] is located at the origin of the observation plane and is proportional to the amplitude of the unobstructed wave. The second term in the equation for the Fraunhofer diffraction pattern [1] is identical to the Fraunhofer diffraction pattern of the original aperture, except for a constant phase. Thus the Fraunhofer diffraction from the two complementary apertures are equal, except for a constant phase and the bias term at the origin. Physically this means that the diffraction intensity distributions of complementary apertures will be identical but their brightness will differ!

Fresnel Diffraction

We can calculate the Fresnel diffraction from an opaque disk by applying Babinet's principle to the diffraction pattern calculated for a circular aperture.

We assume that a circular aperture of radius a is illuminated by a point source a distance Z' from the aperture. We observe the transmitted wave at the point P, located a distance Z from the aperture (see Figure 2).

The Fresnel diffraction integral is

$$\tilde{E}_{\mathrm{P}} = \frac{i\alpha}{\lambda\rho D}\mathrm{e}^{-ikD} \times \int\int f(x,y)\mathrm{e}^{-\frac{ik}{2\rho}\left[(x-x_0)^2+(y-y_0)^2\right]}\,\mathrm{d}x\,\mathrm{d}y \qquad [2]$$

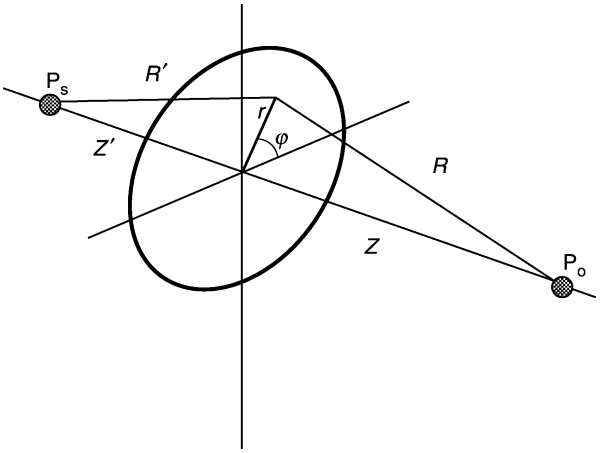

Figure 2 Geometry for the analysis of Fresnel diffraction of a circular aperture. Reproduced with permission from Guenther R (1990) *Modern Optics*. New York: Wiley. Copyright © 1990 John Wiley & Sons.

where the distance between the source and observation point is

$$D = Z + Z' + \frac{(\xi - x_s)^2 + (\eta - y_s)^2}{2(Z+Z')} \qquad \frac{1}{\rho} = \frac{1}{Z} + \frac{1}{Z'}$$

and the coordinates of the stationary point are

$$x_0 = \frac{Z'\xi + Zx_s}{Z+Z'} \qquad y_0 = \frac{Z'\eta + Zy_s}{Z+Z'}$$

The parameters of the integral are simplified by the geometry selected for Figure 2. Both the observation point and source are located on the axis of symmetry of the aperture which lies along the z-axis of a cylindrical coordinate system thus

$$x_0 = y_0 = \xi = \eta = 0 \qquad \text{and} \qquad D = Z' + Z$$

The approximation for the distance from the source and observation point to the aperture yields

$$R + R' \approx Z + Z' + \frac{r^2}{2\rho} = D + \frac{r^2}{2\rho}$$

where $r^2 = x^2 + y^2$· The cylindrical coordinate version of [2] is then

$$\tilde{E}_{\mathrm{P}} = \frac{i\alpha}{\lambda\rho D}\mathrm{e}^{-ikD}\int_0^a\int_0^{2\pi} f(r,\varphi)\mathrm{e}^{-i\frac{kr^2}{2\rho}}\,r\,\mathrm{d}r\,\mathrm{d}\phi \qquad [3]$$

We assume that the transmission function of the aperture is a constant, $f(r,\phi) = 1$, to make the integral as simple as possible. After performing the integration over the angle ϕ, [3] can be

rewritten as

$$\tilde{E}_{\mathrm{Pa}} = \frac{\mathrm{i}\alpha\pi}{D}\mathrm{e}^{-\mathrm{i}kD}\int_0^{\frac{a^2}{\rho\lambda}} \mathrm{e}^{-\mathrm{i}\pi r^2/\rho\lambda}\,\mathrm{d}\left(\frac{r^2}{\rho\lambda}\right) \quad [4]$$

Performing the integration of [4], results in the Fresnel diffraction amplitude

$$\tilde{E}_{\mathrm{Pa}} = \frac{\alpha}{D}\mathrm{e}^{-\mathrm{i}kD}\left[1 - \mathrm{e}^{-\mathrm{i}\pi a^2/\rho\lambda}\right] \quad [5]$$

The intensity of the diffraction field is

$$\begin{aligned} I_{\mathrm{Pa}} &= 2I_0\left(1 - \cos\frac{\pi a^2}{\rho\lambda}\right) \\ &= 4I_0\sin^2\frac{\pi a^2}{2\rho\lambda} \end{aligned} \quad [6]$$

[6] predicts a sinusoidal variation in intensity as the observation point moves toward the aperture.

Babinet's principle can now be used to evaluate Fresnel diffraction by an opaque disk, the same size as the circular aperture, i.e., of radius a. The field for the disk is obtained by subtracting the field, diffracted by a circular aperture, from the field of an unobstructed spherical wave, E_{P}:

$$\begin{aligned} \tilde{E}_{\mathrm{Pd}} &= \tilde{E}_{\mathrm{P}} - \tilde{E}_{\mathrm{Pa}} \\ \tilde{E}_{\mathrm{Pd}} &= \frac{\alpha}{D}\mathrm{e}^{-\mathrm{i}kD} - \tilde{E}_{\mathrm{Pa}} \\ &= \frac{\alpha}{D}\mathrm{e}^{-\mathrm{i}kD}\mathrm{e}^{-\mathrm{i}\pi a^2/\rho\lambda} \end{aligned} \quad [7]$$

The intensity is

$$I_{\mathrm{Pd}} = I_0$$

The result of the application of Babinet's principle is the conclusion that, at the center of the geometrical shadow cast by the disk, there is a bright spot with the same intensity as would exist if no disk were present. This is Poisson's spot. The intensity of this spot is independent of the choice of the observation point along the z-axis.

CHAOS IN NONLINEAR OPTICS

R G Harrison and W Lu, Heriot-Watt University, Edinburgh, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Instabilities in laser emission, notably in the form of spontaneous coherent pulsations, have been observed almost since the first demonstration of laser action. Indeed, the first laser operated in 1960 by Maiman produced noisy spiked output even under conditions of quasi-steady excitation and provided the early impetus for studies of such effects. Subsequent theoretical efforts towards understanding these phenomena occurred up to the 1980s at a modest level, due in part to the wide scope of alternative areas of fertile investigation provided by lasers during this period. However, since the 1990s, there has been a major resurgence of interest in this area. This has been due to profound mathematical discoveries over this period which have revolutionized our understanding of classical dynamical systems. It is now clear that many systems containing some form of nonlinearity are dynamically unstable and even chaotic and that such behavior is deterministic. Further, the discovery that chaos evolves through particular routes with well-defined scenarios and that such routes are universal, has stimulated experimentalists to search for physical systems that exhibit these properties. These phenomena have now been observed in areas as diverse as fluid flow, chemical reactions, population ecology, and superconductor devices. The laser, perhaps the most recent newcomer to the field, is a paradigm for such investigation, owing to its simplicity both in construction and in the mathematics that describe it, and already a wide range of these phenomena have been observed. Along with a proliferation of new observations, many of the instabilities known to occur in these systems are now being reinterpreted in lieu of our new insight in this area. From this, fascinating new concepts of control and synchronization of chaos have emerged and spawned new fields of applications, not least in secure communication. In this article we introduce the general principles of dynamical instabilities, chaos, and control in lasers. For in-depth study, the reader is referred to texts and review articles cited in the Further Reading section at the end of this article.

Laser Physics

Our conventional understanding of laser physics is concerned with how cooperative order evolves from randomness. This transition is explained by first considering the ensemble of lasing atoms in thermal equilibrium. Every atom executes a small motion, giving rise to an oscillating electric dipole, described by linear dynamics. For larger motions, the atomic dipoles interfere with each other's motion and beyond a particular threshold, the motion becomes 'co-operative' or ordered over a long range. The role of the electromagnetic field in the laser cavity in ordering the induced atomic dipoles, is collectively described as giving rise to a macroscopic polarization, the magnitude of which depends on the number of dipoles (excited atoms). The dynamical interplay between the cavity field amplitude (E) as one variable and the atomic material variables of polarization (P) and population (D) of excited atoms, all of which are in general complex quantities, provide a full description of lasing action. For the simplest laser, a single mode two-level system with a homogeneously broadened gain lasing at resonance, these reduce to just three real variables, the Maxwell–Bloch equations:

$$\dot{E} = -\kappa E + \kappa P \qquad [1]$$

$$\dot{P} = \gamma_{\perp} ED - \gamma_{\perp} P \qquad [2]$$

$$\dot{D} = \gamma_{II}(\lambda + 1) - \gamma_{II} D - \gamma_{II} \lambda EP \qquad [3]$$

where κ is the cavity decay rate, $\gamma_\perp$ is the decay rate of atomic polarization, γ_{II} is the decay rate of population inversion, and λ the pumping parameter.

Described in this way the laser acts as a single oscillator in much the same way as a mechanical nonlinear oscillator, where laser output represents damping of the oscillator and excitation of the atoms is the driving mechanism to sustain lasing (oscillation). For ordered or coherent emission, it is necessary for one or both of the material variables (which are responsible for further lasing emission) to respond sufficiently fast to ensure a phase correlation with the existing cavity field. This is readily obtained in many typical lasers with output mirrors of relatively high reflectivity, since the field amplitude within the laser cavity will then vary slowly compared to the fast material variables which may then be considered through their equilibrium values. This situation, commonly referred to as adiabatic elimination of fast variables, reduces the dynamics of lasing action to that of one (or two) variables, the field (and population), all others being forced to adapt constantly to the slowly varying field variable. Our familiar understanding of DC laser action presupposes such conditions to hold. However when, for example, the level of excitation of the atoms is increased to beyond a certain value, i.e., the second laser threshold, all three dynamical variables may have to be considered, which satisfies the minimum requirement of three degrees of freedom (variables) for a system to display chaos. So this simple laser is capable of chaotic motion, for which the emission is aperiodic in time and has a broadband spectrum. Prediction of such behavior was initially made by Haken in 1975 through establishing the mathematical equivalence of the Maxwell–Bloch equations to those derived earlier by Lorentz describing chaotic motion in fluids.

Nonlinear Dynamics and Chaos in Lasers

In general there is no general analytical approach for solving nonlinear systems such as the Maxwell–Bloch equations. Instead solutions are obtained by numerical means and analyzed through geometric methods originally developed by Poincaré as early as 1892. This involves the study of topological structures of the dynamical trajectories in phase space of the variables describing the system. If an initial condition of a dissipative nonlinear dynamical system, such as a laser, is allowed to evolve for a long time, the system, after all the transients have died out, will eventually approach a restricted region of the phase space called an attractor. A dynamical system can have more than one attractor, in which case different initial conditions lead to different types of long-time behavior. The simplest attractor in phase space is a fixed point which is a solution with just one set of values for its dynamical variables; the nonlinear system is attracted towards this point and stays there, giving a DC solution. For other control conditions the system may end up making a periodic motion; the attractor of this motion is called a limit cycle. However, when the operating conditions exceed a certain critical value, the periodic motion of the system breaks down into a more complex dynamical trajectory, which never repeats. This motion represents a third kind of attractor in phase space called a chaotic or strange attractor.

Figure 1 shows a sequence of trajectories of the Lorentz equations in the phase space of (x, y, z) on increasing the value of one of the control parameters; this corresponds to (E, P, D) in the Maxwell–Block equations on increasing the laser pump. For a control setting near zero, all trajectories approach stable equilibrium at the origin, the topological structure of the basin of attraction being hyperbolic about zero (Figure 1a). For the laser equations, this corresponds to operation below lasing threshold for which the magnitude of the control parameter (laser gain) is insufficient to produce lasing. As the control parameter is increased, the basin lifts at its zero point to create an unstable fixed point here but with now two additional fixed points located in the newly formed troughs on either side of the zero point, which is now a saddle point. This is illustrated in Figure 1b where the system eventually settles to one or other of the two new and symmetrical fixed points, depending on the initial conditions. This corresponds to DC or constant lasing as defined by the parameter values of one or other of these points which are indistinguishable. Pictorially, think of a conventional saddle shape comprising a hyperbolic and inverted hyperbolic form in mutually perpendicular planes and connected tangentially at the origin. With the curve of the inverted hyperbola turned up at its extremity and filling in the volume with similar profiles which allow the two hyperbolic curves to merge into a topological volume, one sees that a ball placed at the origin is constrained to move most readily down either side of the inverted hyperbolas into one or other of the troughs formed by this volume. For the Lorentz system, chaotic behavior occurs at larger values of the control parameter when all three fixed points become saddles. Since none of the equilibrium points are now attracting, the behavior of the system cannot be a steady motion. Although perhaps difficult to visualize topologically, it is then possible to find a region in this surface enclosing all three points and

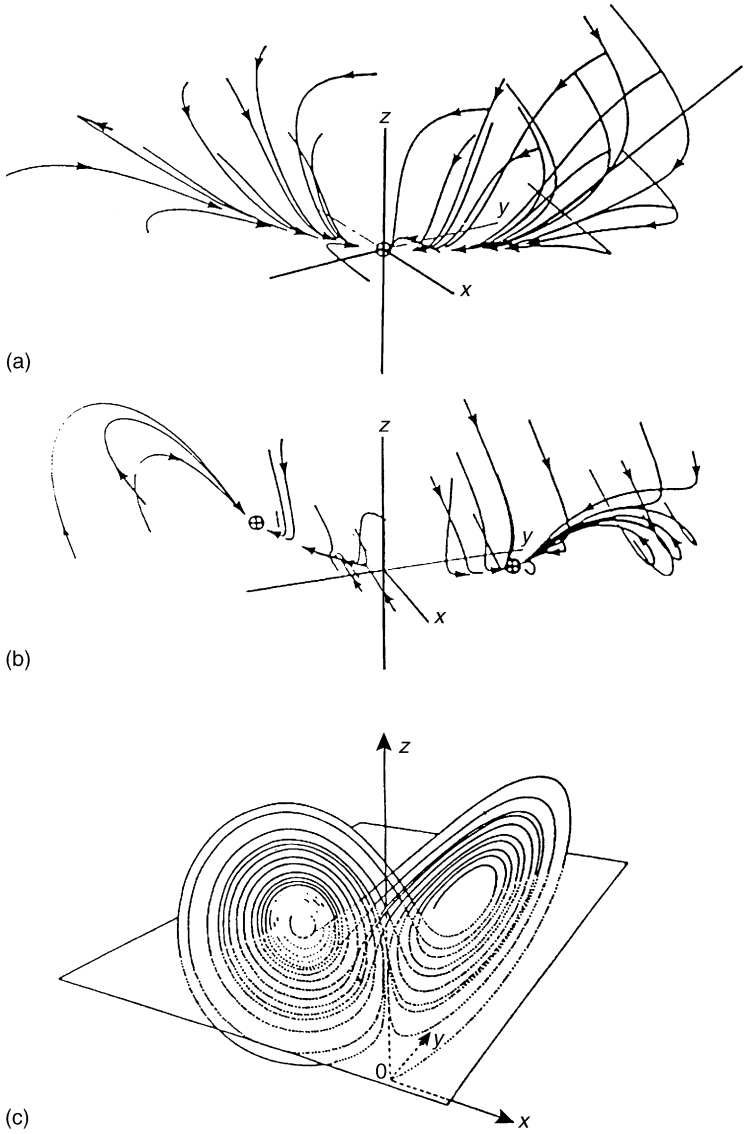

Figure 1 Trajectories in the three-dimensional phase space of the Lorentz attractor on increasing one of the control parameters. (Reproduced with permission from Thompson JMT and Stewart HB (1987) *Nonlinear Dynamics and Chaos*. New York: John Wiley.)

large enough so that no trajectories leave the region. Thus, all initial conditions outside the region evolve into the region and remain inside from then on. A corresponding chaotic trajectory is shown in Figure 1c. A point outwardly spirals from the proximity of one of the new saddle points until the motion brings it under the influence of the symmetrically placed saddle, the trajectory then being towards the center of this region from where outward spiraling again occurs. The spiraling out and switching over continues forever though the trajectory never intersects. In this case, arbitrarily close initial conditions lead to trajectories, which, after a sufficiently long time, diverge widely. Since a truly exact assignment of the initial condition is never possible, even numerically, a solution comprising several such trajectories therefore evolves and, as a consequence, long-term predictability is impossible. This is in marked contrast to that of the fixed point and limit cycle attractors, which settle down to the same solutions. A recording of one of these variables in time, say for a laser the output signal amplitude (in practice recorded as signal intensity, proportional to the square of the field amplitude), then gives oscillatory emission of increasing intensity with sudden discontinuities (resulting from flipping from one saddle to the other in Figure 1c) as expected.

While the Lorentz/Haken model is attractive for its relative simplicity, many practical lasers cannot be reduced to this description. Nevertheless, the

Figure 2 Lorentz-type chaos in the NH_3 laser (emitting at 81 μm optically pumped by a N_2O laser.

underlying topology of the trajectory of solutions in phase space for these systems is often found to be relatively simple and quite similar, as for three-level models descriptive of optically pumped lasers. An experimental example of such behavior for a single mode far infared molecular laser is shown in Figure 2. In other lasers, for which there is adiabatic elimination of one or other of the fast variables, chaotic behavior is precluded if, as a consequence, the number of variables of the system is reduced to less than three. Indeed this is the case for many practical laser systems. For these systems the addition of an independent external control parameter to the system, such as cavity length or loss modulation, have been extensively used as a means to provide the extra degrees of freedom. Examples include gas lasers with saturable absorbers, solid state lasers with loss modulation, and semiconductor lasers with external cavities, to name but a few. In contrast, for multimode rather than single mode lasers, intrinsic modulation of inversion (or photon flux) by multimode parametric interaction ensures the additional degrees of freedom. Furthermore, when the field is detuned from gain center, the dynamical variables E, P, D are complex, providing five equations for single mode systems, which is more than sufficient to yield deterministic chaos for suitable parameter values. Also, of significance is the remarkably low threshold found for the generation of instabilities and chaos in single-mode laser systems in which the gain is inhomogeneously broadened, an example being the familiar He–Ne laser.

Erratic and aperiodic temporal behavior of any of the system's variables implies a corresponding continuous spectrum for its Fourier transform, which is thus a further signature of chaotic motion. Time series, power spectra, and routes to chaos collectively provide evidence of deterministic behavior. Of the wide range of possible routes to chaos, three have emerged as particularly common and are frequently observed in lasers. These are period doubling, intermittency, and two-frequency scenarios. In the first, a solution, which is initially stable is found to oscillate, the period of which successively doubles at distinct values of the control parameter. This continues until the number of fixed points becomes infinite at a finite parameter value, where the variation in time of the solution becomes irregular. For the intermittency route, a signal that behaves regularly in time becomes interrupted by statistically distributed periods of irregular motion, the average number of which increases with the external control parameter until the condition becomes chaotic. The two-frequency route is more readily identified with early concepts of turbulence, considered to be the limit of an infinite sequence of instabilities (Hopf bifurcation) evolving from an initial stable solution each of which creates a new basic frequency. It is now known that only two or three instabilities (frequencies) are sufficient for the subsequent generation of chaotic motion.

Applications of Chaos in Lasers

It has been accepted as axiomatic since the discovery of chaos that chaotic motion is in general neither predictable nor controllable. It is unpredictable because a small disturbance will produce exponentially growing perturbation of the motion. It is uncontrollable because small disturbances lead to other forms of chaotic motion and not to any other stable and predictable alternative. It is, however, this very sensitivity to small perturbations that has been more recently used to stabilize and control chaos, essentially using chaos to control itself. Among the many methods proposed in the late 1980s, a feedback control approach was proposed by Ott, Grebogi, and Yorke (OGY) in which tiny feedback was used to stabilize unstable periodic orbits or fixed points of chaotic attractors. This control strategy can be best understood by a schematic of the OGY control algorithm for stabilizing a saddle point P^*, as shown in Figure 3. Curved trajectories follow a stable (unstable) manifold towards (away from) the saddle point. Without perturbation of a parameter, the starting state, s_1, would evolve to the state s_2.

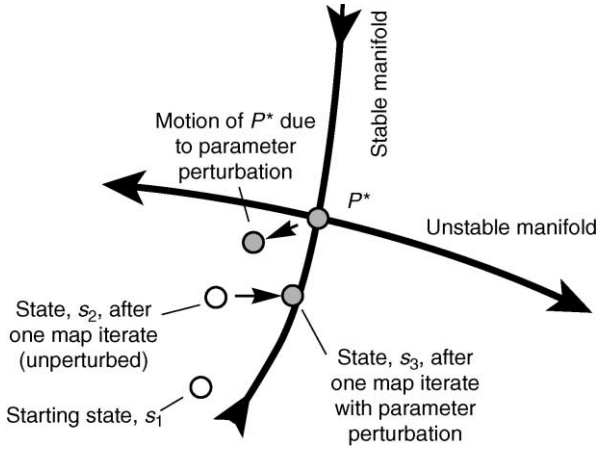

Figure 3 The OGY control strategy for stabilizing an orbit in a chaotic attractor.

The effect of changing a parameter of the system is depicted as shifting states near P^* along the solid black arrows, whereas the combination of the unperturbed trajectory and the effect of the perturbation is to bring the state to a point, s_3, on the stable manifold. Once on the stable manifold, the trajectory naturally tends towards the desired point. This algorithm has been successfully applied in numerous experimental systems without *a priori* modeling of these systems, examples being in cardiology, electronics, and lasers. Based on the concept of feedback control, various other approaches have been developed where emphasis has been given to algorithms which are more readily implemented in practical systems, in particular that utilizing occasional proportional feedback (OPF). These pioneering studies have since inspired prolific activities, both in theory and experiment, of control of chaos across many disciplines, opening up possibilities of utilizing chaos in many diverse systems. In optics, Roy *et al*. first demonstrated dynamical control of an autonomously chaotic and high-dimensional laser system on microsecond time-scales. The laser, a diode pumped solid-state Nd:YAIG system with an intracavity KTP doubling crystal, exhibited chaotic behavior from coupling of the longitudinal modes through nonlinear sum-frequency generation. To control the system, the total laser output was sampled within a window of selected offset and width. A signal proportional the deviation of the sampled intensity from the center of the window was generated and applied to perturb the driving current of the diode laser. The sampling frequency is related to the relaxation oscillation frequency of the system. This control signal repeatedly attempts to bring the system closer to a periodic unstable orbit that is embedded in the chaotic attractor, resulting in a realization of the periodic orbit. By adjusting the frequency of the feedback signal they observed the basic (relaxation oscillation) and many higher-order periodic waveforms of the laser intensity. In a subsequent experiment, Gills *et al*. showed that an unstable steady state of this laser could also be stabilized by the OPF control technique and tracked with excellent stability to higher output power with increase of the pump excitation.

Another area to receive considerable attention in the last few years is that of synchronization of chaos. It may be expected that chaotic systems will defy synchronization because two such identical systems started at nearly the same initial conditions have dynamical trajectories that quickly becomes uncorrelated. However, it has now been widely demonstrated that when these systems are linked, their chaotic trajectories converge to be the same and remain in step with each other. Further, such synchronization is found to be structurally stable and does not require the systems to be precisely identical. Not surprisingly, these findings have attracted interest from the telecommunication community; the natural masking of information by chaotic fluctuations offering a means to a certain degree of security. In this new approach, a chaotic carrier of information can be considered as a generalization of the more traditional sinusoidal carrier. In communication systems that use chaotic waveforms, information can be recovered from the carrier using a receiver synchronized, or tuned, to the dynamics of the transmitter. Optical systems are particularly attractive since they display fast dynamics, offering the possibility of communication at bandwidths of a hundred megahertz or higher. Van Wiggeren and Roy first demonstrated data transmission rates of 10 Mbites per second using erbium-doped fiber ring lasers. These lasers are particularly well-suited for communication purposes since their lasing wavelength is close to the minimum-loss wavelength in optical fiber. Figure 3 shows a schematic of this system. The tiny message, in order of one thousandth of the carrier intensity, is decoded in the transmitter. The receiver tends to synchronize its behavior to the chaotic part of the transmitted wave (but not the message). Subtracting the waveform created in the receiver from the transmitted signal recovers the tiny message. In principle, it is possible to communicate information at ultrahigh data rate with the use of this scheme because the chaotic dynamics in the ring laser has a very large spectral width. In a later experiment they showed that a receiver can recover information at 126 Mbits/sec from the chaotic carrier (Figure 4).

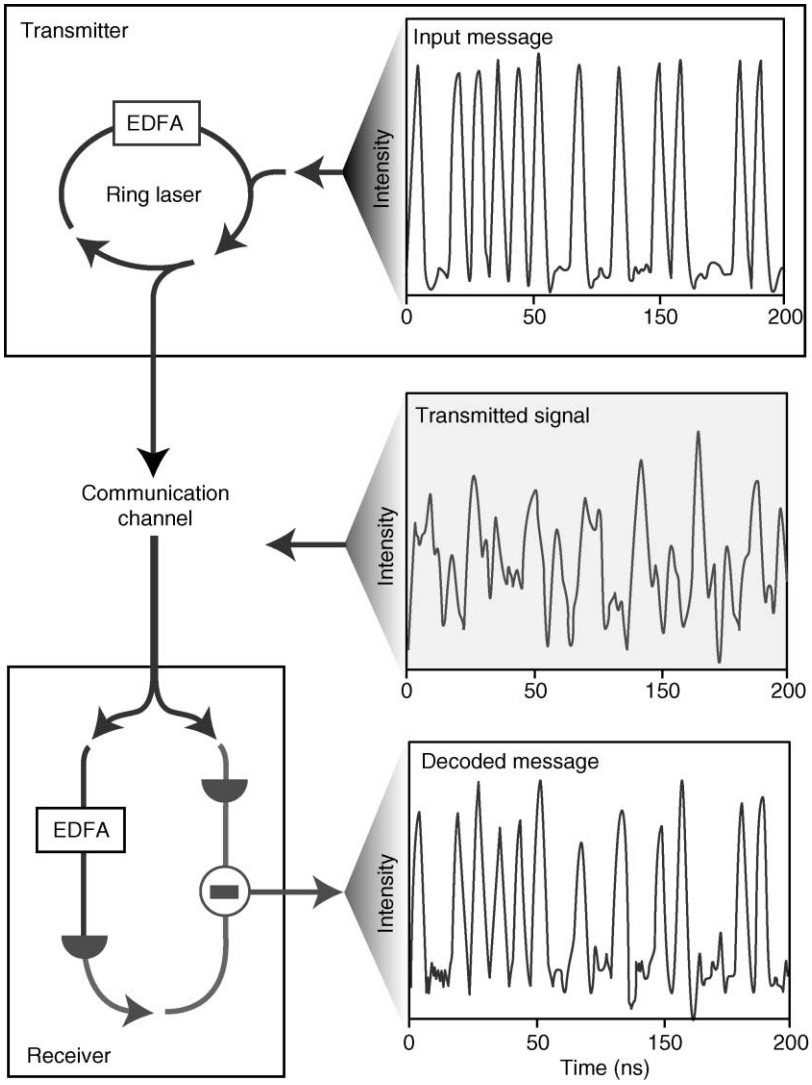

Figure 4 Schematic of communication with chaotic erbium-doped fiber amplifiers (EDFAs). Injecting a message into the transmitter laser folds the data into the chaotic frequency fluctuations. The receiver reverses this process, thereby recovering a high-fidelity copy of the message. (Reproduced with permission from Gauthier DJ (1998) Chaos has come again. *Nature* 279: 1156–1157.)

Introduction

A significant challenge facing experimentalists in the physical and biological sciences is the detection and identification of single molecules. The ability to perform such sensitive and selective measurements is extremely valuable in applications such as DNA analysis, immunoassays, environmental monitoring, and forensics, where small sample volumes and low analyte concentrations are the norm. More generally, most experimental observations of physical systems provide a measurement of ensemble averages, and yield information only on mean properties. In contrast, single molecule measurements permit observation of the interactions and behavior of a heterogeneous population in real time.

Over the past few years a number of techniques with sufficient sensitivity have been developed to detect single molecules. Scanning probe microscopies (most notably scanning tunneling microscopy and atomic force microscopy) have been used to great effect in the analysis of surface bound species, but for the detection of single molecules in liquids, optical methods incorporating the measurement of absorption or emission processes, have proved most successful.

The Absorption–Emission Cycle

The key concept underlying most emissive approaches to single molecule detection is that a single molecule can be cycled repeatedly between its ground state and an excited electronic state to yield multiple photons. The process can be understood by reference to Figure 1. Fluorescence emission in the condensed phase can be described using a four-step cycle. Excitation from a ground electronic state to an excited state is followed by rapid (internal) vibrational relaxation. Subsequently, radiative decay to the ground state is observed as fluorescence emission and is governed by the excited state lifetime. The final stage is internal relaxation back to the original ground state. Under saturating illumination, the rate-limiting step for this cycle is governed by the fluorescence lifetime (τ_f), which is typically of the order of a few nanoseconds. If a single molecule diffuses through an illuminated zone (e.g., the focus of a laser beam) it may reside in that

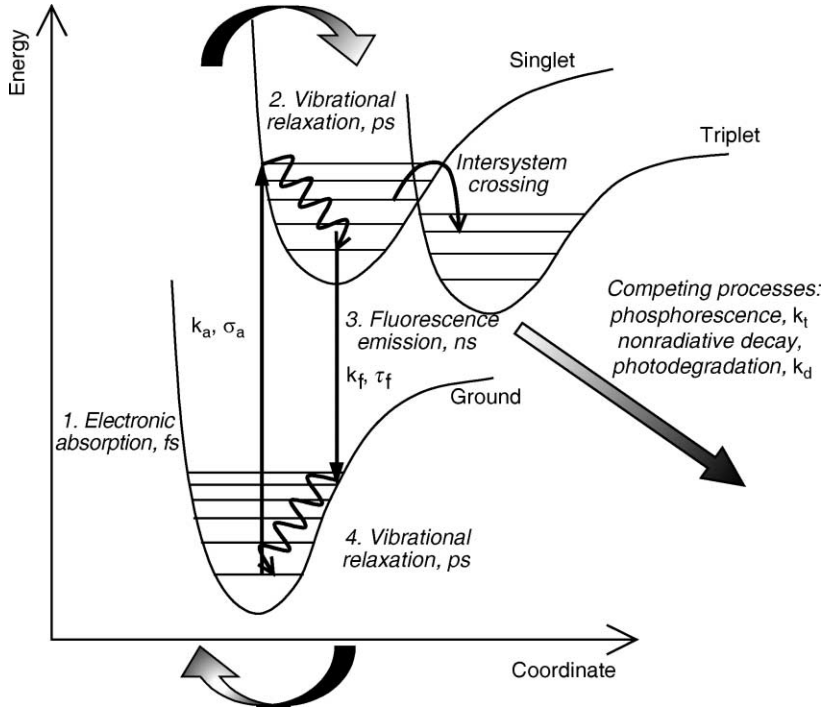

Figure 1 Schematic illustration of the molecular absorption–emission cycle and timescales for the component processes. Competing processes that may reduce the ultimate photon yield are also shown.

region for several milliseconds. The rapid photon absorption-emission cycle may therefore be repeated many times during the residence period, resulting in a burst of fluorescence photons as the molecule transits the beam. The burst size is limited theoretically by the ratio of the beam transit time (τ_r) and the fluorescence lifetime:

$$N_{\text{photons}} = \frac{\tau_r}{\tau_f} \qquad [1]$$

For typical values of τ_r (5 ms) and τ_f (5 ns) up to one million photons may be emitted by the single molecule. In practice, photobleaching and photodegradation processes limit this yield to about 10^5 photons. Furthermore, advances in optical collection and detection technologies enable registration of about 1–5% of all photons emitted. This results in a fluorescence burst signature of up to a few thousand photons or photoelectrons.

Successful single molecule detection (SMD) depends critically on the optimization of the fluorescence burst size and the reduction of background interference from the bulk solvent and impurities. Specifically a molecule is well suited for SMD if it is efficiently excited by an optical source (i.e., possesses a large molecular absorption cross-section at the wavelength of interest), has a high fluorescence quantum efficiency (favoring radiative deactivation of the excited state), has a short fluorescence lifetime, and is exceptionally photostable.

Ionic dyes are often well suited to SMD as fluorescence quantum efficiencies can be close to unity and fluorescence lifetimes below 10 nanoseconds. For example, xanthene dyes such as Rhodamine 6G and tetramethyl-rhodamine isothiocyanate are commonly used in SMD studies. However, other highly fluorescent dyes such as fluorescein are unsuitable for such applications due to unacceptably high photodegradation rate coefficients. Furthermore, some solvent systems may enhance nonradiative processes, such as intersystem crossing, and yield significant reduction in the photon output. Structures of three common dyes suitable for SMD are shown in Figure 2.

Signal vs Background

The primary challenge in SMD is to ensure sufficient reduction in background levels to enable discrimination between signal and noise. As an example, in a 1 nM aqueous dye solution each solute molecule occupies a volume of approximately 1 fL. However, this same volume also contains in excess of 10^{10} solvent molecules. Despite the relatively small scattering cross-section for an individual water molecule ($\sim 10^{-28}$ cm^2 at 488 nm), the cumulative scattering

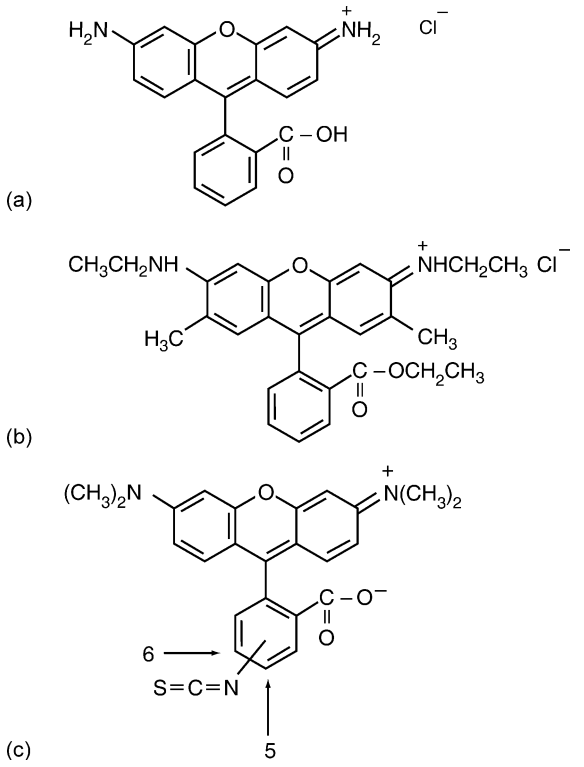

Figure 2 Structures of common dye molecules suitable for SMD in solution: (a) 3,6-diamino-9-(2-carboxyphenyl)-chloride (rhodamine 110); (b) 9-(2-(ethoxycarbonyl)phenyl)-3,6-bis (ethylamino)-2,7-dimethyl chloride (rhodamine 6G); (c) 9-(2-carboxy-isothiocyanatophenyl)-3,6-bis(dimethylamino)-inner salt (tetra methylrhodamine-5-(and-6)-isothiocyanate).

signal from the solvent may swamp the desired fluorescence signal. The principal method of reducing the solvent background is to minimize the optical detection volume: the signal from a single molecule is independent of probe volume dimensions, but the background scales proportionally with the size of the detection region. Although there are several experimental approaches to SMD in solution, several factors hold common:

1. Tiny detection volumes (10^{-12}–10^{-15} L) are used to reduce background signals.
2. A low analyte concentration combined with the small observation volume, ensures that less than one analyte molecule is present in the probe volume on average.
3. High-efficiency photon collection (optics) and detection maximize the proportion of the isotropic fluorescence burst that is registered.
4. Background reduction methods are employed to improve signal-to-noise ratios. These include: optical rejection of Raman and Rayleigh scatter, time-gated discrimination between prompt scatter and delayed emission, and photobleaching of the solvent immediately before detection.

The minute volumes within which single molecules are detected can be generated in a variety of ways. Picoliter volumes can be defined by mutually orthogonal excitation and detection optics focused in a flowing stream. Much smaller, femtoliter probe volumes are generated using confocal microscopes. At this level, background emission is significantly reduced and high signal-to-noise ratios can be achieved. Confocal detection techniques are versatile and have been widely adopted for SMD in freely diffusing systems. Consequently, confocal methods will be discussed in detail in this article. The other general approach to performing SMD in solution involves the physical restriction of single molecules within defined volumes. Of particular note are techniques where single molecules are confined within a stream of levitated microdroplets. Droplet volumes are typically less than 1 fL and imaging of the entire microdroplet enables single molecule fluorescence to be contrasted against droplet 'blanks' with good signal-to-noise. Furthermore, since molecules are confined within discrete volumes, the technique can be utilized for high-efficiency molecular counting applications. More recently, spatial confinement of molecules in capillaries and microfabricated channels (with submicron dimensions) has been used to create probe volumes between 1 fL and 1 pL, and immobilized molecules on surfaces have been individually probed using wide-field microscopy with epi-illumination or evanescent wave excitation.

Single Molecule Detection using Confocal Microscopy

As previously stated, the confocal fluorescence microscope is an adaptable and versatile tool for SMD. In its simplest form, a confocal microscope is one in which a point light source, a point focus in the object plane, and a pinhole detector are all confocal with each other. This optical superposition generates superior imaging properties and permits definition of ultra-small probe volumes. The concepts behind a basic confocal microscope and its use in SMD are schematically illustrated in Figure 3. Coherent light (typically from a laser and tuned to an optical transition of the molecule under investigation) behaves as a point light source and is focused into a sample chamber using a high-numerical aperture objective lens. As a single molecule traverses the laser beam it is continuously cycled between the ground and an excited electronic state, emitting a burst of fluorescence photons. Fluorescence emission is isotropic (spontaneous emission), so photons are emitted in all directions (4π steradians).

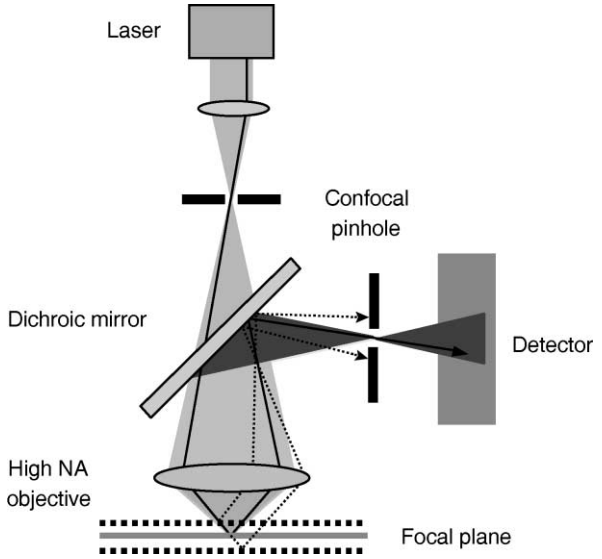

Figure 3 Principle of confocal detection. A confocal pinhole only selects light that emanates from the focal region. Dashed lines indicate paths of light sampled above and below the focal plane that are rejected by the pinhole. The solid ray derives from the focal point, and is transmitted through the pinhole to a detector.

Consequently, the high numerical aperture is used to collect as large a fraction of photons emitted from the focal plane as possible. Designing the objective to be used with an immersion medium, such as oil, glycerin, or water, can dramatically increase the objective numerical aperture, and thus the number of collected photons. Light collected by the objective is then transmitted towards a dichroic beam splitter. In the example shown, fluorescence photons (of lower energy) are reflected towards the confocal detector pinhole, whereas scattered radiation (of higher energy) is transmitted through the dichroic towards the light source. Creation of a precise optical probe volume is effected through the definition of the confocal pinhole. The detector is positioned such that only photons that pass through the pinhole are detected. Consequently, light emanating from the focal plane in the sample is transmitted through the pinhole and detected, whereas light not deriving from the focal plane is rejected by the aperture, and therefore not detected (Figure 3).

To ensure that the maximum number of photons are detected by the system, high efficiency detectors must be used. Photomultiplier tubes (the most common detectors for light-sensing applications) are robust and versatile but have poor detection efficiencies (approximately 5% of all photons that fall on the photocathode yield an electrical signal). Consequently, the most useful detectors for SMD (or low light level) applications are single photon-counting avalanche photodiodes (SPADs). A SPAD is essentially a p–n junction reverse biased above the breakdown voltage, that sustains an avalanche current when triggered by a photon-generated carrier. Detection efficiencies for typical SPADs are normally between 60–70% and are thus ideal for SMD in solution. An approximation of the overall detection efficiency of a confocal system for SMD can be made using eqn [2], which incorporates an estimation of photon losses at all stages of the collection/detection process. Typical transmission efficiencies for each step are also shown.

overall detection efficiency	≈	objective collection efficiency	×	dichroic transmission coefficient	×	additional optical losses	×	detector efficiency

[2]

Optical Probe Volumes

The precise nature of the probe volume is determined by the image of the pinhole in the sample and the spherical aberration of the microscope objective. Routinely, confocal probe volumes are approximated as resembling a cylinder with a radius defined by the diffraction-limited waist of a Gaussian beam. This approximation is useful when the incident beam is narrow or not tightly focused. However, when the radius of the incident beam is large, the corresponding diffraction limited focus is narrowed, and the probe volume more closely resembles a pair of truncated cones. Figure 4a illustrates the dependence of the curvature of the $1/e^2$ intensity contour on the collimated beam radius.

Consequently, it is clear that a simple cylindrical approximation for the probe volume breaks down for wide, tightly focused beams. If a broad incident beam (diameter >1.5 mm) is used, a large noncylindrical contribution to the probe volume is anticipated and a more appropriate model is required. An alternative and more accurate model for the confocal probe volume considers the Gaussian profile of the focused beam. The $1/e^2$ intensity contour radius of a Gaussian waveform with wavelength λ, at some distance z from the beam waist radius w_0, is given by eqn [3]:

$$w(z) = w_0\sqrt{1 + \left(\frac{\lambda z}{\pi w_0^2}\right)^2} \qquad [3]$$

In this case, the probe volume V is given by the volume of rotation of $w(z)$ around the z-axis between Z' and $-Z'$. The volume of rotation can therefore be

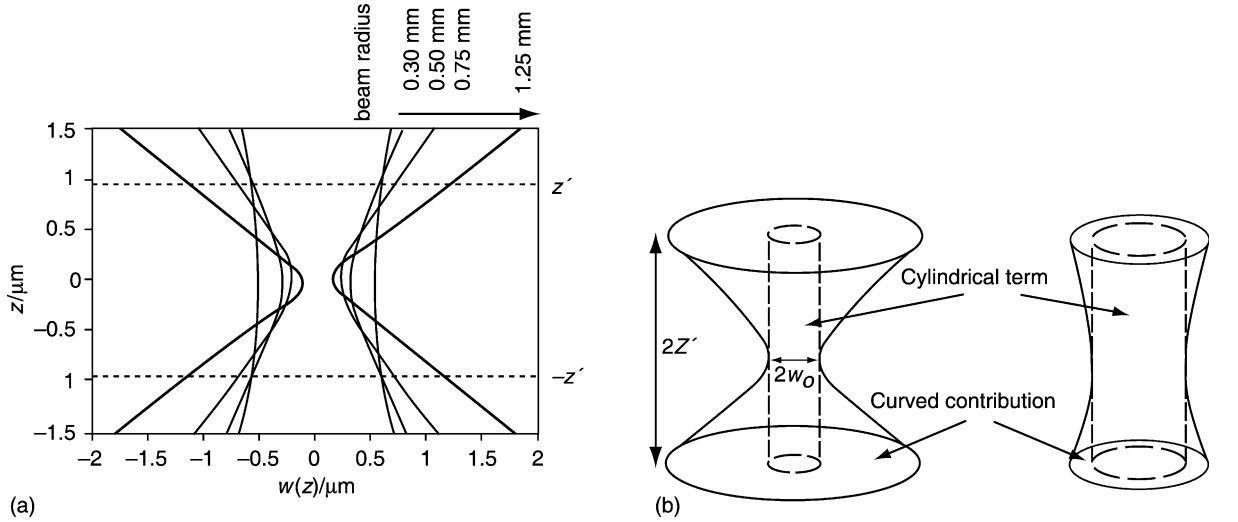

Figure 4 (a) $1/e^2$ Gaussian intensity contours plotted for a series of laser beam radii ($\lambda = 488$ nm, $f = 1.6$ mm, $n = 1.52$). (b) Cylindrical and curved components of the Gaussian probe volume. The curved contribution is more significant for larger beam radii and correspondingly tight beam waists.

simply defined according to,

$$V = \int_{-Z'}^{Z'} \pi w(z)^2 dz \qquad [4]$$

Solution of eqn [4] yields

$$V = 2\pi w_0^2 Z' + \frac{2\lambda^2}{3\pi w_0^2} Z'^3 \qquad [5]$$

The Gaussian volume expression contains two terms. The first term, $2\pi w_0^2 Z'$, corresponds to a central cylindrical volume; the second term has a more complex form that describes the extra curved volume (Figure 4b). The diffraction-limited beam waist radius w_0 can be defined in terms of the focusing objective focal length f, the refractive index n, and the collimated beam radius R according to

$$w_0 = \frac{\lambda f}{n\pi R} \qquad [6]$$

Substitution in eqn [5] yields,

$$V = 2\pi\left(\frac{\lambda f}{n\pi R}\right)^2 Z' + \frac{2\lambda^2}{3\pi}\left(\frac{n\pi R}{\lambda f}\right)^2 Z'^3$$

$$= \frac{2\lambda^2 f^2}{\pi n^2 R^2} Z' + \frac{2\pi n^2 R^2}{3f^2} Z'^3 \qquad [7]$$

The volume is now expressed in terms of identifiable experimental variables and constants. Once again, the first term may be correlated with the cylindrical contribution to the volume, and the second term is the additional volume due to the curved contour. It is clear from Figure 4a that, for a given focal length, the noncylindrical contribution to the probe volume increases with incident beam diameter, when the diffraction limited focus is correspondingly sharp and narrow. Furthermore, it can also be seen that the second term in eqn [7] is inversely proportional to f^2, and thus the extent to which the probe volume is underestimated by the cylindrical approximation increases with decreasing focal length. This fact is significant when performing confocal measurements, since high numerical aperture objectives with short focal lengths are typical. Some realistic experimental parameters give an indication of typical dimensions for the probe volume in confocal SMD systems. For example, if $\lambda = 488$ nm, $f = 1.6$ mm, $Z' = 1.0$ μm and $n = 1.52$, a minimum optical probe volume of 1.1 fL is achievable with a collimated beam diameter of 1.1 mm.

Intensity Fluctuations: Photon Burst Statistics

When sampling a small volume within a system that may freely exchange particles with a large surrounding analyte bath, a Poisson distribution of particles is predicted. A Poisson distribution is a discrete series that is defined by a single parameter μ equating to the mean and variance of the distribution:

$$P(n = x) = \frac{\mu^x e^{-\mu}}{x!} \qquad [8]$$

Common Poisson processes include radioactive disintegration, random walks and Brownian motion. Although particle number fluctuations in the excitation volume are Poissonian in nature, the corresponding fluorescence intensity modulation induces a stronger correlation between photon counts. For a single molecular species the model is described by two parameters: an intrinsic molecular brightness and the average occupancy of the observation volume. A super-Poissonian distribution has a width or variance that is greater than its mean; in a Poisson distribution the mean value and the variance are equal. The fractional deviation Q is defined as the scaled difference between the variance and the expectation value of the photon counts, and gives a measure of the broadening of the photon counting histogram (PCH). Q is directly proportional to the molecular brightness factor ε and the shape factor γ of the optical point spread function. (γ is constant for a given experimental geometry.)

$$Q = \frac{\langle \Delta n^2 \rangle - \langle n \rangle}{\langle n \rangle} = \gamma \varepsilon \qquad [9]$$

A pure Poisson distribution has $Q = 0$; for super-Poissonian statistics $Q > 0$. Deviation from the Poisson function is maximized at low number density and high molecular brightness.

In a typical SMD experiment raw data are generally collected with a multichannel scalar and photons are registered in binned intervals. Figure 5 illustrates typical photon burst scans demonstrating the detection of single molecules (R-phycoerythrin) in solution. Fluorescence photon bursts, due to single molecule events, are clearly distinguished above a low background baseline (top panel) of less than 5 counts per channel in the raw data. It is noticeable that bursts vary in both height and size. This is in part due to the range of possible molecular trajectories through the probe volume, photobleaching kinetics, and the nonuniform illumination intensity in the probe region. In addition, it can be seen that the burst frequency decreases as bulk solution concentration is reduced. This effect is expected since the properties of any given single-molecule event are determined by molecular parameters alone (e.g., photophysical and diffusion constants) and concentration merely controls the frequency/number of events.

Although many fluorescence bursts are clearly distinguishable from the background, it is necessary to set a count threshold for peak discrimination in order to correctly identify fluorescence bursts above the background. A photocount distribution can be used as the starting point for determining an appropriate threshold for a given data set. The overlap between signal and background photocount distributions affects the efficiency of molecular detection. Figure 6 shows typical signal and background photocount probability distributions, with a threshold set at approximately 2 photocounts per channel. The probability of spurious (or false)

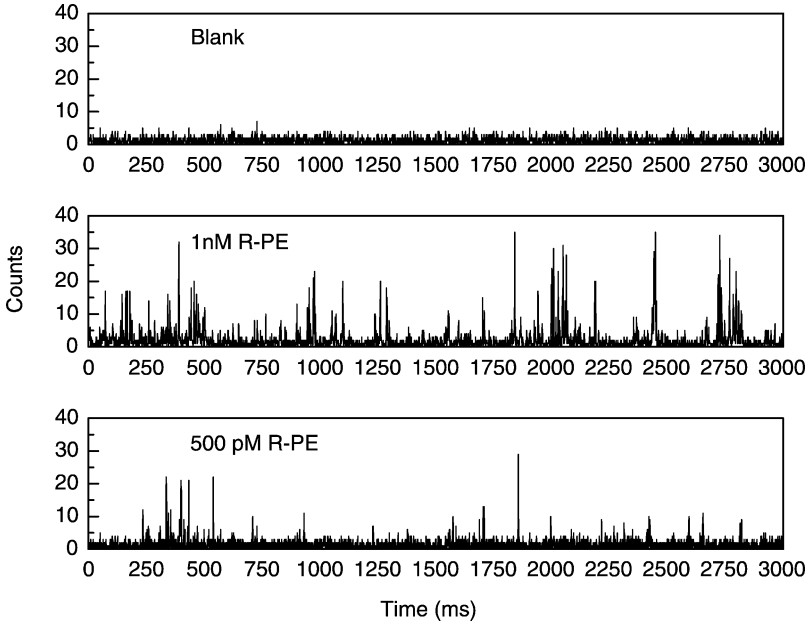

Figure 5 Photon burst scans originating from 1 nM and 500 pM R-phycoerythrin buffered solutions. Sample is contained within a 50 μm square fused silica capillary. Laser illumination = 5 μW, channel width = 1 ms. The top panel shows a similar burst scan originating from a deionized water sample measured under identical conditions.

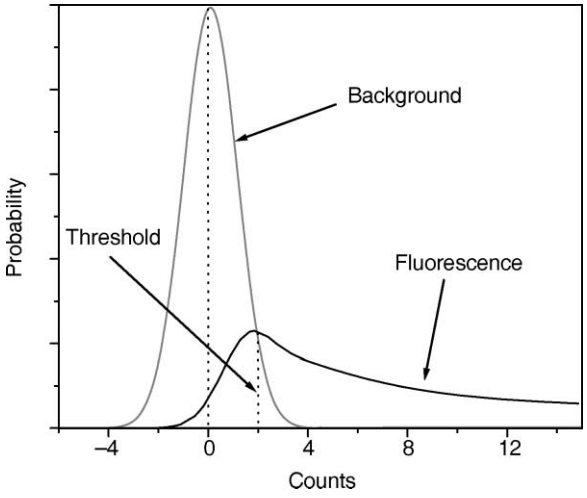

Figure 6 Simulated fluorescence and background photocount probability distributions. The vertical dashed line at 2 counts represents an arbitrarily defined threshold value for peak determination.

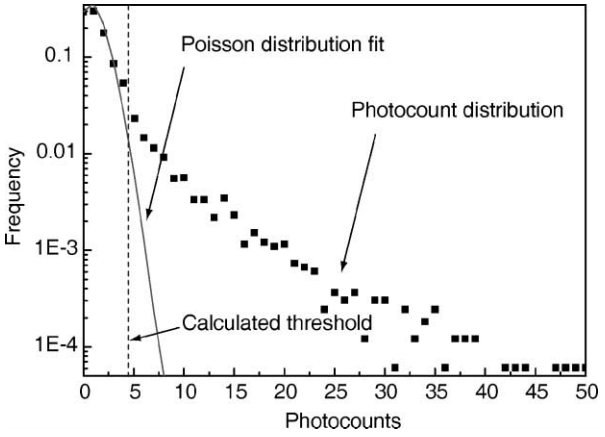

Figure 7 A photon counting histogram generated from a 16 second photon burst scan originating from a 10 μg/mL solution of 1000 nm fluorescent microbeads. The dotted curve shows a least-squares fit of early channels to a Poisson distribution, and the dashed vertical line marks the peak threshold (defined as $\mu + 3\sqrt{\mu} = 4.47$ counts).

detection resulting from statistical fluctuations in the background can be quantified by the area under the 'background' curve at photocount values above the threshold. Similarly, the probability that 'true' single molecule events are neglected can be estimated by the area under the 'fluorescence' curve at photocount values below the threshold. Choice of a high threshold value will ensure a negligible probability of calling a false positive, but will also exclude a number of true single molecule events that lie below the threshold value. Conversely, a low threshold value will generate an unacceptably high number of false positives. Consequently, choice of an appropriate threshold is key in efficient SMD.

Since the background shot noise is expected to exhibit Poisson statistics, the early part of the photocount distribution (i.e., the portion that is dominated by low, background counts) can be modeled with a Poisson distribution, to set a statistical limit for the threshold. Photon counting events above this threshold can be defined as photon bursts associated with the presence of single molecules. In an analogy with Gaussian systems the selected peak discrimination threshold can be defined as three standard deviations from the mean count rate:

$$n_{\text{threshold}} = \mu + 3\sqrt{\mu} \qquad [10]$$

Adoption of a threshold that lies 3 standard deviations above the mean yields a confidence limit that is typically greater than 99%. Figure 7 illustrates a sample photocount distribution, a least-squares fit to an appropriate Poisson distribution, and the calculated threshold that results. Once the threshold has been calculated, its value is subtracted from all channel counts and a peak search utility used to identify burst peaks in the resulting data set.

Data Filtering

As stated, the primary challenge in detecting single molecules in solution is not the maximization of the detected signal, but the maximization of the signal-to-noise ratio (or the reduction of background interferences). Improving the signal-to-noise ratio in such experiments is important, as background levels can often be extremely high.

Several approaches have been used to smooth SMD data with a view to improving signal-to-noise ratios. However, the efficacy of these methods is highly dependent on the quality of the raw data obtained in experiment. As examples, three common methods are briefly discussed. The first method involves the use of a weighted quadratic sum (WQS) smoothing filter. The WQS function creates a weighted sum of adjacent terms according to

$$\tilde{n}_{k,WQS} = \sum_{j=0}^{m-1} w_j (n_{k+j})^2 \qquad [11]$$

The range of summation m is the same order as the burst width, and the weighting factors w_j are chosen

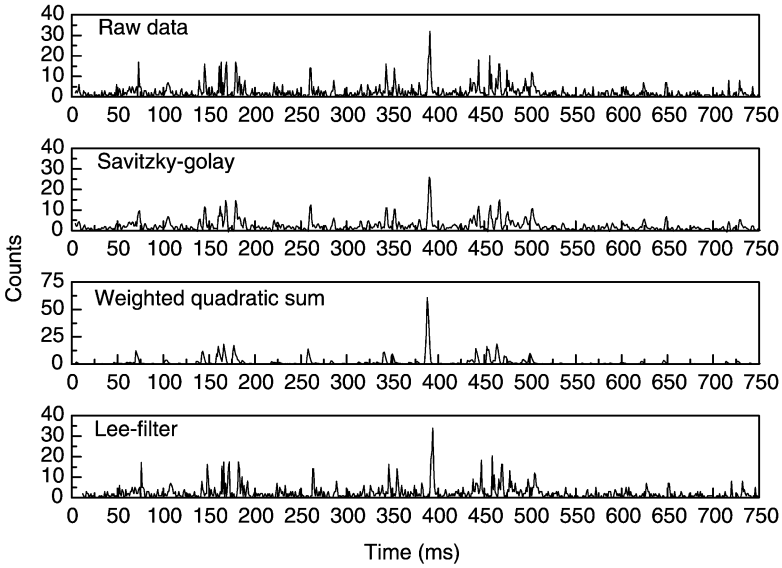

Figure 8 Effect of various smoothing filters on a 750 ms photon burst scan originating from a 1 nM R-phycoerythrin buffered solution. Raw data are shown in the top panel.

to best discriminate between single-molecule signals and random background fluctuations. This method proves most useful for noisy systems, in which the raw signal is weak. There is a practical drawback, in that peak positions are shifted by the smoothing function, and subsequent burst analysis is therefore hampered.

Another popular smoothing filter is the Lee-filtering algorithm. The Lee filter preferentially smoothes background photon shot noise and is defined according to

$$\tilde{n}_k = \bar{n}_k + (n_k - \bar{n}_k)\frac{\sigma_k^2}{\sigma_k^2 + \sigma_0^2} \qquad [12]$$

where the running mean (n_k) and running variance (σ_k^2) are defined by

$$\bar{n}_k = \frac{1}{(2m+1)}\sum_{j=-m}^{m} n_{k+j} \quad m < k \leq N - m \qquad [13]$$

$$\sigma_k^2 = \frac{1}{(2m+1)}\sum_{j=-m}^{m} (n_{k+j} - \bar{n}_{k+j})^2 \quad 2m < k \leq N - 2m \qquad [14]$$

for a filter $(2m+1)$ channels wide. Here, n_k is the number of detected photons stored in a channel k, σ_0 is a constant filter parameter, and N is the total number of data points.

A final smoothing technique worth mentioning is the Savitsky-Golay smoothing filter. This filter uses a least-squares method to fit an underlying polynomial function (typically a quadratic or quartic function) within a moving window. This approach works well for smooth line profiles of a similar width to the filter window and tends to preserve features such as peak height, width and position, which may be lost by simple adjacent averaging techniques. Figure 8 shows the effects of using each approach to improve signal-to-noise for raw burst data.

Photon Burst Statistics

A valuable quantitative analysis method for analysis of fluorescence bursts utilizes the analysis of Poisson statistics. Burst interval distributions are predicted to follow a Poissonian model, in which peak separation frequencies adopt an exponential form. The probability of a single molecule (or particle) event occurring after an interval Δt is given by eqn [15]:

$$N(\Delta t) = \lambda \exp(-\beta t) \qquad [15]$$

where λ is a proportionality constant and β is a characteristic frequency at which single molecule events occur. The recurrence time τ_R can then be simply defined as

$$\tau_R = \frac{1}{\beta} \qquad [16]$$

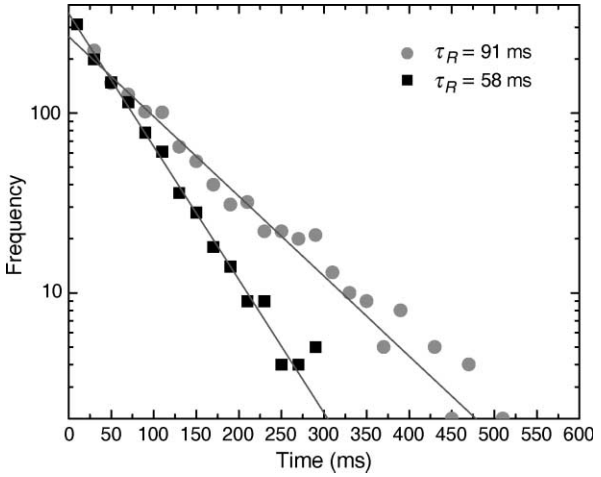

Figure 9 Burst interval distribution analysis of photon burst scans. Data originate from 1 μm fluorescent beads moving through 150 μm wide microchannels at flow rates of 200 nL min^{-1} (circles) and 1000 nL min^{-1} (squares). Least squares fits to a single exponential function are shown by the solid lines.

Equation [6] simply states that longer intervals between photon bursts are less probable than shorter intervals. Furthermore, the recurrence time reflects a combination of factors that control mobility, probe volume occupancy, or other parameters in the single molecule regime. Consequently, it is expected that τ_R should be inversely proportional to concentration, flow rate or solvent viscosity in a range of systems. Figure 9 shows an example of frequency $N(\Delta t)$ versus time plots for two identical particle systems moving at different velocities through the probe volume. A least-squares fit to a single exponential function yields values of $\tau_R = 91$ ms for a volumetric flow rate of 200 nL/min and $\tau_R = 58$ ms for a volumetric flow rate of 1000 nL/min.

Temporal Fluctuations: Autocorrelation Analysis

Autocorrelation analysis is an extremely sensitive method for detecting the presence of fluorescence bursts in single molecule experiments. This approach essentially measures the average of a fluctuating signal as opposed to the mean spectral intensity. As previously discussed, the number of molecules contained within a probe volume at any given time is governed by Poisson statistics. Consequently, the root mean square fluctuation can be defined according to eqn [17],

$$\frac{\sqrt{\langle(\delta N)^2\rangle}}{\langle N\rangle} = \frac{\sqrt{\langle(N-\langle N\rangle)^2\rangle}}{\langle N\rangle} = \frac{1}{\sqrt{\langle N\rangle}} \quad [17]$$

where N is the number of molecules. It is observed that the relative fluctuation diminishes as the number of particles measured is increased. Hence, it is important to minimize the number of molecules present in the probe volume. It should be noted, however, that if there are too few molecules in the solution there will be long dark periods were no single molecule bursts are observed. If the probe volume is bathed in radiation of constant intensity, fluctuation of the resulting fluorescence signal can simply be defined as deviations from the temporal signal average:

$$\langle F(t)\rangle = \frac{1}{T}\int_0^T F(t)\mathrm{d}t \quad [18]$$

Here, t is defined as the total measurement time, $F(t)$ is the fluorescence signal at time t, and $\langle F(t)\rangle$ is the temporal signal average. Fluctuations in the fluorescence intensity, $\delta F(t)(\delta F(t) = F(t) - \langle F(t)\rangle)$, with time t, about an equilibrium value $\langle F\rangle$, can be statistically investigated by calculating the normalized autocorrelation function, $G(\tau)$, where

$$G(\tau) = \frac{\langle F(t+\tau)F(t)\rangle}{\langle F\rangle^2} = \frac{\langle \delta F(t+\tau)\delta F(t)\rangle}{\langle F\rangle^2} + 1 \quad [19]$$

In dedicated fluorescence correlation spectroscopy experiments, the autocorrelation curve is usually generated in real time in a high-speed digital correlator. Post data acquisition calculation is also possible using the following expression

$$G(\tau) = \sum_{t=0}^{N-1} g(t)g(t+\tau) \quad [20]$$

Here $g(t)$ is the total number of counts during the time interval $(t, t+\Delta t)$, $g(t+\tau)$ is the number of counts detected in an interval of Δt at a later time $t+\tau$, and N is the total number of time intervals in the dataset. In a diffusion controlled system with a single fluorescent molecule that is irradiated with a three dimensional Gaussian intensity profile, the autocorrelation curve is governed by the mean probe volume occupancy N and the characteristic diffusion time (τ_D). The laser beam waist radius ω and the probe depth $2z$ describe the Gaussian profile:

$$G(\tau) = 1 + \frac{1}{N}\left(1+\frac{\tau}{\tau_d}\right)^{-1}\left(1+\left(\frac{\omega}{z}\right)^2\frac{\tau}{\tau_d}\right)^{-1/2} \quad [21]$$

The diffusion time is a characteristic molecular residence time in the probe volume and inversely

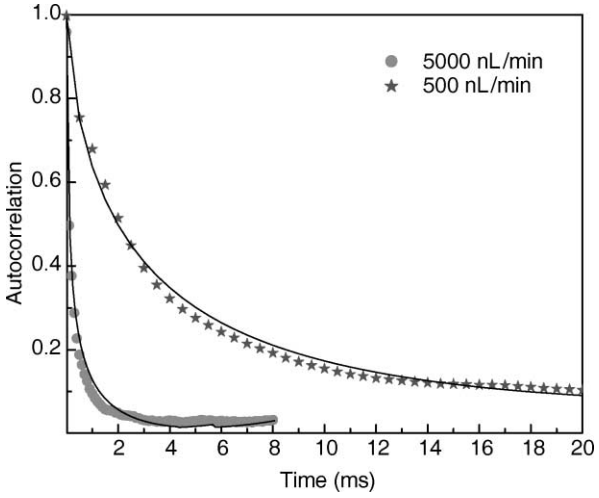

Figure 10 Autocorrelation analysis of photon burst scans of 1 μm fluorescent beads moving through 150 μm wide microchannels at flow rates of 500 nL min^{-1} (stars) and 1000 nL min^{-1} (circles). Solid lines represent fits to the data according to eqn [23].

related to the translational diffusion coefficient for the molecule:

$$D = \frac{w^2}{4\tau_D} \qquad [22]$$

In a flowing system, the autocorrelation function depends on the average flow time through the probe volume τ_{flow}. A theoretical fit to the function can be described according to

$$G(\tau) = 1 + \frac{1}{N} A \exp\left\{\left(\frac{\tau}{\tau_{flow}}\right)^2 A\right\}$$
$$A = \left(1 + \frac{\tau}{\tau_d}\right)^{-1}\left(1 + \left(\frac{\omega}{z}\right)^2 \frac{\tau}{\tau_d}\right) \qquad [23]$$

where N is the mean probe volume occupancy; the flow velocity v can then be extracted from the characteristic flow time according to

$$v = \frac{w}{\tau_{flow}} \qquad [24]$$

It should be noted that in the case that directed flow is negligible or defined to be zero, the autocorrelation function simplifies to eqn [21].

Figure 10 illustrates experimentally determined autocorrelation curves for two identical particle systems moving at different velocities through the probe volume. As particle flow velocity is increased, the width of the autocorrelation curves is seen to narrow as a result of the reduced residence time in the probe volume. A plot of the reciprocal of the full width half maximum of the autocorrelation curve as a function of volumetric flow rate is linear, and provides a simple way of calculating particle/molecule velocities within flowing systems.

Applications

The basic tools and methods outlined in this chapter have been used to perform SMD in a variety of chemically and biologically relevant systems, and indeed there is a large body of work describing the motion, conformational dynamics and interactions of individual molecules (see Further Reading). A primary application area has been in the field of DNA analysis, where SMD methods have been used in DNA fragment sizing, single-molecule DNA sequencing, high-throughput DNA screening, single-molecule immunoassays, and DNA sequence analysis. SMD methods have also proved highly useful in studying protein structure, protein folding, protein-molecule interactions, and enzyme activity.

More generally, SMD methods may prove to be highly important as a diagnostic tool in systems where an abundance of similar molecules masks the presence of distinct molecular anomalies that are markers in the early stages of disease or cancer.

Diffuse-Reflectance Laser Flash Photolysis

D R Worrall and S L Williams, Loughborough University, Loughborough, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Flash photolysis was developed as a technique to study short-lived intermediates in photoinduced reactions by George Porter (later Lord Porter of Luddenham) and Ronald Norrish in 1949, drawing on Porter's wartime experience with radar techniques. Such was the impact of this development that it earned the Nobel prize jointly for Porter, Norrish, and Eigen in 1967. In this article we will describe the application of flash photolysis to opaque, scattering samples, detailing how light propagation in such samples can be treated theoretically, and will discuss methods by which the data obtained from diffuse reflectance flash photolysis experiments may be analyzed.

The technique of flash photolysis was originally based on using an intense flash of light (the photolysis flash) from a xenon tube to excite the sample, followed a certain time delay later by a spectroscopic flash of lower intensity from a second flash tube, the light from the latter being detected using a photographic plate. The photolysis flash is of sufficient intensity to produce a large population of intermediates (radicals, ions, excited states, isomers) in the sample, which then absorb light from the spectroscopic flash depending on the concentration of intermediates according to the Beer–Lambert law:

$$A = \varepsilon c l \qquad [1]$$

where A is the sample absorbance, ε the molar absorption coefficient, c the concentration and l the pathlength. The absorbance is related to the incident and transmitted intensities as

$$A = \log_{10} I_0/I \qquad [2]$$

With I_0 the incident and I the transmitted intensities, there is therefore an exponential fall-off of intensity with pathlength for a homogeneous absorber. Hence, by monitoring the evolution of the absorption spectra, the changes in concentration of the photoproduced intermediates and hence the kinetics of the processes in which they are involved are elucidated.

Flash photolysis has evolved subsequently to make use of laser sources and sophisticated electronic detection apparatus to push the limits of time resolution to the femtosecond regime. Indeed, recently the Nobel prize for chemistry was awarded to Ahmed Zewail for his work with ultrafast pump-probe techniques. However, in its conventional geometry, flash photolysis is limited to transparent samples, since it is necessary to be able to probe the excited species by monitoring the absorption spectra.

Many biological systems and industrially important samples are opaque or highly scattering, and hence the attenuation of light through the sample is no longer described by the Beer–Lambert law. In 1981, Frank Wilkinson and Rudolph Kessler had the idea of using diffusely reflected light to interrogate the changes in concentration within a scattering sample subjected to a high-intensity excitation pulse. When photons enter a sample, they may be absorbed or scattered. Those which are scattered may re-emerge from the irradiated surface as diffusely reflected light. The intensity of diffusely reflected light emerging from the surface at a particular wavelength is a unique function of the ratio of scattering to absorption. The more scattering events occurring before absorption, the more likely the photon is to escape from the sample as diffusely reflected light. Hence the probability of escape decreases as the absorption probability increases, and the diffusely reflected light is deficient in those wavelengths where the absorption is strongest, i.e., the ratio of the incident to absorbed light intensity at a given wavelength is related to the absorption of the sample at that wavelength.

Kubelka–Munk Theory of Reflectance

The theory which describes the relationship between incident and scattered light intensity, absorption and scatter, and concentration which is widely applied in this context, is the Kubelka–Munk theory of reflectance. The theory was originally developed to describe the reflectance characteristics of paint films but it works quite well for many samples containing a homogeneous distribution of scatterers and absorbers. The limiting assumption in this theory is that the scatterers from which the scattering layer is composed are very much smaller than the total layer thickness. Additionally, the layer should be optically thick such that all of the light entering the layer should be either absorbed or reflected, with a negligible fraction transmitted.

For a layer of thickness X diffusely irradiated with monochromatic light, the diagram shown in Figure 1

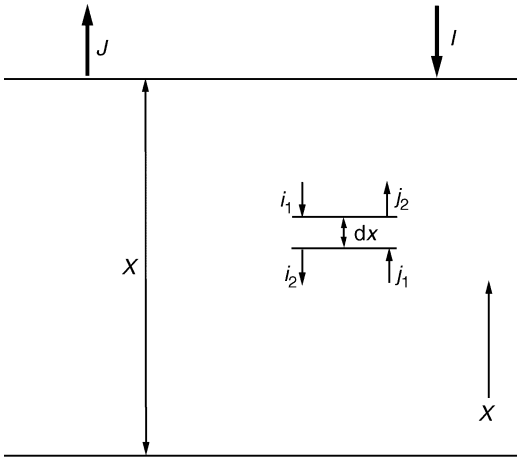

Figure 1 Schematic of counterpropagating fluxes in a diffusely irradiated scattering medium.

can be constructed, with I the incident flux and J the diffusely reflected flux, and i and j the fluxes traveling upwards and downwards through an infinitesimally small thickness element dx. Two further parameters may be defined which are characteristic of the medium.

K The absorption coefficient. Expresses the attenuation of light due to absorption per unit thickness.
S The scattering coefficient. Expresses the attenuation of light due to scattering per unit thickness.

Both of these parameters can be thought of as arising due to the particle (or chromophore) acting as a sphere of characteristic size, which casts a shadow either due to the prevention of on-axis transmission or due to absorption. The scattering or absorption coefficient then depends on the effective size of this sphere, and the number density of spheres in the medium. In each case, the probability P of a photon being transmitted through a particular thickness X of a medium is related exponentially to the absorption or scattering coefficient:

$$P = \exp(-KX) \qquad [3]$$

$$P = \exp(-SX) \qquad [4]$$

The scattering coefficient S depends on the refractive index difference between the particle and the dispersion medium. The scattering coefficient is also dependent upon the particle size, and shows an inverse correlation, i.e., the scattering coefficient increases as the particle size decreases. This effect is a function of the size of the particle relative to the wavelength of light impinging on it, with the scattering coefficient increasing as the wavelength decreases. However, this change with wavelength is small provided the particle size is large relative to the wavelength of the light.

The effect of the material in the element dx on the counterpropagating fluxes i and j depends on the absorption and scattering coefficients. Both i and j will be attenuated by both absorption and scattering:

$$i_2 = i_1 - i_1(S + K)\mathrm{d}x \qquad [5]$$

$$j_2 = j_1 - j_1(S + K)\mathrm{d}x \qquad [6]$$

Both i and j are reinforced by backscattering from the other flux:

$$i_2 = i_1 + j_1 S\mathrm{d}x \qquad [7]$$

$$j_2 = j_1 + i_1 S\mathrm{d}x \qquad [8]$$

The net effect of this in the attenuation of the flux propagating into the sample (i) and the flux backscattered from the sample (j) can be expressed as the following differential equations:

$$\mathrm{d}i = (S + K)i_1\mathrm{d}x - j_1 S\mathrm{d}x \qquad [9]$$

$$\mathrm{d}j = -(S + K)j_1\mathrm{d}x + i_1 S\mathrm{d}x \qquad [10]$$

For a sample of infinite thickness, these equations can be solved to give an analytical solution for the observed reflectance of the sample in terms of the absorption and scattering coefficients:

$$\frac{K}{S} = \frac{(1 - R_\infty)^2}{2R_\infty} \qquad [11]$$

where R_∞ is the reflectance from a sample of such thickness that an increase in sample thickness has no effect on the observed reflectance. The absorption coefficient K is dependent upon the concentration of absorbers in the sample through

$$K = 2\varepsilon c \qquad [12]$$

with ε the naperian absorption coefficient, c the concentration of absorbers and the factor 2 which is the geometrical factor for an isotropic scatterer. For multiple absorbers, K is simply the linear sum of absorption coefficients and concentrations. Hence for a diffusely scattering medium, an expression analogous to the Beer–Lambert law can be derived to relate concentration to a physically measurable parameter, in this case the sample reflectance. The ratio K/S is usually referred to as the Kubelka–Munk remission function, and is the parameter usually quoted in this context. It is important to note that the relationship

with concentration is only valid for a homogeneous distribution of absorbers within a sample.

Transient Concentration Profiles

As has been discussed in the previous section, a light flux propagating through a scattering medium is attenuated by both scattering and absorption events, whilst in a nonturbid medium attenuation is by absorption only. Hence even in a sample with a very low concentration of absorbers, the light flux is rapidly attenuated as it penetrates into the sample by scattering events. This leads to a significant flux gradient through the sample, resulting in a reduction in the concentration of photo-induced species as penetration depth into the sample increases. There are three distinct concentration profiles which may be identified within a scattering sample which are dependent on the scattering and absorption coefficients. These concentration profiles are interrogated by a beam of analyzing light, and hence an understanding of the effect of these differing profiles on the diffusely reflected intensity is vital in interpreting transient absorption data. The transient depth profiles are illustrated in Figure 2.

Kubelka–Munk Plug

This occurs when the photolysis flash, i.e., laser fluence is high and the absorption coefficient is low at the laser wavelength. If we assume a simple photophysical model involving simply the ground state S_0, the first excited singlet state S_1 and first excited triplet state T_1, and we assume that either the quantum yield of triplet state production is high or the S_1 lifetime is very much shorter than the laser pulse allowing re-population of the ground state, then it is possible at high enough fluence to completely convert all of the S_0 states to T_1 states within the sample. Provided the fluence is high enough, this complete conversion will penetrate some way into the sample (Figure 2). Under circumstances where the T_1 state absorbs strongly at some wavelength other than the photolysis wavelength, probing at this wavelength will result in the probe beam being attenuated significantly within a short distance of the surface of the sample, and thus will only interrogate regions where there is a homogeneous excited state concentration. Under these circumstances the reflectance of the sample as a function of the concentration of excited states is described by the Kubelka–Munk equation, and the change in remission function can be used to probe the change in excited state concentration.

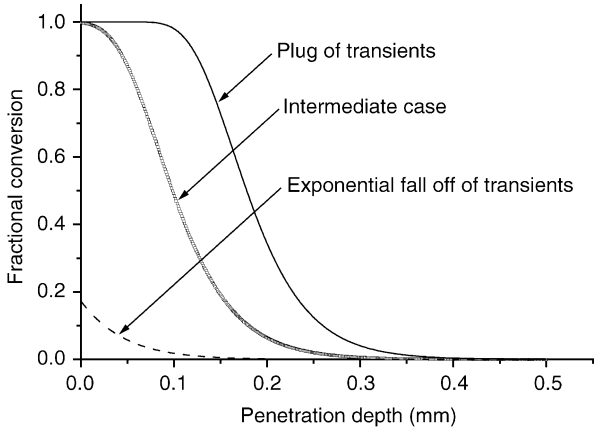

Figure 2 Transient concentration profiles following pulsed laser excitation of a scattering and absorbing sample.

Exponential Fall-Off of Concentration

This occurs when the laser fluence is low and the absorption coefficient at the laser wavelength high. Again considering the simple photophysical model, most of the laser flux will be absorbed by the ground state in the first few layers of sample, and little will penetrate deeply into the sample. In the limiting case this results in an exponential fall-off of transient concentration with penetration depth into the sample (Figure 2). Here the distribution of absorbers is not random and the limiting Kubelka–Munk equation is no longer applicable since the mean absorption coefficient varies with sample penetration depth. Lin and Kan solved eqs [9] and [10] with the absorption coefficient K varying exponentially with penetration depth and showed that the series solution converges for changes in reflectance of less than 10% such that the reflectance change is a linear function of the number of absorbing species.

Intermediate Case

Between the two extremes described above is a case where significant transient conversion takes place at the front surface, but with little penetration into the sample. This can occur, for example, with high laser fluences and large ground state absorption coefficients at the laser wavelength. Under these circumstances, illustrated in Figure 2, the analyzing light interrogates not only the transient concentration profile, but also a significant amount of the analyzing light may penetrate through the transient layer into the unconverted sample behind, if the transient absorption at the analyzing wavelength is low. This creates a more complex problem for analysis since effectively the sample is irradiated from both front and back faces, with consequent effects on the diffusely reflected intensity. It is possible to numerically model the reflectance change as a function of

transient concentration under these circumstances but a precise knowledge of the absorption and scattering coefficients is required. Under most circumstances, this case is avoided and diffuse reflectance flash photolysis experiments are arranged such that one of the two limiting cases above, generally the exponential fall-off (usually achieved by attenuation of the laser beam), prevails in a particular experiment.

Sample Geometry

In the case of conventional nanosecond laser flash photolysis, it is generally the case that right-angled geometry is employed for the photolysis and probe beams (Figure 3a). This geometry has a number of advantages over alternatives. The photolysis beam and analyzing beam are spatially well separated, such that the analyzing beam intensity is largely unaffected by scattered photolysis light. Also, the fluorescence generated by the sample will be emitted in all directions, whilst the analyzing beam is usually collimated allowing spatial separation of fluorescence and analyzing light; sometimes an iris is used to aid this spatial discrimination. This geometry is appropriate for quite large beam diameters and fluences; where smaller beams are used collinear geometry may be more appropriate in order to achieve long interaction pathlengths.

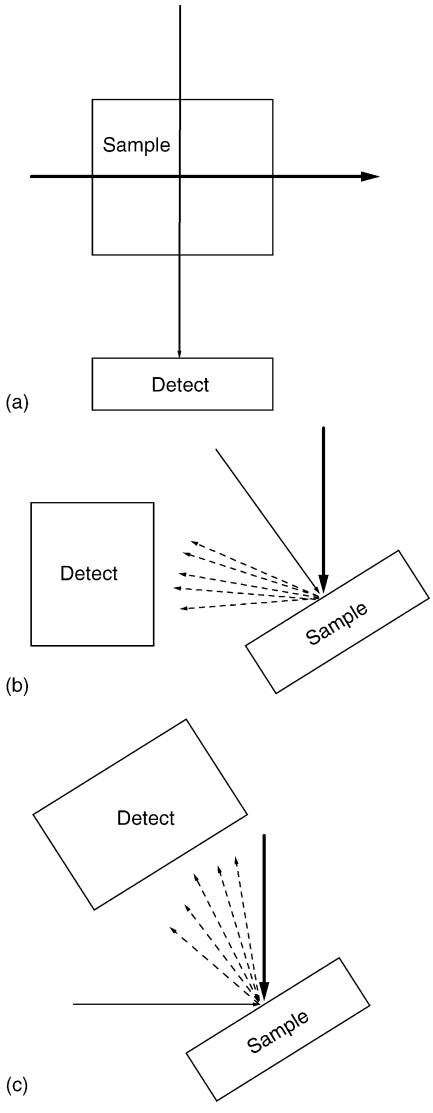

Figure 3 Sample geometries for (a) conventional and (b,c) diffuse reflectance flash photolysis. ⟶, photolysis beam; ⟶, analyzing beam.

In the case of nanosecond diffuse reflectance flash photolysis, the geometry required is quite different (Figure 3b,c). Here, the photolysis beam and analyzing beam must be incident on the same sample surface, and the diffusely reflected analyzing light is collected from the same surface. The geometry is often as shown in Figure 3b, where the analyzing light is incident almost perpendicularly on the sample surface, with the photolysis beam incident at an angle such that the specular reflection of the photolysis beam passes between detector and analyzing beam (not shown). Alternatively, the geometry shown in Figure 3c may be employed, where diffusely reflected light is detected emerging perpendicular to the sample surface. In both cases, the geometry is chosen such that specular (mirror) reflection of either exciting or analyzing light from the sample is not detected, since specular reflection is light which has not penetrated the sample and therefore contains no information regarding the concentrations of species present. A requirement, as in conventional flash photolysis, is that the analyzing beam probes only those areas which are excited by the photolysis beam, requiring the latter to be larger than the former. The nature of the scattering described previously means that the required geometry does not give spatial discrimination at the detector between photolysis and analyzing light, and fluorescence. This is since both analyzing and photolysis light undergo scattering and absorption processes (although with wavelength-dependent absorption and scattering coefficients) and emerge with the same spatial profiles. Fluorescence, principally that stimulated by the photolysis beam since this is of greatest intensity, originates from within the sample but again undergoes absorption and scattering and emerges with the same spatial distribution as the exciting light. In diffuse reflectance flash photolysis, separation of the analyzing light from the excitation or fluorescence must be achieved using spectral (filters and/or monochromators) or temporal, rather than spatial discrimination. Time-gated charge coupled devices

(CCD) or photodiode array detectors can be effectively used in nanosecond laser flash photolysis to exclude excitation light and fluorescence, since these occur on time-scales usually much shorter than the transient absorption of species of interest. The usual analyzing light source used in nanosecond diffuse reflectance flash photolysis is a xenon arc lamp, due to its good spectral coverage and high intensity. High probe intensity is particularly important in diffuse reflectance flash photolysis since the scattered intensities are often low, and the scattered light emerges in a large solid angle, only part of which can be effectively collected and detected. Also, high intensities allow for the light from the analyzing source to dominate over fluorescence if the latter is relatively weak.

In femtosecond diffuse reflectance laser flash photolysis, sample geometry considerations are also important. Such experiments are performed using the pump-probe technique, with the probe often being a femtosecond white-light continuum. The sample geometry employed is illustrated in Figure 4.

Here the pump and probe are almost colinear, and are incident on the same sample area; again, the requirement is for the pumped area to be larger than the probed area. Diffusely reflected light is then collected and analyzed, time resolution being achieved by varying the delay between pump and probe beams. It should be noted that the temporal resolution is worse than in conventional pump-probe techniques. In conventional femtosecond flash photolysis, the time resolution is generally limited by the widths of pump and probe pulses; in diffuse reflectance mode, the pulses undergo numerous refractions, reflections, and diffractions such that the pulse is temporally broadened during its transit through the material. The extent of this broadening is a sensitive function of the optical properties of the individual sample.

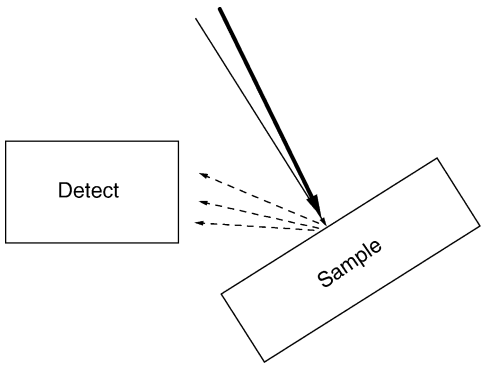

Figure 4 Sample geometry for femtosecond diffuse reflectance flash photolysis. ⟶, photolysis beam; ⟶, analyzing beam.

Kinetic Analysis

Kinetic analysis, and of course time-resolved spectroscopic analysis, require a quantitative treatment of the concentration changes within a sample following an excitation pulse as a function of time. When studying transient absorption phenomena in opaque samples, it is usual to define the reflectance change in terms of the sample reflectance before and after excitation, such that in spectrally resolved data a transient difference spectrum rather than an absolute reflectance spectrum of the transient species is obtained. The latter can, however, be reconstructed from a knowledge of the absorption coefficients and concentration of the species involved. It is possible to define the reflectance change as

$$\frac{\Delta J_t}{J_0} = 1 - \frac{R_t}{R_0} \qquad [13]$$

where R_0 and R_t represent the intensity of probe light diffusely reflected from the sample before excitation and at a time t after excitation, respectively. Frequently reflectance change is expressed as '% absorption', which is defined in eqn [14].

$$\%\ \text{absorption} = 100 \times \left(1 - \frac{R_t}{R_0}\right) \qquad [14]$$

These parameters are often used as being proportional to transient concentration, subject to satisfying the criteria for an exponential fall-off of transient concentration with penetration depth as discussed previously, and are used to replace transient concentration in kinetic equations used in data analysis.

It is generally the case that the samples studied using diffuse reflectance laser flash photolysis have either some degree of heterogeneity, for example paper, microcrystalline cellulose, silica gel or alumina, or have well-defined porous structures such as zeolites. Molecules adsorbed to these supports may be present on the surface, within micro- or mesopores, or intimately included within the structure. Hence each molecule may experience its own unique environment, and this will obviously influence its observed photophysics. It is therefore the case that in these systems, even very simple photo-induced reactions such as unimolecular photoisomerizations do not follow first-order kinetics; rather, a distribution of rates is observed which reflect the differing environments experienced by the molecules, and hence the molecules act as probes of this heterogeneity.

There are a number of approaches to kinetic analysis in opaque, often heterogeneous systems, as described below.

Rate Constant Distributions

Here the sample heterogeneity is treated as producing a series of micro-environments, and the reaction studied will have its own unique rate constant in each of these environments. The width of the observed rate constant distribution therefore describes the number of these possible environments, with the distribution amplitude at any particular rate constant, reflecting the probability of the molecule existing in the corresponding environment.

Exponential series lifetime distribution analysis is the simplest approach to distributed lifetime analysis. This analysis has the inherent advantage that there are no presuppositions regarding the kinetic model describing the data. Rather, a large number of exponentials with fixed rate constants and with amplitudes as adjustable parameters are applied to the data, and a least-squares procedure used to optimize the amplitude of each exponential. Generally there is a relationship between the rate constants, they being equally spaced on either a linear or logarithmic scale. Physically this can be interpreted as a large number of first-order or pseudo-first-order (in the case of bimolecular reactions) rates arising from the sample heterogeneity. Hence the rate constant distribution emerges naturally from the fitting procedure, with no preimposed constraints. Since there are a large number of adjustable parameters, these models are applied most successfully to data with good signal-to-noise.

Alternative approaches involve imposing a distribution shape onto a set of exponentials, and optimizing this distribution to the data. This approach has the advantage that by assuming a rate constant distribution, the relative amplitudes of the exponentials are fixed and hence the number of fitting parameters greatly reduced. One of the more successful models applied in this context is that developed by Albery *et al*. In the development of their model it is assumed that, for the reaction in question, the free energy of activation, $\Delta G^{\neq}$, is distributed normally around a mean value $\Delta \bar{G}^{\neq}$ according to eqn [15]:

$$\Delta G^{\neq} = \Delta \bar{G}^{\neq} - \gamma x RT \qquad [15]$$

with γ being the width of the distribution for $\infty \geq x \geq -\infty$. This assumed normal distribution of the free energy of activation leads to a log-normal distribution of the decay rate constants distributed around some average rate constant $\bar{k}$. The dispersion in the first-order rate constant is then

$$\ln(k) = \ln(\bar{k}) + \gamma x \qquad [16]$$

The equation used to describe the data is given as:

$$\frac{c}{c_0} = \frac{\int_{-\infty}^{\infty} \exp(-t^2) \exp\left[- \bar{k}t \exp(\gamma t)\right] \mathrm{d}t}{\int_{-\infty}^{\infty} \exp(-t^2) \mathrm{d}t} \qquad [17]$$

with c and c_0 being concentration at time $t = t$ and $t = 0$ relative to the excitation flash, respectively. Where reflectance change is proportional to transient concentration, reflectances can be used directly in place of concentrations. This equation can be solved by making the following substitutions:

$$\int_{-\infty}^{\infty} \exp(-t^2) \mathrm{d}t = \pi^{1/2} \qquad [18]$$

$$\int_{-\infty}^{\infty} \exp(-t^2) \exp\left[-\bar{k}t \exp(\gamma t)\right] \mathrm{d}t = \int_0^1 \lambda^{-1} \exp\Big(-(\ln \lambda^2)\Big)\Big(\exp(-\bar{k}t\lambda^{\gamma}) + \exp(-\bar{k}t\lambda^{-\gamma})\Big) \mathrm{d}\lambda \qquad [19]$$

Hence here there are only two fitting parameters, namely the width of the distribution γ and the distribution center, $\bar{k}$. Note that for $\gamma = 0$, eqn [17] reduces to a single exponential function.

A further model which constrains the rate constant distribution, which has been successfully applied to describe the rates of photo-induced processes on silica gel surfaces, is a Lévy stable distribution of rate constants, described as:

$$\mathrm{P}(\bar{k}, \alpha, \gamma) = \frac{1}{\pi} \int_0^{\infty} \exp(- \gamma q^{\alpha}) \cos(\bar{k}\mathrm{q}) \mathrm{dq} \qquad [20]$$

where α is the characteristic power law exponent ($0 < \alpha \leq 2$) and γ is the distribution width ($\gamma > 0$). Special cases of the Lévy stable distribution occur for $\alpha = 1$ and $\alpha = 2$, where the distribution shape becomes Lorentzian and Gaussian, respectively. The Lévy distribution gives an increasing weighting to the tails of the distribution as the distribution width decreases, and can be described as a random walk consisting of long jumps followed by several short walks. It has been shown that this type of foraging behavior is more efficient at seeking out randomly distributed targets than a simple random walk. The Lévy stable distribution has three adjustable parameters which allows greater flexibility in the distribution of rate constants than does the Gaussian model, but still constrains the distribution to be symmetrical about some mean value.

Physical Models

A number of these have been applied to very specific data sets, where parameters of the systems are accurately known. These include random walk models in zeolites, and time-dependent fractal-dimensional rate constants to describe kinetics on silica gel surfaces. The advantage of these methods over rate constant distributions is that since they are based on the physical description of the system, they yield physically meaningful parameters such as diffusion coefficients from analysis of kinetic data. However, for many systems the parameters are known in insufficient detail for accurate models to be developed.

Examples

An example of bimolecular quenching data is shown in Figure 5. Here, anthracene at a concentration of 1 μmol g^{-1} is co-adsorbed to silica gel from acetonitrile solution together with azulene at a concentration of 0.8 μmol g^{-1}. Laser excitation at 355 nm from an Nd:YAG laser produces the excited triplet state of the anthracene, which undergoes energy transfer to the co-adsorbed azulene molecule as a result of the rapid diffusion of the latter.

The data shown in Figure 5 are recorded monitoring at 420 nm, and the laser energy (approximately 5 mJ per pulse) is such that an exponential fall-off of transient concentration with penetration depth is expected such that reflectance change is proportional to transient concentration (see section on Transient Concentration Profiles above). The data are shown on a logarithmic time axis for clarity. The fitted line is obtained by applying the model of Albery *et al.*

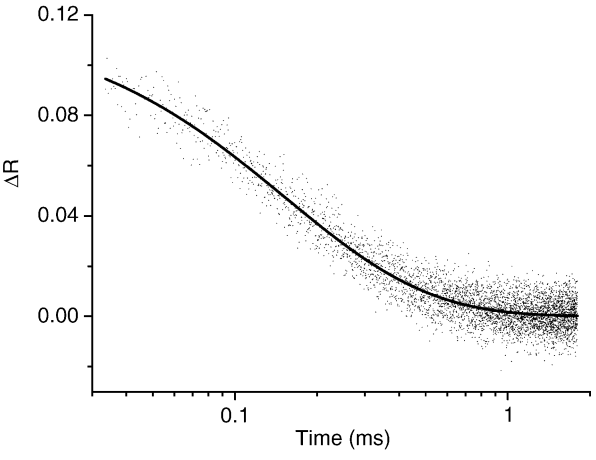

Figure 5 Transient absorption decay for anthracene (1 μmol g^{-1}) co-adsorbed with azulene (0.8 μmol g^{-1}) to silica gel monitored at 420 nm. Fitted using the model of Albery *et al.*

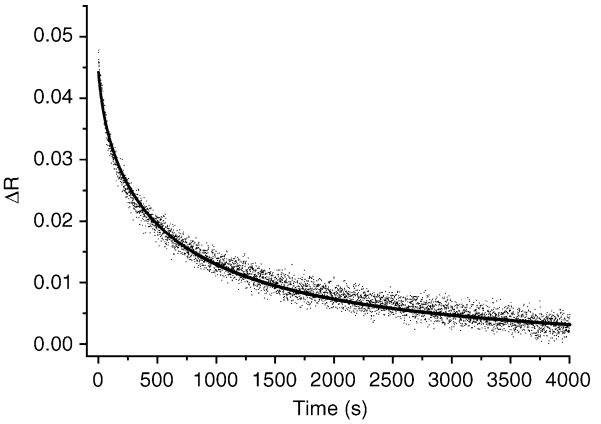

Figure 6 Transient absorption decay for the naphthalene (1 μmol g^{-1}) radical cation monitored at 680 nm on silica gel. Fitted using a Lévy stable distribution.

(see section on Rate Constant Distributions above) with fitting parameters $\bar{k} = 1.01 \times 10^4$ s^{-1} and $\gamma = 0.73$.

Where ion–electron recombination is concerned, the Albery model often fails to adequately describe the data obtained since it does not allow sufficient small rate constants relative to the value of $\bar{k}$, given the constraints of the Gaussian distribution. The Lévy stable distribution is ideal in this application since it allows greater flexibility in the shape of the distribution.

Figure 6 shows example data for naphthalene adsorbed to silica gel (1 μmol g^{-1}). The laser pulse energy at 266 nm (approximately 40 mJ per pulse) is such that photo-ionization of the naphthalene occurs producing the radical cation. The subsequent decay of the radical cation via ion–electron recombination can be monitored at 680 nm. Note that decay is observed on a time-scale of several thousand seconds. The fitted line is according to a Lévy stable distribution with parameters $\bar{k} = 8.2 \times 10^{-4}$ s^{-1}, $\gamma = 0.5$ and $\alpha = 1.7$ (see section on Rate Constant Distributions above). This model allows the shape of the distribution to deviate from a Gaussian, and can be more successful than the model of Albery *et al.* in modeling the complex kinetics which arise on surfaces such as silica gel. Note that where the model of Albery *et al.* can successfully model the data, the data can also be described by a Lévy stable distribution with $\alpha = 2$.

List of Units and Nomenclature

A	Sample absorbance
c	Concentration
I	Incident flux
J	Diffusely reflected flux

k	Rate constant
$\bar{k}$	Mean rate constant
K	Absorption coefficient (absorption per unit thickness) [cm^{-1}]
l	Pathlength [cm]
P	Probability of transmission of a photon through a sample of defined thickness
R_∞	Reflectance of an infinitely thick sample
S	Scattering coefficient (scattering per unit thickness) [cm^{-1}]
t	Time
X	Thickness of sample layer [cm]
α	Characteristic Lévy power law exponent
γ	Width of rate constant distribution
$\Delta G^{\neq}$	Free energy of activation [kJ mol^{-1}]
$\Delta \bar{G}^{\neq}$	Mean free energy of activation [kJ mol^{-1}]
ε	Molar decadic or naperian absorption coefficient

Laser Manipulation in Polymer Science

S Ito, Y Hosokawa and H Masuhara, Osaka University, Osaka, Japan

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Laser manipulation is a method for manipulating single particles with a size of less than a few tens of microns in which optical pressure of a focused laser beam is used to trap and control the particles without any mechanical contact. As infrared lasers, as a trapping light source, have become more user-friendly, even operators who are not familiar with lasers and microscopes can perform laser manipulation. Those laser manipulators already on sale have attracted significant attention as a new tool. It is especially interesting to combine this method with nanotechnology and biotechnology, which have progressed rapidly during the 1990s. In this article,

the principle and method of laser manipulation is described and then its applications and possibilities in nanotechnology and biotechnology are summarized.

Principle and Method

When light is reflected or refracted at the interface between two media with different refractive indices, the momentum of photons is changed, which leads to the generation of photon force as a reaction to the momentum change. For example, when a laser beam is reflected by a mirror, the momentum of photons is changed by Δp (Figure 1a). As a result, a photon force, F_{phot}, acts on the mirror to deflect it vertically away from the reflected beam. In refraction, the momentum of photons is also changed, so that the photon force acts on the interface, as shown in Figure 1b. Thus light does not only give its energy to materials via absorption but also applies a mechanical force to them. However, when we are exposed to light, such as from a halogen lamp, we are never aware of the photon force because its magnitude is less than an order of pN. However, the photon force of the pN order acquired from a focused laser beam is sufficient to manipulate nm–μm-sized particles in solution, under an optical microscope.

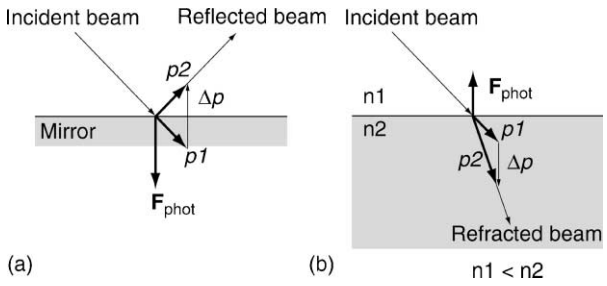

Figure 1 Optical pressure originating from the momentum change of photons.

Principle of Laser Trapping

If the size of a particle is larger than the wavelength of a trapping laser beam (μm-sized particles), the principle of single-beam gradient force optical trapping can be explained in terms of geometrical optics. When a tightly focused laser beam is irradiated onto a transparent dielectric particle, an incident laser beam is refracted at the interface between the particle and medium, as represented by Figure 2a. The propagation direction of the beam is changed, i.e., the momentum of the photon is changed, and consequently, a photon force is generated. As the laser beam leaves the particle and enters the surrounding medium, this refraction causes a photon force to be exerted again on that interface. Summing up the force contributions of all rays, if the refractive index of the particle is higher than that of the medium, a resultant force exerted on the particle is directed toward the focal point as an attractive force. However, reflection at the surface of the particle is negligible if that particle is transparent and the refractive index ratio of the particle to medium is close to unity. Therefore, the incident beam is reflected at two surfaces by a small amount, and as a result, the particle is directed slightly to the propagation direction of the incident light. Where the particle absorbs the incident beam, the photon force is also generated to push it in the propagation direction. The negligible effects of the

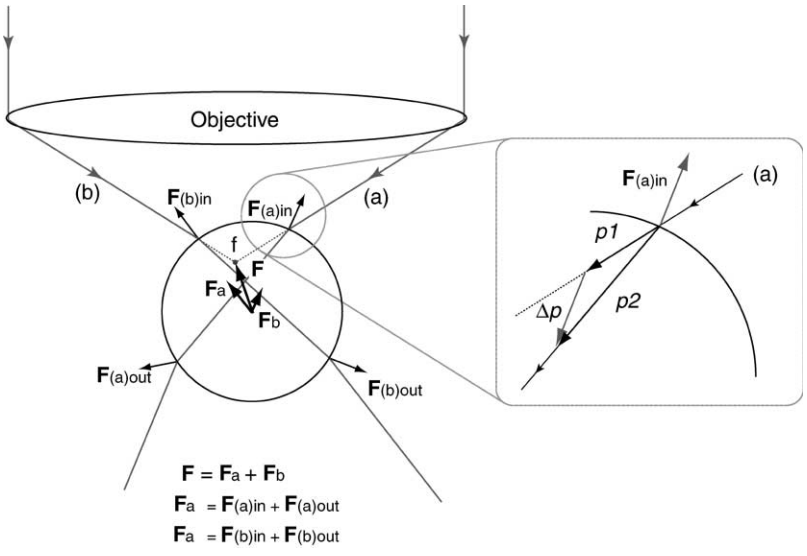

Figure 2 Principle of single-beam gradient force optical trapping explained by ray optics.

reflection and absorption occur in trapping experiment of transparent particles, such as polymer particles, silica microspheres, etc. However, particles with high reflectance and absorption coefficients such as metallic particles, exert a more dominant force at the surface where absorption and reflection occurs. This force is a repulsive force away from the focal point; consequently, metallic microparticles cannot be optically trapped.

If a dielectric particle is much smaller than the wavelength of a trapping light (nm-sized), it can be regarded as a point dipole (Rayleigh approximation) and the photon force ($\mathbf{F}_{\text{phot}}$) acted on it is given by

$$\mathbf{F}_{\text{phot}} = \mathbf{F}_{\text{grad}} + \mathbf{F}_{\text{scat}} \qquad [1]$$

Here, $\mathbf{F}_{\text{grad}}$ and $\mathbf{F}_{\text{scat}}$ are called the gradient force and scattering force, respectively. The scattering force is caused by the scattering of light, and it pushes the particle toward the direction of light propagation. On the other hand, the gradient force is generated when a particle is placed in a heterogeneous electric field of light. If the dielectric constant of the particle is higher than that of the surrounding medium, the gradient force acts on the particle to push it toward the higher intensity region of the beam. In the case of laser trapping of dielectric nanoparticles, the magnitude of gradient force is much larger than the scattering force. Consequently, the particle is trapped at the focal point of the trapping laser beam, where the beam intensity (electric field intensity) is maximum. The photon force can be expressed as follows:

$$\mathbf{F}_{\text{phot}} \cong \mathbf{F}_{\text{grad}} = \frac{1}{2}\varepsilon_{\text{m}}\alpha\nabla|\mathbf{E}|^2 \qquad [2]$$

$$\alpha = 3V\frac{\varepsilon_{\text{p}} - \varepsilon_{\text{m}}}{\varepsilon_{\text{p}} + 2\varepsilon_{\text{m}}} \qquad [3]$$

where, $\mathbf{E}$ is electric field of the light, V is volume of the particle, and ε_{p} and ε_{m} are dielectric constants of the particle and medium. In trapping nanoparticles that absorb the laser beam, such as gold nanoparticles, the complex dielectric constant and attenuation of the electric field in the particle need to be taken into consideration. Although the forces due to light absorption and scattering are both propelling the particle toward the direction of light propagation, the magnitude of gradient force is much larger than these forces. This is in contrast to the μm-sized metallic particle, which cannot be optically trapped.

Laser Manipulation System

An example of a laser micromanipulation system, with a pulsed laser to induce photoreactions, is shown in Figure 3. A linearly polarized laser beam from a CW Nd^{3+}:YAG laser is modulated to the circularly polarized light by a λ/4 plate and then split into horizontally and vertically polarized beams by a

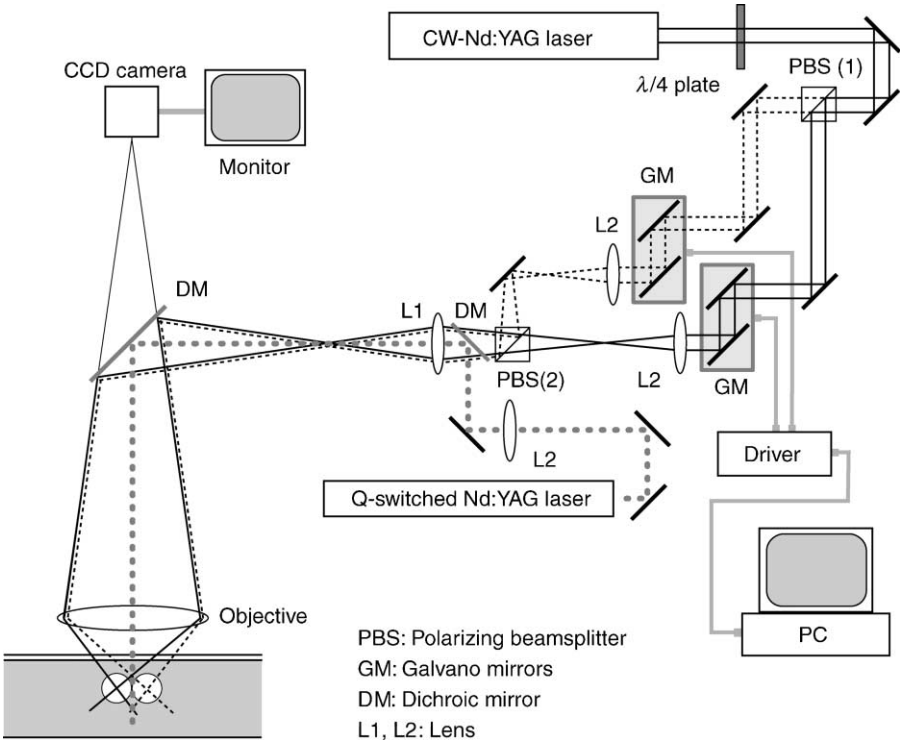

Figure 3 A block diagram of a dual beam laser manipulation-reaction system.

polarizing beamsplitter (PBS1). Both laser beams are combined by another (PBS2), introduced coaxially into an optical microscope, and then focused onto a sample through a microscope objective. The focal spots of both beams in the sample solution can be scanned independently by two sets of computer-controlled galvano mirrors. Even if the beams are spatially overlapping, interference does not take place because of their orthogonal polarization relation. Pulsed lasers, such as a Q-switched Nd^{3+}:YAG laser, are used to induce photoreactions, such as photopolymerization, photothermal reaction, laser ablation, etc.

Laser Manipulation and Patterning of Nanoparticles

Laser manipulation techniques enable us to capture and mobilize fine particles in solution. Most studies using this technique have been conducted on μm-sized objects such as polymer particles, microcrystals, living cells, etc. Because it is difficult to identify individual nanoparticles with an optical microscope, laser manipulation techniques have rarely been applied to nanotechnology and nanoscience. However, the laser trapping technique can be a powerful tool for manipulation of nanoparticles in solution where individual particles can be observed. This is achieved by detection of fluorescence emission from labeled dyes or scattered light. Now, even single molecule fluorescence spectroscopy has been achieved by the use of a highly sensitive photodetector, and a single metallic nanoparticle can be examined by detecting the light scattered from it. There have been several reports on the application of laser manipulation techniques for patterning of nm-sized particles. Here, fixation methods of nanoparticles, using the laser manipulation technique and local photoreactions, are introduced.

Patterning of Polymer Nanoparticles

Patterning of individual polymer nanoparticles onto a substrate can be achieved by using local photopolymerization. The following example shows the strength of this method. Polystyrene nanoparticles of 220 nm with fluorescent dye were dispersed in ethylene glycol solution containing polymerizable vinyl monomer (acrylamide, 31 wt%), crosslinker (*N*,*N*′-methylenebisacrylamide, 2.2 wt%), and radical photoinitiator (Irgacure2959, Ciba Specialty Chemicals, 1.1 wt%). When the sample was irradiated by blue light from a high-pressure mercury lamp, green fluorescence from dye molecules within each nanoparticle was observed. A nanoparticle that entered the region, irradiated by a near-infrared laser beam (1064 nm), was trapped at the focal point, and moved onto the surface of the glass substrate by handling the 3D stage of the microscope. An additional fixation laser beam (355 nm, 0.03 μJ, pulse duration ~6 ns, repetition rate ~5 Hz) was then focused to the same point for ~10 s, which led to the generation of acrylamide gel around the trapped nanoparticle. By repeating the procedure, patterning of single polymer nanoparticles on a glass substrate was achieved, and a fluorescence image of single nanoparticles as a letter 'H', is shown in Figure 4. A magnified atomic force microscope (AFM) image of one of the fixed nanoparticles is also shown, which confirms that only one polymer nanoparticle was contained in the polymerized gel.

Multiple polymer nanoparticles can also be gathered, patterned, and fixed on a glass substrate by scanning both trapping and fixation laser beams with the use of two pairs of galvano mirrors. The optical transmission and fluorescence images of the 'H' patterned nanoparticles on a glass substrate are shown in Figure 5a and b, respectively. The letter 'H' consists of three straight lines of patterned and fixed nanoparticles. The trapping laser beam (180 mW) was scanned at 30 Hz along each line with a length of ~10 μm on a glass substrate for 300 s. Nanoparticles were gathered and patterned along the locus of the focal point on the substrate. Then the fixation laser beam (0.097 μJ) was scanned for another 35 s. As a result, the straight lines of

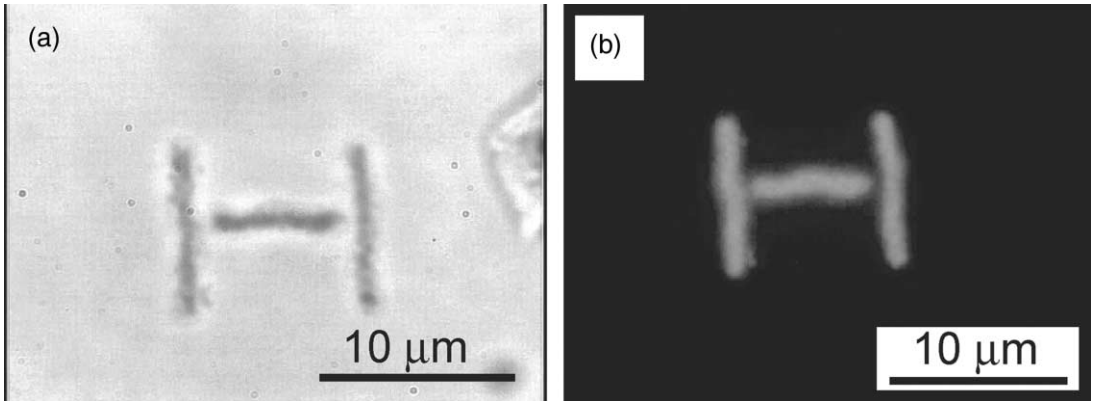

Figure 5 Optical transmission (a) and fluorescence (b) images of patterned and fixed polymer nanoparticles on the glass substrate, as the letter 'H'.

patterned nanoparticles were fixed in generated acrylamide gel on the substrate. Combining several simple fixed patterns, a more complex arrangement can be created with use of the present manipulation and fixation techniques.

Fixation of Individual Gold Nanoparticles

Manipulation and fixation of single metallic nanoparticles in solution has been achieved by means of photo-induced transient melting of nanoparticles. As an example, the following method describes this technique. Gold nanoparticles (diameter ~ 80 nm) were dispersed in ethylene glycol. In order to identify a single gold nanoparticle, extinction of light from the halogen lamp of the optical microscope by the particle was utilized. Thus, the trapped particle was observed as a black spot in transmission image. The optically trapped single gold nanoparticle was then transferred to a precise position on the surface of glass substrate in the sample solution. The focused 355 nm pulse was additionally irradiated onto the pressed nanoparticle, which led to a transient temperature elevation of the gold nanoparticle to enable its fixation. It was confirmed by AFM observation that, at suitable laser fluence ($32-64$ mJ cm^{-2}), a gold nanoparticle was fixed on the glass substrate without fragmentation. Repeating the same manipulation and fixation procedure, single gold nanoparticles could be patterned on a glass substrate. Figure 6 shows an AFM image of successive spatial patterning of single 80 nm gold particles.

The significance of the laser manipulation-fixation technique is that we can trap, manipulate, and fix single and/or many nanoparticles in solution at room temperature. We have already demonstrated assembling entangled polymer chains of $10-20$ nm mean radius by laser trapping, and formation of a single μm-sized particle. Thus, these various kinds of

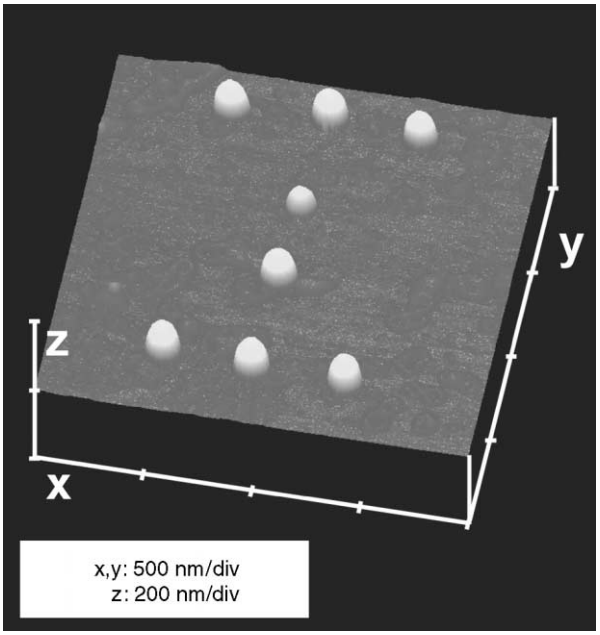

Figure 6 An AFM image of fixed and patterned gold nanoparticles, as the letter I.

nanoscopic materials can be well manipulated using these techniques and it is believed that the present nanomanipulation-fixation method will be useful for future nanoscience and nanotechnology.

Application to Biotechnology

Recent progress in biotechnology, using single cell manipulation by laser and microscope, has been attracting significant attention. In conventional methods, cell manipulation has been performed by mechanical manipulation using microneedles and micropipettes. However, laser manipulation can be applied as microtweezers. In comparison with the former, this form of laser manipulation has the

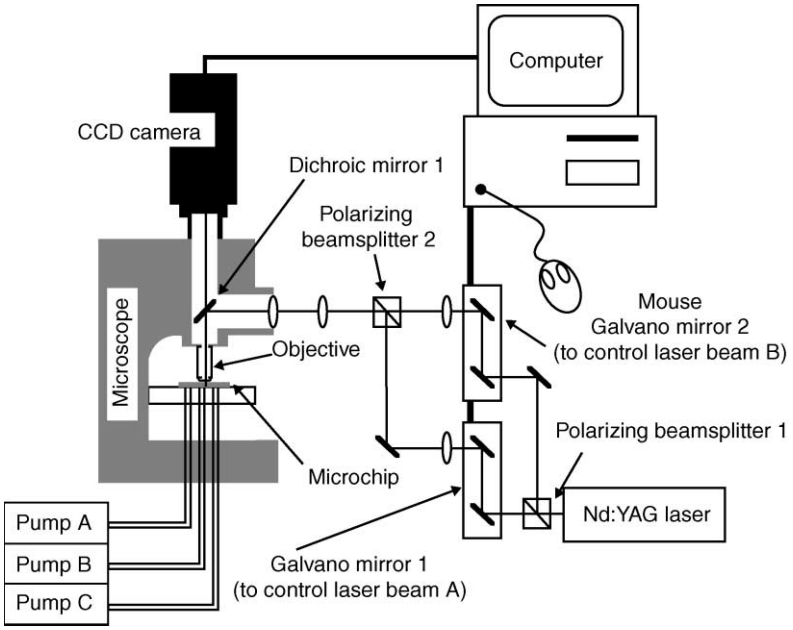

Figure 7 An experimental setup of dual-beam laser manipulation and microfluidic devices.

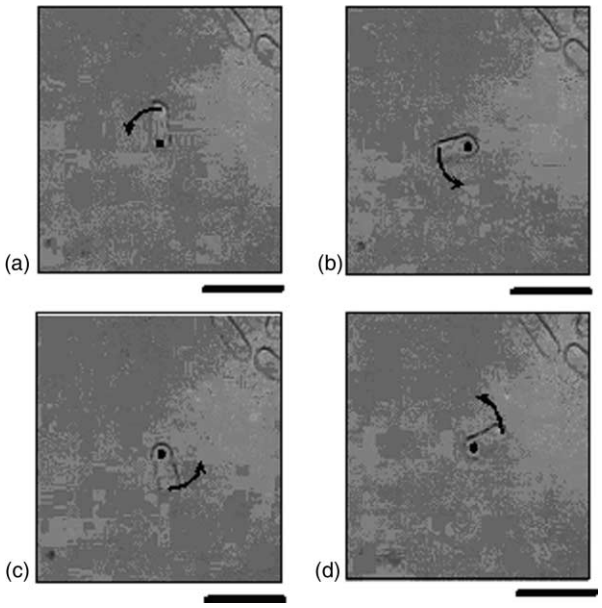
advantage of no contact with cells and can perform some complex and characteristic movement, for example, rotation, separation, accumulation, etc. Furthermore, by combining it with a microcutter using laser ablation, cell fusion and extraction/injection of organs from/into the cells can be achieved. In this section, single-cell manipulation achieved by using the laser manipulation, is introduced.

Noncontact Rotation of Cells Using Dual Beam Laser Manipulation

As a special feature of laser-cell manipulation, it is noticeable that multiple laser tweezers can be operated independently without any contact. Here, noncontact rotation of the fission yeast, *Schizosaccharomyces pombe* (h^-), demonstrates this method. The yeast has the shape of an ellipse of length 8 and 3 μm for major and minor axes, and is shown set on a dual-beam laser manipulation system in Figure 7. One trapping beam A was focused at the end of the cell to anchor it, and another beam, B, was at the other end and scanned circularly around beam A by controlling the Galvano mirrors. The rotation of the yeast cell was realized at a frequency of less than 2 Hz, as shown in Figure 8. Such a cell manipulation is impossible by mechanical manipulation and indicates the superior performance of laser manipulation.

Transfer of Cells in Microchannel

A flow cytometry to physically separate and identify specific types of cells from heterogeneous populations



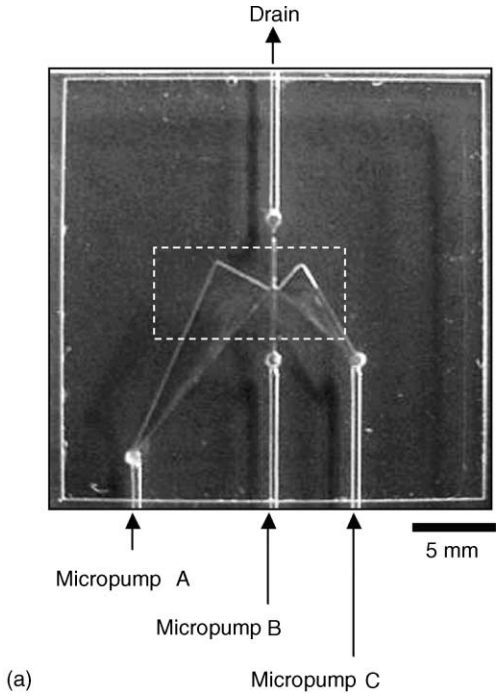


Figure 8 Rotation of fission yeast cells using dual-beam laser manipulation. The bars are 10 μm.

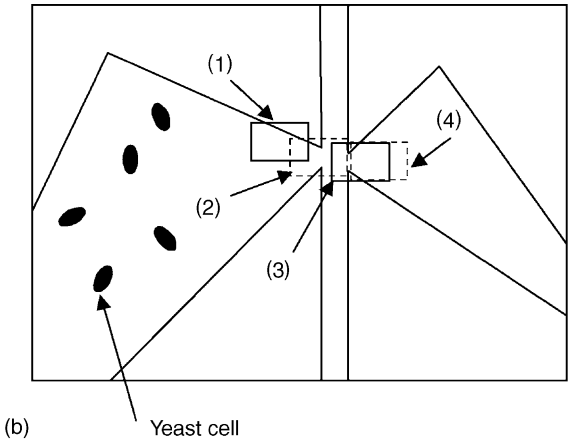

by fluorescence, which is called fluorescence-activated cell sorter (FACS), has attracted significant attention as an important technique in biotechnology. In the separation process, charged single droplets containing single, fluorescence labeled cells are selected by passing them between two high-voltage deflection plates. Since it is a sequential process, which does not use microscopy, flexible and high-purity cell separation is limited. To overcome this problem, a selective cell separation system,

combining the laser trapping with the microchannel, is used. The method using microscopy is useful and flexible, because cells are not simply detected by fluorescence but also identified by their shape, size, surface morphology, absorption, etc. However, cell sorting under a microscope is not processed efficiently by laser trapping. A more effective method is described by the following.

The microchannel was prepared with laser microfabrication and photopolymerization, whose top view is shown in Figure 9a, and was then set on the microscope stage. Three syringes were equipped with homemade pumps A, B, and C, and connected with a microchip. There were two wing-like chambers in the microchip, that were connected with pumps A and C. Between chambers, there was a microchannel 100 μm wide, which joined these chambers and crossed a long microchannel connected with the pump B, thus forming a drain. Thickness of these chambers was 100 μm. By controlling these pumps, the left and right chambers were filled by the culture medium including the yeast cells and the neat culture medium, respectively, as shown in Figure 9b.

Individual cells were transferred from left to right chambers by using a single laser beam and handling an electrically movable microscope stage. The trapping laser irradiated a yeast cell in the left chamber and the trapped cell was transferred to the right chamber. A representative demonstration is given in Figure 9c. The position of the trapped yeast cell was controlled by the microscope stage with the velocity of 20 μm/s. The single yeast cells were successfully transferred from left to right chambers at the rate of 26 s. By combining laser trapping with the microchannel, single separation of cells was achieved under a microscope.

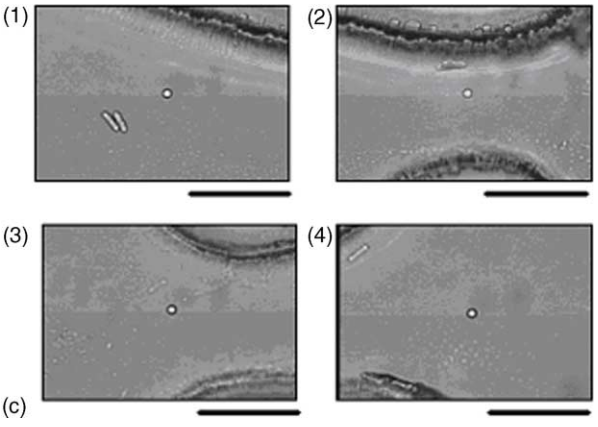

Figure 9 (a) A microchip fabricated by laser polymerization technique and (b) its schematic representation corresponding to dashed area in the microchip. (c) Cell transfer in microchip using laser trapping. The bars are 100 μm. A trapping laser beam is fixed at the center of each picture, by which a particle is trapped and transferred from left to right chambers. The position of each picture is shown in (b).

Collection and Alignment of Cells

When cell sorting using laser trapping is applied to biotechnology, the time to transfer cells should be short compared to the above-mentioned times. One method is to transfer multiple cells simultaneously by developing dual-beam laser manipulation, which is shown schematically in Figure 10. One trapping beam A was scanned on a line given as an arrow in Figure 10a at a rate faster than motions of cells.

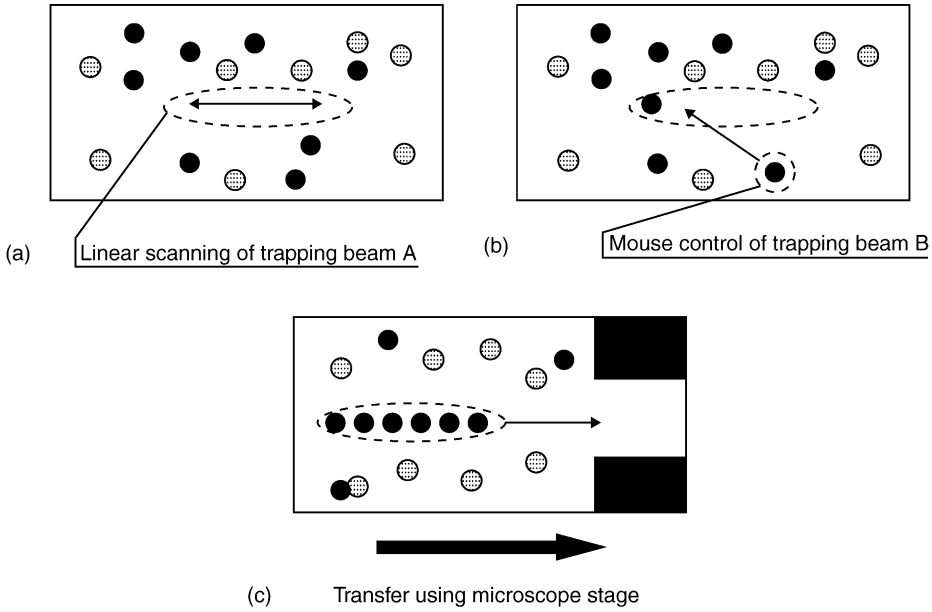

Figure 10 A schematic illustration of efficient collection and transfer of cells based by dual-beam laser manipulation.

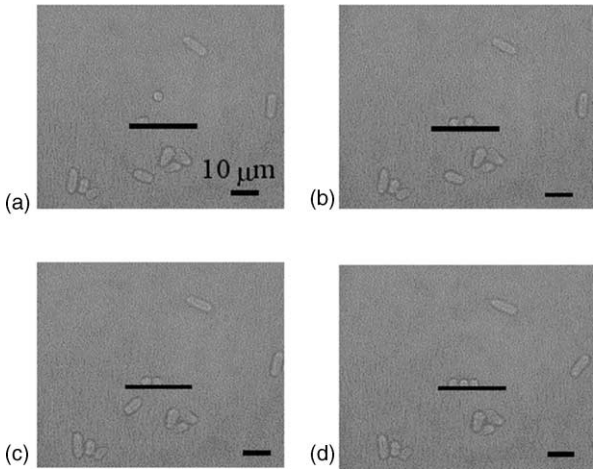

Figure 11 Collection and alignment of fission yeast cells using dual-beam laser manipulation.

The other trapping beam B was used to move individual cells to the line sequentially (Figure 10b). Finally, by moving the microscope stage, many particles trapped at the scanning line can be transferred to another chamber (Figure 10c).

An example is shown in Figure 11. The trapping beam A was scanned on a line with the rate of 15 Hz whose length was 30 μm. The trapping beam B was used to trap a yeast cell and move it to the line, which was controlled by a computer mouse pointer. The cells stored on the line were successfully isolated and with this method three cells can be collected within 15 s. Furthermore, the cells could be transferred with the velocity of 20 μm/s by driving the microscope stage. By improving the presented cell-sorting system, it is expected to realize flexible and high-purity cell separation.

Nonlinear Spectroscopies

S R Meech, University of East Anglia, Norwich, UK

Introduction

Chemistry is concerned with the induction and observation of changes in matter, where the changes are to be understood at the molecular level. Spectroscopy is the principal experimental tool for connecting the macroscopic world of matter with the microscopic world of the molecule, and is, therefore, of central importance in chemistry. Since its invention, the laser has greatly expanded the capabilities of the spectroscopist. In linear spectroscopy, the monochromaticity, coherence, high intensity, and high degree of polarization of laser radiation are ideally suited to high-resolution spectroscopic investigations of even the weakest transitions. The same properties allowed, for the first time, the investigation of the nonlinear optical response of a medium to intense radiation. Shortly after the foundations of nonlinear optics were laid, it became apparent that these nonlinear optical signals could be exploited in molecular spectroscopy, and since then a considerable number of nonlinear optical spectroscopies have been developed. This short article is not a comprehensive review of all these methods. Rather, it is a discussion of some of the key areas in the development of the subject, and indicates some current directions in this increasingly diverse area.

Nonlinear Optics for Spectroscopy

The foundations of nonlinear optics are described in detail elsewhere in the encyclopedia, and in some of the texts listed in the Further Reading section at the end of this article. The starting point is usually the nonlinearity in the polarization, P_i, induced in the sample when the applied electric field, E, is large:

$$P_i = \varepsilon_0\left[\chi_{ij}^{(1)}E_j + \frac{1}{2}\chi_{ijk}^{(2)}E_jE_k + \frac{1}{4}\chi_{ijkl}^{(3)}E_jE_kE_l + \cdots\right] \quad [1]$$

where ε_0 is the vacuum permittivity, $\chi^{(n)}$ is the nth order nonlinear susceptibility, the indices represent directions in space, and the implied summation over repeated indices convention is used. The signal field, resulting from the nonlinear polarization, is calculated by substituting it as the source polarization in Maxwell's equations and converting the resulting field to the observable, which is the optical intensity.

The nonlinear polarization itself arises from the anharmonic motion of electrons under the influence of the oscillating electric field of the radiation. Thus, there is a microscopic analog of eqn [1] for the induced molecular dipole moment, μ_i:

$$\mu_i = [\varepsilon_0\alpha_{ij}d_j + \varepsilon_0^{-2}\beta_{ijk}d_jd_k + \varepsilon_0^{-3}\gamma_{ijkl}d_jd_kd_l + \cdots] \quad [2]$$

in which α is the polarizability, β the first molecular hyperpolarizability, γ the second, etc. The power series is expressed in terms of the displacement field $\mathbf{d}$ rather than $\mathbf{E}$ to account for local field effects. This somewhat complicates the relationship between the molecular hyperpolarizabilities, for example, γ_{ijkl} and

the corresponding macroscopic susceptibility, $\chi^{(3)}_{ijkl}$, but it is nevertheless generally true that a molecule exhibiting a high value of γ_{ijkl} will also yield a large third-order nonlinear polarization. This relationship between the macroscopic and microscopic para meters is the basis for an area of chemistry which has influenced nonlinear optics (rather than the inverse). The synthesis of molecules which have giant molecular hyperpolarizabilities has been an active area, because of their potential applications in lasers and electro-optics technology. Such molecules commonly exhibit a number of properties, including an extended linear π electron conjugation and a large dipole moment, which changes between the ground and excited electronic states. These properties are in accord with the predictions of theory and of quantum chemical calculations of molecular hyperpolarizabilities.

Nonlinear optical spectroscopy in the frequency domain is carried out by measuring the nonlinear signal intensity as a function of the frequency (or frequencies) of the incident radiation. Spectroscopic information is accessible because the molecular hyperpolarizability, and therefore the nonlinear susceptibility, exhibits resonances: the signal is enhanced when one or more of the incident or generated frequencies are resonant with the frequency of a molecular transition. The rich array of nonlinear optical spectroscopies arises in part from the fact that with more input fields there are more accessible resonances than is the case with linear spectroscopy. As an example we consider the third-order susceptibility, $\chi^{(3)}_{ijkl}E_jE_kE_l$, in the practically important case of two incident fields at the same frequency, ω_1, and a third at ω_2. The difference between the two frequencies is close to the frequency of a Raman active vibrational mode, Ω_{rg} (Figure 1). The resulting susceptibility can be calculated to have the form:

$$\chi^{(3)}_{ijkl}(-2\omega_1+\omega_2;\omega_1,\omega_1,-\omega_2) = \frac{N\Delta\rho_{rg}\Omega_{rg}(\alpha^{\mathrm{R}}_{ij}\alpha^{\mathrm{R}}_{kl}+\alpha^{\mathrm{R}}_{ik}\alpha^{\mathrm{R}}_{jl})}{12\hbar[\Omega^2_{rg}-(\omega_1-\omega_2)^2+\Gamma^2-2\mathrm{i}(\omega_1-\omega_2)\Gamma]} \quad [3]$$

in which the α^{R} are elements of the Raman susceptibility tensor, Γ is the homogeneous linewidth of the Raman transition, $\Delta\rho_{rg}$ a population difference, and N the number density. A diagram illustrating this process is shown in Figure 1, where the signal field is at the anti-Stokes Raman frequency ($2\omega_1-\omega_2$). The spectroscopic method which employs this scheme is called coherent anti-Stokes Raman spectroscopy (CARS) and is one of the most widely applied nonlinear optical spectroscopies (see below). Clearly, from eqn [3] we can see that the signal will be enhanced when the difference frequency is resonant with the Raman transition frequency.

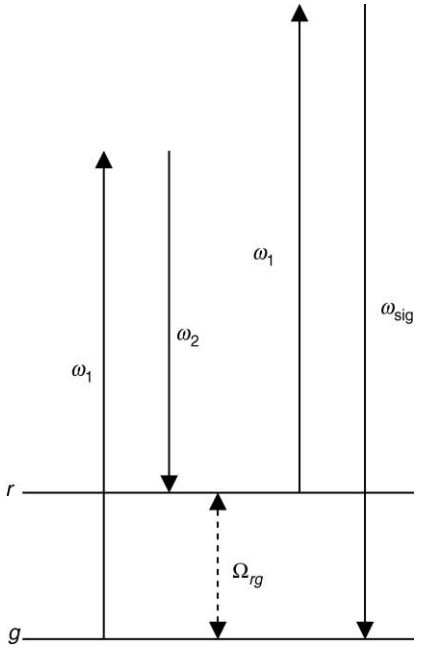

Figure 1 An illustration of the resonance enhancement of the CARS signal, $\omega_{sig} = 2\omega_1 - \omega_2$ when $\omega_1 - \omega_2 = \Omega_{rg}$.

With essentially the same experimental geometry there will also be nonlinear signals generated at both the Stokes frequency ($2\omega_2 - \omega_1$) and at the lower of the incident frequencies, ω_2. These signals have distinct phase matching conditions (see below), so they can easily be discriminated from one another, both spatially and energetically. Additional resonance enhancements are possible if either of the individual frequencies is resonant with an electronic transition of the molecule, in which case information on Raman active modes in the excited state is also accessible.

It is worthwhile noting here that there is an equivalent representation of the nth order nonlinear susceptibility tensor $\boldsymbol{\chi}^{(n)}(\omega_{\mathrm{sig}}:\omega_1,\ldots,\omega_n)$ as a time domain response function, $\mathbf{R}^{(n)}(\tau_1,\ldots,\tau_n)$. While it is possible to freely transform between them, the frequency domain representation is the more commonly used. However, the response function approach is increasingly applied in time domain nonlinear optical spectroscopy when optical pulses shorter than the homogeneous relaxation time are used. In that case, the time ordering of the incident fields, as well as their frequencies, is of importance in defining an experiment.

An important property of many nonlinear optical spectroscopies is the directional nature of the signal, illustrated in Figure 2. The directional nonlinear

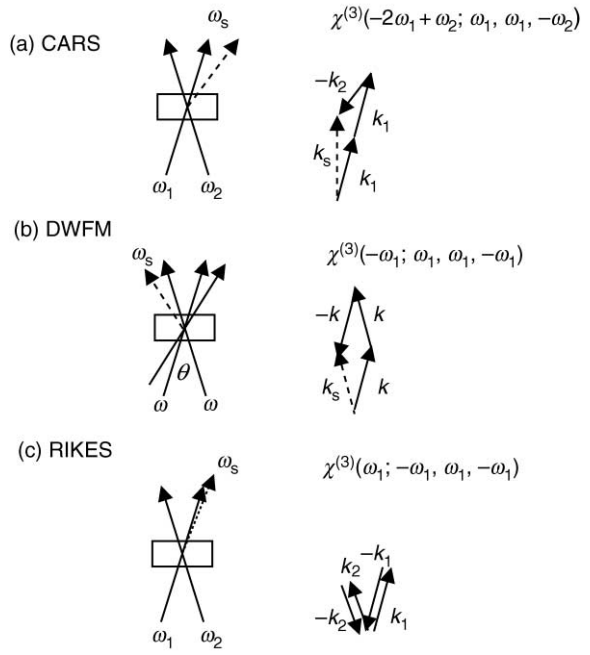

Figure 2 Experimental geometries and corresponding phase matching diagrams for (a) CARS (b) DFWM (c) RIKES. Note that only the RIKES geometry is fully phase matched.

signal arises from the coherent oscillation of induced dipoles in the sample. Constructive interference can lead to a large enhancement of the signal strength. For this to occur the individual induced dipole moments must oscillate in phase – the signal must be phase matched. This requires the incident and the generated frequencies to travel in the sample with the same phase velocity, $k_\omega/\omega = c/n_\omega$ where n_ω is the index of refraction and k_ω is the wave propagation constant at frequency ω. For the simplest case of second-harmonic generation (SHG), in which the incident field oscillates at ω and the generated field at 2ω, phase matching requires $2k_\omega = k_{2\omega}$. The phase-matching condition for the most efficient generation of the second harmonic is when the phase mismatch, $\Delta k = 2k_\omega - k_{2\omega} = 0$, but this is not generally fulfilled due to the dispersion of the medium, $n_\omega < n_{2\omega}$. In the case of SHG, a coherence length L can be defined as the distance traveled before the two waves are 180° out of phase, $L = |\pi/\Delta k|$. For cases in which the input frequencies also have different directions, as is often the case when laser beams at two frequencies are combined (e.g., CARS), the phase-matching condition must be expressed as a vectorial relationship, hence, for CARS, $\Delta\mathbf{k} = \mathbf{k}_{AS} - 2\mathbf{k}_1 + \mathbf{k}_2 \approx 0$, where $\mathbf{k}_{AS}$ is the wavevector of the signal at the anti-Stokes frequency (Figure 2). Thus for known input wavevectors one can easily calculate the expected direction of the output signal, $\mathbf{k}_s$. This is illustrated for a number of important cases in Figure 2.

Nonlinear Optical Spectroscopy in Chemistry

As already noted, there is a vast array of nonlinear optical spectroscopies, so it is clear some means of classification will be required. For coarse graining the order of the nonlinear process is very helpful, and that is the scheme we will follow here.

Second-Order Spectroscopies

Inspection of eqn [1] shows that in gases, isotropic liquids, and solids where the symmetry point group contains a center of inversion, $\boldsymbol{\chi}^{(2)}$ is necessarily zero. This is required to satisfy the symmetry requirement that polarization must change sign when the direction of the field is inverted, yet for a quadratic, or any even order dependence on the field strength, it must remain positive. Thus second-order nonlinearities might not appear very promising for spectroscopy. However, there are two cases in which second-order nonlinear optical phenomena are of very great significance in molecular spectroscopy, harmonic generation and the spectroscopy of interfaces.

Harmonic conversion

Almost every laser spectroscopist will have made use of second-harmonic or sum frequency generation for frequency conversion of laser radiation. Insertion of an oscillating field of frequency ω into eqn [1] yields a second-order polarization oscillating of 2ω. If two different frequencies are input, the second-order polarization oscillates at their sum and difference frequencies. In either case, the second-order polarization acts as a source for the second-harmonic (or sum, or difference frequency) emission, provided $\boldsymbol{\chi}^{(2)}$ is nonzero. The latter can be arranged by selecting a noncentrosymmetric medium for the interaction, the growth of such media being an important area of materials science. Optically robust and transparent materials with large values of $\boldsymbol{\chi}^{(2)}$ are available for the generation of wavelengths shorter than 200 nm to longer than 5 μm. Since such media are birefringent by design, a judicious choice of angle and orientation of the crystal with respect to the input beams allows a degree of control over the refractive indices experienced by each beam. Under the correct phase matching conditions $n_\omega \approx n_{2\omega}$, and very long interaction lengths result, so the efficiency of signal generation is high.

Higher-order harmonic generation in gases is an area of growing importance for spectroscopy in the

deep UV and X-ray region. The generation of such short wavelengths depends on the ability of amplified ultrafast solid state lasers to generate extremely high instantaneous intensities. The mechanism is somewhat different to the one outlined above. The intense pulse is injected into a capillary containing an appropriate gas. The high electric field of the laser causes ionization of atoms. The electrons generated begin to oscillate in the applied laser field. The driven recombination of the electrons with the atoms results in the generation of the high harmonic emission. Although the mechanism differs from the SHG case, questions of phase matching are still important. By containing the gas in a corrugated waveguide phase matching is achieved, considerably enhancing the intensity of the high harmonic. Photon energies of hundreds of electronvolts are possible using this technique. The generation of such high energies is not yet routine, but a number of potential applications are already apparent. A powerful coherent source of X-ray and vacuum UV pulses will certainly aid surface analysis techniques such as UV photoemission and X-ray photoelectron spectroscopy. Much excitement is currently being generated by the possibility of using intense ultrashort X-ray pulses to record structural dynamics on an ultrafast timescale.

Surface second-order spectroscopy

At an interface inversion symmetry is absent by definition, so the second-order nonlinear susceptibility is finite. If the two bulk phase media are themselves isotropic, then even a weak second-order signal necessarily arises from the interface. This surface-specific all-optical signal is unique, because it can be used to probe the interface between two condensed phases. This represents a great advantage over every other form of surface spectroscopy. In linear optical spectroscopy, the signal due to species at the interface are usually swamped by contributions from the bulk phase. Other surface-specific signals do exist, but they rely on the scattering of heavy particles (electrons, atoms) and so can only be applied to the solid vacuum interface. For this reason the techniques of surface SHG and SFG are widely applied in interface spectroscopy.

The most widely used method is sum frequency generation (SFG) between temporally overlapped tuneable infrared and fixed frequency visible lasers, to yield a sum frequency signal in the visible region of the spectrum. The principle of the method is shown in Figure 3. The surface nonlinear susceptibility exhibits resonances at vibrational frequencies, which are detected as enhancements in the visible SFG intensity. Although the signal is weak, it is directional and background free, so relatively easily measured by photon counting techniques. Thus, SFG is used to measure the vibrational spectra of essentially any optically accessible interface. There are, however, some limitations on the method. The surface must exhibit a degree of order – if the distribution of adsorbate orientation is isotropic the signal again becomes zero by symmetry. Second, a significant enhancement at the vibrational frequency requires the transition to be both IR and Raman allowed, as suggested by the energy level diagram (Figure 3).

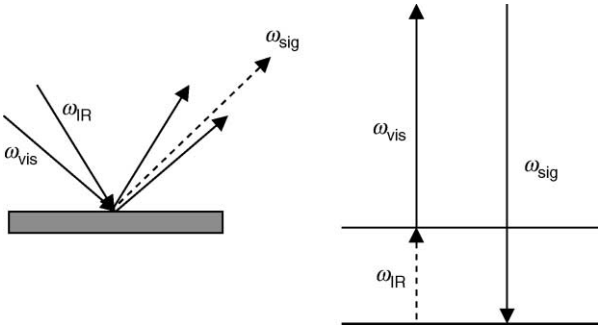

Figure 3 The experimental geometry for SFG, and an illustration of the resonance enhancement of $\omega_{sig} = \omega_{IR} + \omega_{vis}$ at a Raman and IR allowed vibrational transition.

The SHG signal can also be measured as a function of the frequency of the incident laser, to recover the electronic spectrum of the interface. This method has been used, particularly in the study of semiconductor surfaces, but generally the electronic spectra of adsorbates contain less information than their vibrational spectra. However, by measuring the SHG intensity as a function of time, information on adsorbate kinetics is obtained, provided some assumptions connecting the surface susceptibility to the molecular hyperpolarizability are made. Finally, using similar assumptions, it is possible to extract the orientational distribution of the adsorbate, by measuring the SHG intensity as a function of polarization of the input and output beams. For these reasons, SHG has been widely applied to analyze the structure and dynamics of interfaces.

Third-Order Spectroscopies

The third-order coherent Raman spectroscopies were introduced above. One great advantage of these methods over conventional Raman is that the signal is generated in a coherent beam, according to the appropriate phase matching relationship (Figure 2). Thus, the coherent Raman signal can easily be distinguished from background radiation by spatial filtering. This has led to CARS finding widespread application in measuring spectra in (experimentally)

hostile environments. CARS spectroscopy has been widely applied to record the vibrational spectra of flames. Such measurements would obviously be very challenging for linear Raman or IR, due to the strong emission from the flame itself. The directional CARS signal in contrast can be spatially filtered, minimizing this problem. CARS has been used both to identify unstable species formed in flames, and to probe the temperature of the flame (e.g., from measured population differences eqn [3]). A second advantage of the technique is that the signal is only generated when the two input beams overlap in space. Thus, small volumes of the sample can be probed. By moving the overlap position around in the sample, spatially resolved information is recovered. Thus, it is possible to map the population of a particular transient species in a flame.

CARS is probably the most widely used of the coherent Raman methods, but it does have some disadvantages, particularly in solution phase studies. In that case the resonant $\boldsymbol{\chi}^{(3)}$ signal (eqn [3]) is accompanied by a nonresonant third-order background. The interference between these two components may result in unusual and difficult to interpret lineshapes. In this case, some other coherent Raman methods are more useful. The phase matching scheme for Raman-induced Kerr effect spectroscopy (RIKES) was shown in Figure 2. The RIKES signal is always phase matched, which leads to a long interaction length. However, the signal is at ω_2 and in the direction of ω_2, which would appear to be a severe disadvantage in terms of detection. Fortunately, if the input polarizations are correctly chosen the signal can be isolated by its polarization. In an important geometry, the signal (ω_2) is isolated by transmission through a polarizer oriented at 45° to a linearly polarized pump (ω_1). The pump is overlapped in the sample with the probe (ω_2) linearly polarized at $-45°$. Thus the probe is blocked by the polarizer, but the signal is transmitted. This geometry may be viewed as pump-induced polarization of the isotropic medium to render it birefringent, thus inducing ellipticity in the transmitted probe, such that the signal leaks through the analyzing polarizer (hence the alternative name optical Kerr effect).

In this geometry, it is possible to greatly enhance signal-to-noise ratios by exploiting interference between the probe beam and the signal. Placing a quarterwave plate in the probe beam with its fast axis aligned with the probe polarization, and reorienting it slightly ($<1°$) yields a slightly elliptically polarized probe before the sample. A fraction of the probe beam, the local oscillator (LO), then also leaks through the analyzing polarizer, temporally and spatially overlapped with the signal. Thus, the signal and LO fields are seen by the detector, which measures the intensity as:

$$I(t) = \frac{nc}{8\pi}|\mathbf{E}_{\mathrm{LO}}(t) + \mathbf{E}_{\mathrm{S}}(t)|^2$$

$$= I_{\mathrm{LO}}(t) + I_{\mathrm{S}}(t) + \frac{nc}{4\pi}\mathrm{Re}[\mathbf{E}^*_{\mathrm{S}}(t)\cdot\mathbf{E}_{\mathrm{LO}}(t)] \qquad [4]$$

where the final term may be very much larger than the original signal, and is linear in $\boldsymbol{\chi}^{(3)}$. This term is usually isolated from the strong I_{LO} by lock-in detection. This method is called optical heterodyne detection (OHD), and generally leads to excellent signal to noise. It can be employed with other coherent signals by artificially adding the LO to the signal, provided great care is taken to ensure a fixed phase relationship between LO and signal. In the RIKES experiment, however, the phase relationship is automatic. The arrangement described yields an out-of-phase LO, and measures the real part of $\boldsymbol{\chi}^{(3)}$, the birefringence. Alternatively, the quarterwave plate is omitted, and the analyzing polarizer is slightly reoriented, to introduce an in-phase LO, which measures the imaginary part of $\boldsymbol{\chi}^{(3)}$, the dichroism. This is particularly useful for absorbing media. The OHD-RIKES method has been applied to measure the spectroscopy of the condensed phase, and has found particularly widespread application in transient studies (below).

Degenerate four wave mixing (DFWM) spectroscopy is a simple and widely used third-order spectroscopic method. As the name implies, only a single frequency is required. The laser beam is split into three, and recombined in the sample, in the geometry shown in Figure 2. The technique is also known as laser-induced grating scattering. The first two beams can be thought of as interfering in the sample to write a spatial grating, with fringe spacing dependent on the angle between them. The signal is then scattered from the third beam in the direction expected for diffraction from that grating. The DFWM experiment has been used to measure electronic spectra in hostile environments, by exploiting resonances with electronic transitions. It has also been popular in the determination of the numerical value of $\boldsymbol{\chi}^{(3)}$, partly because it is an economical technique, requiring only a single laser, but also because different polarization combinations make it possible to access different elements of $\boldsymbol{\chi}^{(3)}$. The technique has also been used in time resolved experiments, where the decay of the grating is monitored by diffraction intensity from a time delayed third pulse.

Two-photon or, more generally, multiphoton excitation has applications in both fundamental spectroscopy and analytical chemistry. Two relevant level

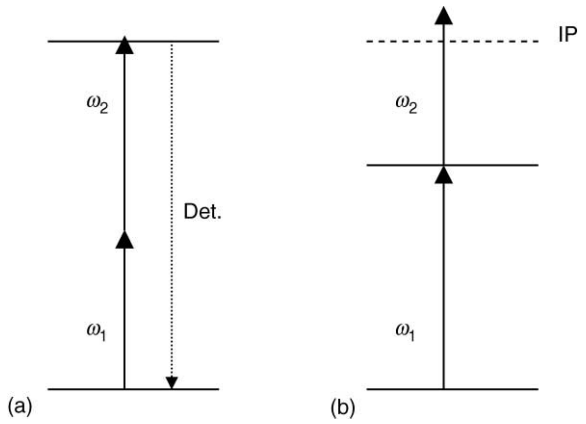

Figure 4 Two cases of resonant two photon absorption. In (a) the excited state is two-photon resonant, and the process is detected by the emission of a photon. In (b) the intermediate state is resonant, and the final energy is above the ionization potential (IP) so that photocurrent or mass detection can be used.

schemes are shown in Figure 4. Some property associated with the final state permits detection of the multiphoton absorption, for example, fluorescence in (a) and photocurrent in (b).

Excitation of two-photon transitions, as in Figure 4a, is useful in spectroscopy because the selection rules are different to those for the corresponding one-photon transition. For example the change in angular momentum quantum number, ΔL, in a two-photon transition is 0, ± 2, so, for example, an atomic S to D transition can be observed. High spectroscopic resolution may be attained using Doppler free two-photon absorption spectroscopy. In this method, the excitation beams are arranged to be counter-propagating, so that the Doppler broadening is cancelled out in transitions where the two excitation photons arise from beams with opposing wavevectors. In this case, the spectroscopic linewidth is governed only by the homogeneous dephasing time.

The level scheme in Figure 4b is also widely used in spectroscopy, but in this case the spectrum of the intermediate state is obtained by monitoring the photocurrent as a function of ω_1. The general technique is known as resonance enhanced multiphoton ionization (REMPI) and yields high-quality spectra of intermediate states which are not detectable by standard methods, such as fluorescence. The sensitivity of the method is high, and it is the basis of a number of analytical applications, often in combination with mass spectrometry.

Ultrafast Time Resolved Spectroscopy

The frequency and linewidth of a Raman transition may be extracted from the CARS measurement, typically by combining two narrow bandwidth pulsed lasers, and tuning one through the resonance while measuring the nonlinear signal intensity. The time resolved analogue requires two pulses, typically of a few picoseconds duration (and therefore a few wavenumbers bandwidth) at ω_1 and ω_2 to be incident on the sample. This pair coherently excites the Raman mode. A third pulse at ω_1 is incident on the sample a time t later, and stimulates the CARS signal at $2\omega_1 - \omega_2$ in the phase-matched direction. The decay rate of the vibrational coherence is measured from the CARS intensity as a function of the delay time. Thus, the frequency of the mode is measured in the frequency domain, but the linewidth is measured in the time domain. If very short pulses are used (such that the pulsewidth is shorter than the inverse frequency of the Raman active mode) the Raman transition is said to be impulsively excited, and the CARS signal scattered by the time delayed pulse reveals an oscillatory response at the frequency of the Raman active mode, superimposed on its decay. Thus, in this case, spectroscopic information is measured exclusively in the time domain. In the case of nonlinear Raman spectroscopy, similar information is available from the frequency and the time domain measurements, and the choice between them is essentially one of experimental convenience. For example, time domain CARS, RIKES, and DFWM spectroscopy have turned out to be particularly powerful routes to extracting low-frequency vibrational and orientational modes of liquids and solutions, thus providing detailed insights into molecular interactions and reaction dynamics in the condensed phase.

Other time domain experiments contain information that is not accessible in the frequency domain. This is particularly true of photon echo methods. The name suggests a close analogy with nuclear magnetic resonance (NMR) spectroscopy, and the (optical) Bloch vector approach may be used to describe both measurements, although the transition frequencies and time-scales involved differ by many orders of magnitude. In the photon echo experiment, two or three ultrafast pulses with carefully controlled interpulse delay times are resonant with an electronic transition of the solute. In the two-pulse echo, the echo signal is emitted in the phase match direction at twice the interpulse delay, and its intensity as a function of time yields the homogeneous dephasing time associated with the transition. In the three-pulse experiment the pulses are separated by two time delays. By measuring the intensity of the stimulated echo as a function of both delay times it is possible to separately determine the dephasing time and the population relaxation time associated with the resonant transition. Such information is not accessible from linear spectroscopy, and can be extracted

only with difficulty in the frequency domain. The understanding of photon echo spectroscopy has expanded well beyond the simple description given here, and it now provides unprecedented insights into optical dynamics in solution, and thus informs greatly our understanding of chemistry in the condensed phase. The methods have recently been extended to the infra red, to study vibrational transitions.

Higher-Order and Multidimensional Spectroscopies

The characteristic feature of this family of spectroscopies is the excitation of multiple resonances, which may or may not require measurements at $\chi^{(n)}$ with $n > 3$. Such experiments require multiple frequencies, and may yield weak signals, so they only became experimentally viable upon the availability of stable and reliable solid state lasers and optical parametric generators. Measurements are made in either the time or the frequency domain, but in either case benefit from heterodyne detection.

One of the earliest examples was two-dimensional Raman spectroscopy, where multiple Raman active modes are successively excited by temporally delayed pulse pairs, to yield a fifth-order nonlinear signal. The signal intensity measured as a function of both delay times (corresponding to the two dimensions) allows separation of homogeneous and inhomogeneous contributions to the line shape. This prodigiously difficult $\chi^{(5)}$ experiment has been completed in a few cases, but is plagued by interference from third-order signals.

More widely applicable are multidimensional spectroscopies using infrared pulses or combinations of them with visible pulses. The level scheme for one such experiment is shown in Figure 5 (which is one of many possibilities). From the scheme, one can see that the nonlinear signal in the visible depends on two resonances, so both can be detected. This can be regarded as a multiply resonant nondegenerate four-wave mixing (FWM) experiment. In addition, if the two resonant transitions are coupled, optical excitation of one affects the other. Thus, by measuring the signal as a function of both frequencies, the couplings between transitions are observed. These appear as cross peaks when the intensity is plotted in the two frequency dimensions, very much as with 2D NMR. This technique is already providing novel information on molecular structure and structural dynamics in liquids, solutions, and proteins.

Spatially Resolved Spectroscopy

A recent innovation is nonlinear optical microscopy. The nonlinear dependence of signal strength on

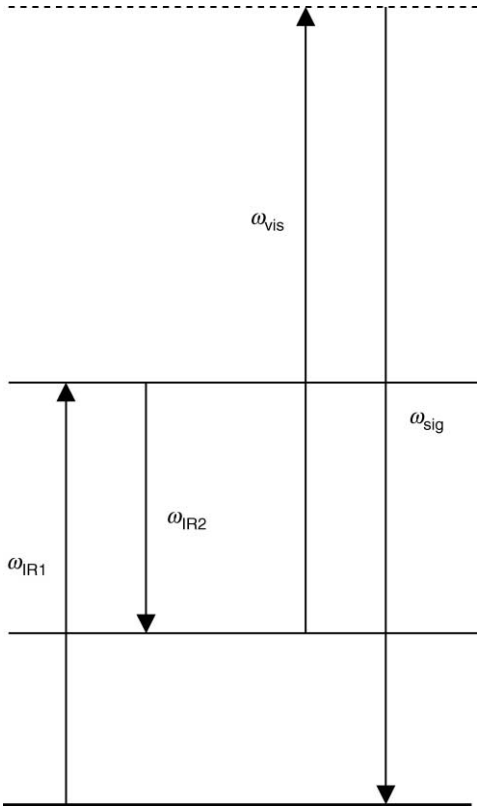

Figure 5 Illustration of multiple resonance enhancements in a FWM geometry, from which 2D spectra may be generated.

intensity means that nonlinear processes are localized at the focal point of a lens. When focusing is strong, such as in a microscope objective, spatial localization of the nonlinear signal can be dramatic. This is the basis of the two-photon fluorescence microscopy method, where a high repetition rate source of low-energy ultrafast pulses is focused by a microscope objective into a sample labeled with a fluorescent molecule, which has absorption at half the wavelength of the incident photons (Figure 4). The fluorescence is necessarily localized at the focal point because of its dependence on the square of the incident intensity. By measuring intensity while scanning the position of the focal point in space, a 3D image of the distribution of the fluorophore is constructed. This technique turns out to have a number of advantages over one photon fluorescence microscopy, most notably in terms of ease of implementation, minimization of sample damage, and depth resolution. The technique is widely employed in cell biology.

Stimulated by the success of two-photon microscopy, further nonlinear microscopies have been developed, all relying on the spatial localization of the signal. CARS microscopy has been

demonstrated to yield 3D images of the distribution of vibrations in living cells. It would be difficult to recover such data by linear optical microscopy. SHG has been applied in microscopy. In this case, by virtue of the symmetry selection rule referred to above, a 3D image of orientational order is recovered. Both these and other nonlinear signals provide important new information on complex heterogeneous samples, most especially living cells.

Photodynamic Therapy of Cancer

Introduction

One of the most active areas of photomedical research, in recent years, has been the exploration of the use of light-activated drugs known as photosensitizers. These compounds may be activated using light, usually provided by a laser via an optical fiber which is placed at the site of the target lesion. This treatment is known as photodynamic therapy (PDT) and is being applied to the local destruction of malignant tumors and certain nonmalignancies. Activation of the photosensitizer results in the

generation of reactive oxidizing intermediates which are toxic to cells, and this process ultimately leads to tumor destruction. PDT is a relatively low-power, nonthermal, photochemical technique that uses fluence rates not exceeding 200 mW/cm^2 and total light doses or fluences of typically 100 J/cm^2. Generally red or near-infrared light is used, since tissue is relatively transparent at these wavelengths. It is a promising alternative approach to the local destruction of tumors for several reasons. First, it is a minimally invasive treatment since laser light can be delivered with great accuracy to almost any site in the body via thin flexible optical fibers with minimal damage to overlying normal tissues. Second, the nature of PDT damage to tissues is such that healing is safer and more complete than after most other forms of local tissue destruction (e.g., radiotherapy). PDT is also capable of some degree of selectivity for tumors when the sensitizer levels, light doses, and irradiation geometry are carefully controlled. This selectivity is based on the higher sensitizer retention in tumors after administration relative to the adjacent normal tissues in which the tumor arose (generally 3:1 for extracranial tumors but up to 50:1 for brain tumors).

The photosensitizer is administered intravenously to the patient and time allowed (3–96 hours depending on the sensitizer) for it to equilibrate in the body before the light treatment (Figure 1). This time is called the drug–light interval. PDT may also be useful for treating certain nonmalignant conditions, in particular, psoriasis and dysfunctional menorrhagia (a disorder of the uterus), and local treatment of infections; such as genital papillomas, infections in the mouth and the upper gastrointestinal tract. In certain cases, the photosensitizer may be applied directly to the lesions, particularly for treatment of skin tumors, as discussed later. The main side-effect of PDT is skin photosensitivity, owing to retention of the drug in the skin, so patients must avoid exposure to sunlight in particular for a short period following treatment. Retreatment is then possible once the photosensitizer has cleared from the skin since these drugs have little intrinsic toxicity, unlike many conventional chemotherapy agents.

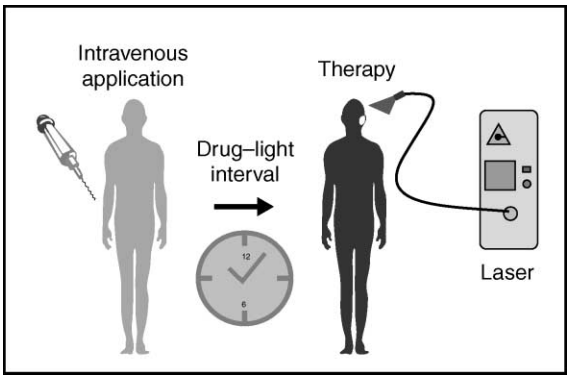

Figure 1 Photodynamic therapy: from sensitization to treatment.

Photoproperties of Photosensitizers

By definition, there are three fundamental requirements for obtaining a photodynamic effect: (a) light of the appropriate wavelength matched to the photosensitizer absorption; (b) a photosensitizer; and (c) molecular oxygen. The ideal photochemical and biological properties of a photosensitizer may be easily summarized, although the assessment of a sensitizer in these terms is not as straightforward as might be supposed because the heterogeneous nature of biological systems can sometimes profoundly affect these properties. Ideally though, a sensitizer should possess the following attributes: (a) red or near infrared light absorption; (b) nontoxic, and with low skin photosensitizing potency; (c) selective retention in tumors relative to normal adjacent tissue; (d) an efficient generator of cytotoxic species, usually singlet oxygen; (e) fluorescence, for visualization; (f) a defined chemical composition, and (g) preferably water soluble. A list of several photosensitizers possessing the majority of the above-mentioned attributes is given in Table 1.

The reasons for these requirements are partly self-evident, but worth amplifying. Strong absorption is desirable in the red and near-infrared spectral region, where tissue transmittance is optimum enabling penetration of the therapeutic light within the tumor (Figure 2). To minimize skin photosensitization by solar radiation, the sensitizer absorption spectrum should ideally consist of a narrow red wavelength band, with little absorption at other wavelengths down to 400 nm, below which solar irradiation falls off steeply. Another advantage of red wavelength irradiation is that the potential mutagenic effects encountered with UV-excited sensitisers (e.g., psoralens) are avoided. Since the object of the treatment is the selective destruction of tumor tissue, leaving surrounding normal tissue undamaged, some degree of selective retention of the dye in tumor tissue is desirable. Unfortunately, the significance of this aspect has been exaggerated in the literature and in many cases treatment selectivity owes more to careful light irradiation geometry. Nevertheless, many normal tissues have the capacity to heal safely following PDT damage.

The key photochemical property of photosensitizers is to mediate production of some active

Table 1 Properties of several photosensitizers

Compound	*λ/nm (ε/M^{-1} cm^{-1})*	*Drug dose/mg kg^{-1}*	*Light dose/J cm^{-2}*	*Diseases treated*
Hematoporphyrin (HpD–Photofrin–Photosan)	628 (3.0×10^3)	1.5–5	75–250	Early stage esophagus, bladder, lung, cervix, stomach, and mouth cancers. Palliative in later stages
ALA (converted to protoporphyrin IX)	635 (5×10^3)	60	50–150	Skin, stomach, colon, bladder, mouth cancers. Esophageal dysplasia. Various nonmalignant conditions
Benzoporphyrin derivative (BpD)	690 (3.5×10^4)	4	150	Age-related macular degeneration (AMD)
Tin etiopurpurin (SnET2–Purlytin)	665 (3.0×10^4)	1.2	150–200	Breast and skin cancers, AMD
Monoaspartyl chlorin e_6 (MACE)	660 (4.0×10^4)	1.0	25–200	Skin cancers
Lutetium texaphyrin (Lu–Tex)	732 (4.2×10^4)	1.0	150	Metastatic brain tumors, breast cancers, atherosclerotic plaques
Aluminum disulfonated phthalocyanine	675 (2.0×10^5)	1.0	50–200	Brain, colon, bladder, and pancreatic cancers. Head and neck cancers in animal studies only
Metatetrahydroxychlorin (mTHPC–temoporphin–Foscan)	652 (3.5×10^4)	0.15	5–20	Head, neck, prostate, pancreas, lung, brain, biliary tract, and mouth cancers. Superior to HpD and ALA in mouth cancers
Palladium pheophorbide (Tookad)	763 (8.6×10^4)	2.0	–	Prostate cancer
Hypericin	590 (3×10^4)	–	–	Psoriasis

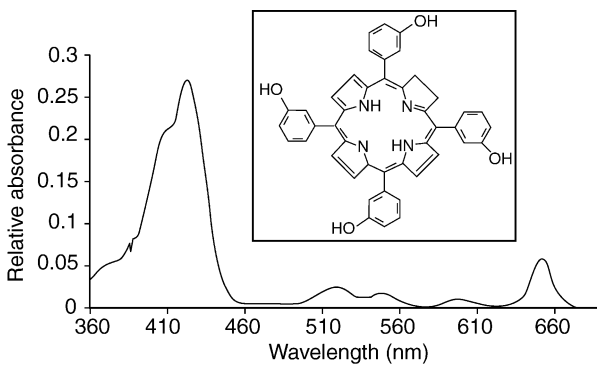

Figure 2 The absorption spectrum of m-THPC. The structure of m-THPC is shown in the inset.

molecule which is cytotoxic, that is, will destroy cells. The first electronically excited state of molecular oxygen, so-called singlet oxygen, fulfills this role very well and may be produced via the interaction of an excited electronic state of the sensitizer with oxygen present in the tissue. Thus, in summary, to achieve effective photosensitization, a sensitizer should exhibit appreciable absorption at red to near-infrared wavelengths and generate cytotoxic species via oxygen-dependent photochemical reactions. The first clinical photosensitizer was hematoporphyrin derivative (HpD), which is derived synthetically from hematoporphyrin by reaction with acetic and sulfuric acids to give a complex mixture of porphyrins. A purified fraction of these (Photofrin) is available commercially, and this has been used most widely in clinical applications to date. Second-generation (photosensitizers are now becoming available, including phthalocyanine and chlorin compounds as shown in Table 1.

A new approach to PDT has recently emerged involving the administration of a natural porphyrin precursor, 5-aminolaevulinic acid (ALA), which is metabolized within cells to produce protoporphyrin IX (see Table 1). This porphyrin is known to be a powerful photosensitizing agent but suffers from the drawback of being a poor tumor localizer when used directly. In contrast, administration of ALA induces protoporphyrin biosynthesis, particularly in rapidly proliferating cells, which may then be destroyed using irradiation at 630 nm. Therefore, this new therapy may offer enhanced treatment selectivity with little risk of skin photosensitivity owing to the rapid clearance after 24 h of the protoporphyrin. Investigation of this new approach has already proved successful in clinical treatment of

skin tumors using topical application of ALA in a thick emulsion.

Considerable effort is also being expended on exploiting the retention of sensitizers in tumors for diagnostic purposes, although the results are rather mixed to date. The prospects with ALA-induced protoporphyrin IX are, however, more promising, as illustrated in Figure 3 where the fluorescence is selectively confined to the skin tumor (basal cell carcinoma).

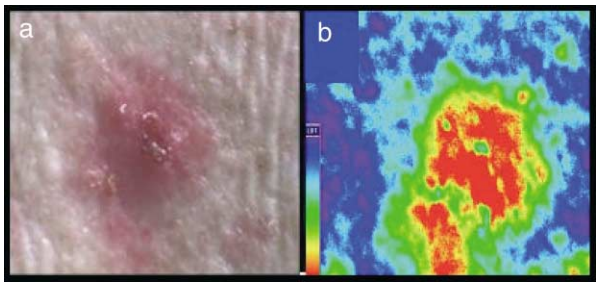

Figure 3 (a) Image of a basal cell carcinoma; (b) fluorescence imaging of the same lesion after ALA sensitization and 405 nm light excitation.

Mechanisms of Photodynamic Therapy

The main principles of the photosensitization mechanism are now well established with the initial step being excitation of the sensitizer from its electronic ground state to the short-lived fluorescent singlet state. The lifetime of the singlet state is generally only a few nanoseconds and the main role of this state in the photosensitization mechanism is to act as a precursor of the metastable triplet state through intersystem crossing. Efficient formation of this metastable state is required because it is the interaction of the triplet state with tissue components that generates cytotoxic species such as singlet oxygen. Thus the triplet state quantum yield (i.e., probability of triplet state formation per photon absorbed) of photosensitizers should ideally approach unity. Interaction of the metastable triplet state (which in de-aerated solutions has a lifetime extending to the millisecond range) with tissue components may proceed via either a type I or II mechanism or a combination (see Figure 4). A type I process can involve hydrogen abstraction from the sensitizer to

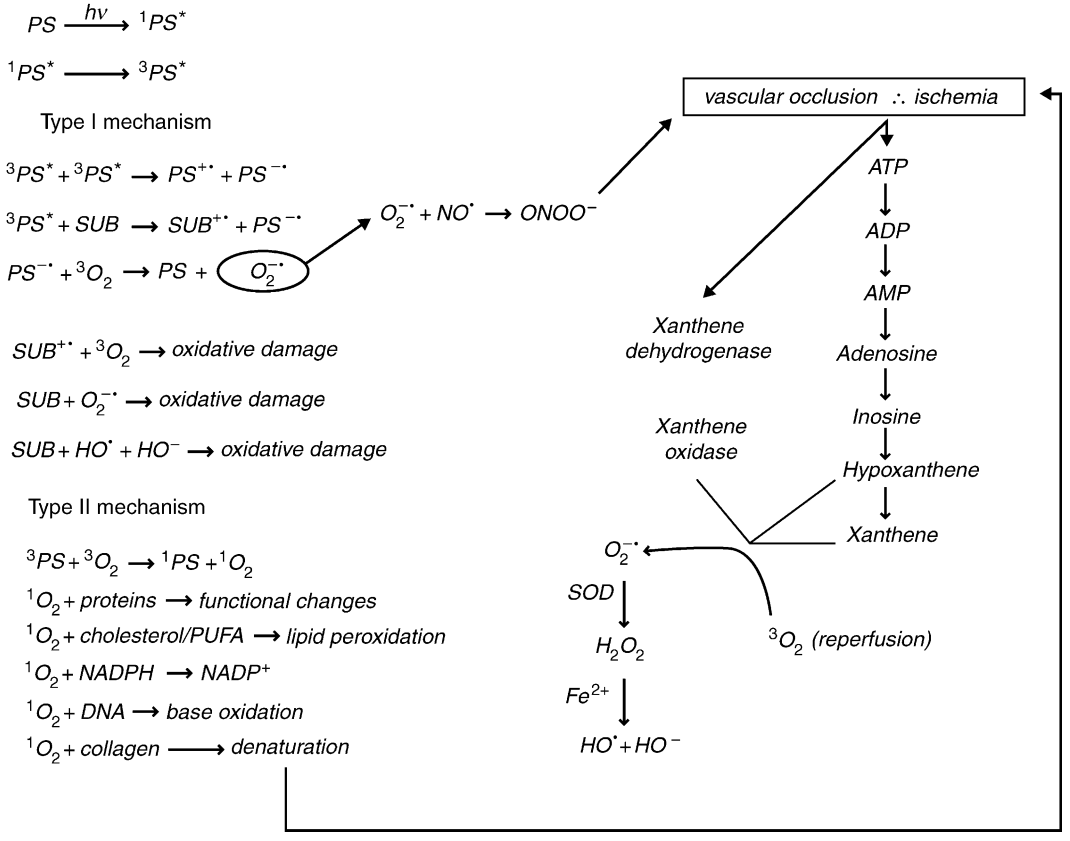

Figure 4 The photophysical and photochemical mechanisms involved in PDT. PS denotes the photosensitizer, SUB denotes the substrate, either biological, a solvent or another photosensitizer; * denotes the excited state and • denotes a radical.

produce free radicals or electron transfer, resulting in ion formation. The type II mechanism, in contrast, exclusively involves interaction between molecular oxygen and the triplet state to form singlet oxygen which is highly reactive in biological systems. The near-resonant energy transfer from the triplet state to O_2 can be highly efficient and the singlet oxygen yield can approach the triplet state yield provided that the triplet state energy exceeds 94 kJ/mol, the singlet oxygen excitation energy. It is widely accepted that the type II mechanism underlies the oxygen-dependent phototoxicity of sensitizers used for photodynamic therapy. Both proteins and lipids (the main constituents of membranes) are susceptible to photooxidative damage induced via a type II mechanism which generally results in the formation of unstable peroxide species. For example, unsaturated lipids may be oxidized by the 'ene' reaction where the singlet oxygen reacts with a double bond. Other targets include such important biomolecules as cholesterol, certain amino acid residues, collagen, and the coenzyme, NADPH. Another synergistic mode of action involves the occlusion of the microcirculation to tumors and reperfusion injury. Reperfusion injury relates to the formation of xanthene oxidase from xanthene dehydrogenase in anoxic conditions which reacts with xanthene or hypoxanthene products of ATP dephosphorylation to convert the restored oxygen into superoxide anion which directly or via the Fenton reaction causes cellular damage.

An important feature of the type II mechanism, which is sometimes overlooked, is that when the sensitizer transfers electronic energy to O_2 it returns to its ground state. Thus the cytotoxic singlet oxygen species is generated without chemical transformation of the sensitizer which may then absorb another photon and repeat the cycle. Effectively, a singlet photosensitizer molecule is capable of generating many times its own concentration of singlet oxygen, which is clearly a very efficient means of photosensitization provided the oxygen supply is adequate.

Lasers in PDT

Lasers are the most popular light source in PDT since they have several key characteristics that differentiate them from conventional light sources, namely coherence, monochromaticity, and collimated output. The two main practical features that make them so useful in PDT are their monochromaticity and their combination with fiber-optic delivery. The monochromaticity is important since the laser can be tuned to a specific absorption peak of a photosensitizer, thus ensuring that all the energy delivered is utilized for the excitation and photodynamic activation of the photosensitizer. This is not true for a conventional light source (as for example a tungsten lamp) where the output power is divided over several hundred nanometers throughout the UV, visible, and IR regions and only a fraction of the power lies within the absorption band of the photosensitizer. To numerically illustrate this, let us simplify things by representing the lamp output as a square profile and also consider a photosensitizer absorption band about 30 nm full width half maximum. If a laser with a frequency span of about 2 nm and a lamp with the same power but with a frequency span of about 600 nm are used, then the useful portion of it is about 0.05 and if we consider a Gaussian profile for the sensitizer absorption band, the above fraction drops even lower, perhaps even to 0.01. That means that the lamp would achieve 100 times less the excitation rate of the laser, or in other words, we would require a lamp with an output power of 100 times that of the laser to achieve the same rate of excitation and consequently the same time of treatment, provided we use a low enough laser power to remain within the linear regime of the photosensitizer excitation. The other major disadvantage of a lamp source is the lack of collimation which results in low efficiency for fiber-optic delivery.

We now review the different lasers that have found application in PDT. Laser technology has significantly advanced in recent years and there are now a range of options in PDT laser sources for closely matching the absorption profiles of the various photosensitizers. Moreover, since PDT is becoming more widely used clinically, practical considerations, such as portability and turn-key operation are increasingly important. In Figure 5 the optical spectrum is shown from about 380 nm (violet–blue) to 800 nm (near-infrared, NIR). We have superimposed on this spectrum, the light penetration depth of tissue to roughly illustrate how deeply light can penetrate (and consequently activate photosensitizer molecules) into lower-lying tissue layers. The term 'penetration depth' is a measure of the light attenuation by the tissue so the figure of 2 mm corresponds to $1/e$ attenuation of the incident intensity at a tissue depth of 2 mm. It is obvious that light at the blue end of the spectrum has only a superficial effect whereas the more we shift further into the red and NIR regions the penetration depth increases. This is due to two main reasons: absorption and scattering of light by various tissue component molecules. For example, in the blue/green region for the absorption of melanin and hemoglobin is relatively high. But there is a noticeable increase in penetration depth beyond about 600 nm leading to an optimal wavelength region, or

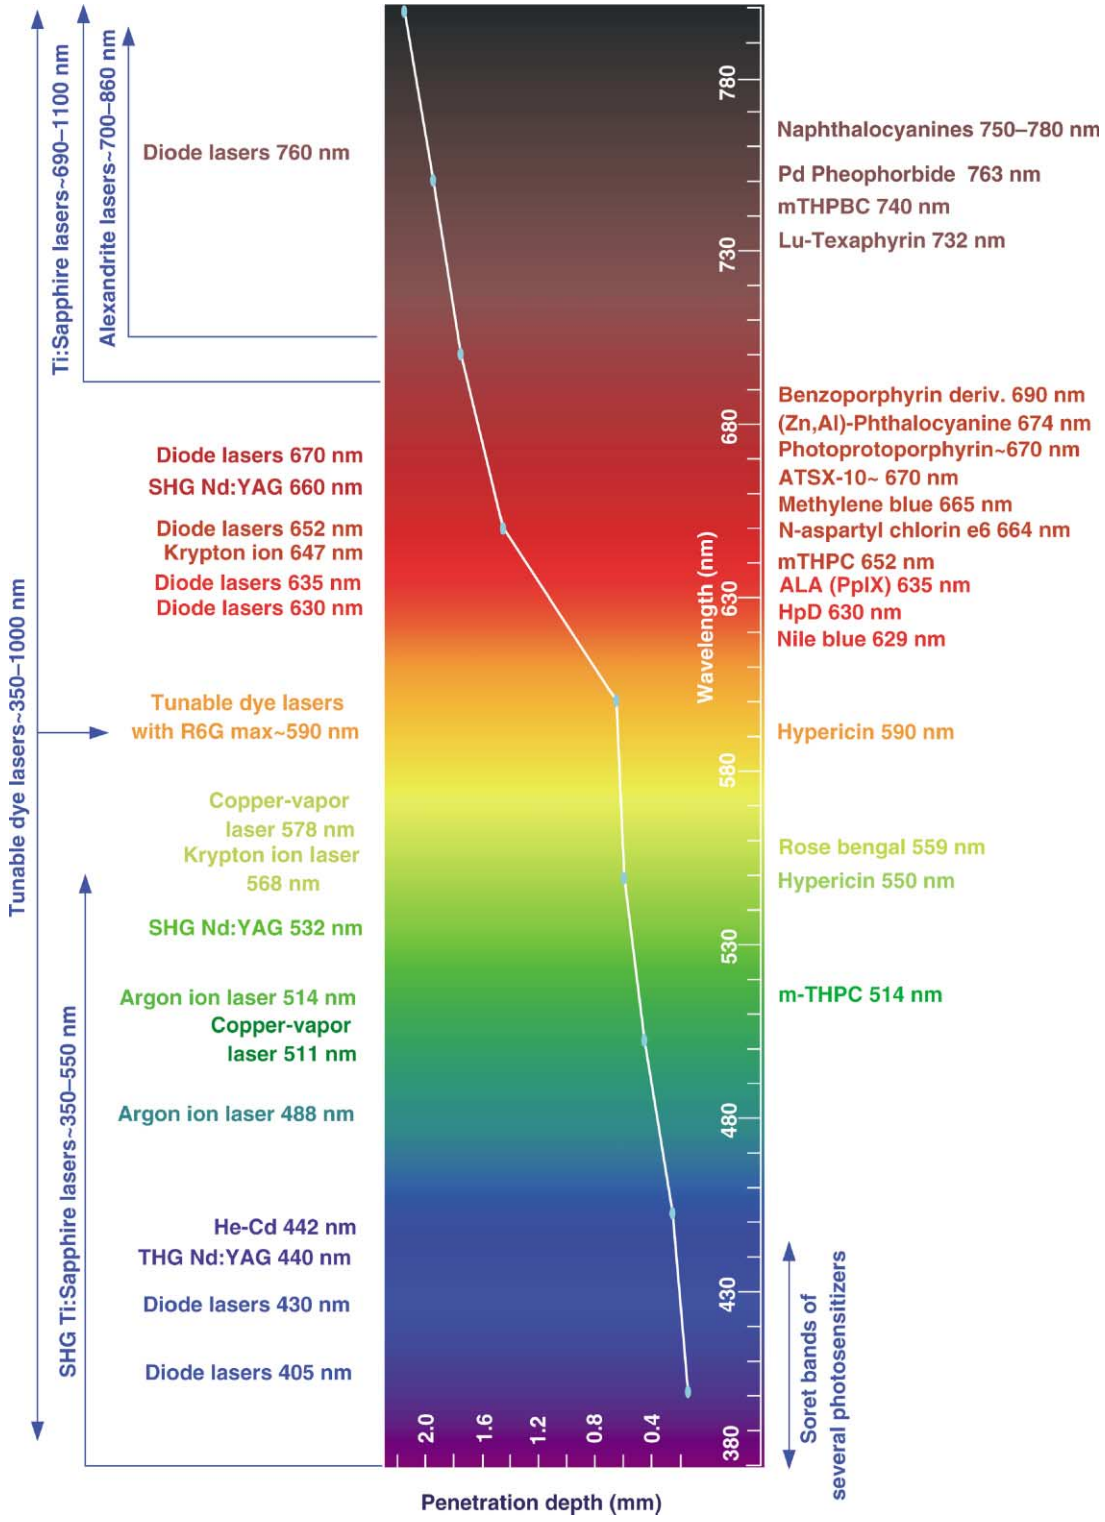

Figure 5 Photosensitizers and laser light sources available in the visible and near-infrared spectral regions.

'therapeutic window' for laser therapy of around 600–1100 nm (Figure 5).

The fundamental wavelength of the Nd:YAG laser lies within this therapeutic window at 1064 nm and this laser is now widely used in thermal laser therapy. The Nd:YAG lasers can be operated either in cw (output power ~ 200 W multimode), long-pulse (~500 W average power at 50 Hz), or Q-switched

(50 MW peak power at around 10 ns pulse duration) modes. Nd:YAG is a solid-state laser with a yttrium aluminum garnet crystal doped with about 1% of trivalent Nd ions as the active medium of the laser; and with another transition of the Nd ion, this laser (with the choice of different optics) can also operate at 1320 nm. Although dyes are available which absorb from 800–1100 nm, the generation of singlet oxygen via the type II mechanism is energetically unfavorable because the triplet state energies of these dyes are too low. However, the fundamental frequency of the laser can be doubled (second-harmonic generation, SHG) or tripled (third-harmonic generation, THG) with the use of nonlinear crystals, to upconvert the output radiation to the visible range, thus rendering this laser suitable for PDT: i.e., frequency doubling to 532 nm and tripling to 355 nm. Note that the 532 nm output is suitable for activation of the absorption band of hypericin with a maximum at 550 nm even though it is not tuned to the maximum of this absorption.

In the early days of PDT and other laser therapies, ion lasers were widely used. The argon ion laser uses ionized argon plasma as gain medium, and produces two main wavelengths at 488 nm and 514 nm. The second of the two lies exactly at the maximum of the 514 nm m-THPC absorption. Argon ion lasers are operated in cw mode and usually have output powers in the region of 5–10 W at 514 nm (the most powerful argon ion line). Krypton ion lasers, which emit at 568 or 647 nm, are similar to their argon ion counterparts; however, they utilize ionized krypton plasma as gain medium. The 568 nm output can be used to activate the Rose Bengal peak at 559 nm, whereas the 647 nm most powerful line of krypton ion lasers, has been used for activation of m-THPC (652 nm).

Ideally, for optimal excitation, it is best to exactly tune the laser wavelength to the maxima of photosensitizer absorption bands. For this reason tunable organic dye lasers have been widely used for PDT. In these lasers the gain medium is an organic dye with a high quantum yield of fluorescence. Due to the broad nature of their fluorescence gain profile, tuning elements within the laser cavity can be used for selection of the lasing frequency within the gain band. Tunable dye lasers with the currently available dyes can quite easily cover the range from about 350–1000 nm. However, their operation is not of a 'turn key' nature since they require frequent replacement of their active material either for tuning to a different spectral region or for a better performance when the dye degrades. Tunable dye lasers also need to be pumped by some other light source like an argon ion laser, an excimer laser, a solid state laser (e.g., Nd:YAG 532 or 355 nm), a copper vapor laser, or lamps. Dye lasers have been used for the excitation of HpD at 630 nm, protoporphyrin IX at 635 nm, photoprotoporphyrin at 670 nm, and phthalocyanines around 675 nm. A further example is hypericin which, apart from the band at 550 nm, has a second absorption band at 590 nm. This is the optimum operation wavelength of dye lasers with rhodamine 590, better known as rhodamine 6G.

Dye lasers can operate in either pulsed or cw mode. However, there is a potential disadvantage in using a pulsed laser for PDT which becomes apparent when using lower repetition rates and higher pulse energies (>1 mJ per pulse) laser excitation. High pulse energies can induce saturation or transient bleaching of the sensitizer during the laser pulse and consequently much of the energy supplied is not efficiently absorbed by the sensitizer. It has been suggested that this effect accounts for the lack of photosensitized damage in tissue sensitized with a phthalocyanine and irradiated by a 5 Hz, 25 mJ-per-pulse flash lamp pumped dye laser. However, using a low pulse energy, high repetition rate copper vapor pumped dye laser (see below), the results were indistinguishable from cw irradiation with an Argon ion dye laser.

Another laser that has found clinical application in PDT is the copper vapor laser. In this laser the active medium is copper vapor at high temperature maintained in the tube by a repetitively pulsed discharge current. The copper vapor lasers are pulsed with typical pulse duration of about 50 ns and repetition rates reaching 20 kHz. Copper vapor lasers have been operated at quite high average powers up to about 40 W. The output radiation is produced at two distinct wavelengths, namely 511 and 578 nm both of which have found clinical use. Copper vapor pumped dye lasers have also been widely used for activating red-absorbing photosensitizers, and the analogous gold vapor lasers operating at 628 nm have been used to activate HpD.

A relatively new class of tunable lasers is the solid state Ti:Sapphire laser. The gain medium in this laser is a $\sim$1%Ti doped sapphire (Al_2O_3) crystal and its output may be tuned throughout the 690–1100 nm region, covering many photosensitizer absorption peaks. For example, most of the bacteriochlorin type photosensitizers have their absorption bands in that spectral region, e.g., m-THPBC with an absorption maximum at 740 nm. Also, Texaphyrin sensitizers absorb highly in this spectral region: lutetium texaphyrin has an absorption maximum at 732 nm.

Although tunable dye or solid-state lasers are widely used in laboratory studies for PDT, fixed-wavelength semiconductor diode lasers are gradually supplanting tunable lasers, owing to their practical convenience. It is now generally the case that when

a photosensitizer enters clinical trials or enters standard clinical use, laser manufacturers provide dedicated diode lasers with outputs matched to the chosen sensitizer. In this context there are diode lasers available at 630 nm for use with HpD, at 635 nm for use with ALA-induced protoporphyrin IX, 670 nm for ATSX-10 or phthalocyanines, or even in the region of 760 nm, for use with bacteriochlorins. The advantage of these diode lasers is that they are tailormade for use with a particular photosensitizer, they are highly portable, and they have a relatively easy turn-key operation.

So far we have concentrated on red wavelengths but most of the porphyrin and chlorin family of photosensitizers exhibit quite strong absorption bands in the blue region, known as 'Soret' bands. Despite the fact that tissue penetration in this spectral region is minimal, these bands are far more intense than the corresponding red absorption bands of the sensitizer. In this respect it is possible to activate these sensitizers at blue wavelengths, especially in the case of treatment of superficial (e.g., skin) malignant lesions. There are now blue diode lasers (and light-emitting diodes) for the activation of these bands, in particular at 405 nm where the Soret band of protoporphyrin IX lies or at 430 nm for selective excitation of the photoprotoporphyrin species. For very superficial lesions (e.g., in the retina) it may even be possible to use multiphoton excitation provided by femtosecond diode lasers operating at about 800 nm.

Clinical Applications of Lasers in PDT

In the previous section we reviewed the various types of lasers being used for PDT but their combination with fiber-optic delivery is also of key importance for their clinical application. The laser light may be delivered to the target lesion either externally using surface irradiation, or internally within the lesion which is denoted as interstitial irradiation, as depicted in **Figure 6**. For example, in case of superficial cutaneous lesions the laser irradiation is applied externally (**Figure 6a**). The area of the lesion is marked prior to treatment to determine the diameter of the laser spot. For a given fluence rate (100–200 W/cm^2) and the area of the spot, the required laser output power is then calculated. A multimode optical fiber, terminated with a microlens to ensure uniform irradiation, is then positioned at a distance from the lesion yielding the desired beam waste, and the surrounding normal tissue is shielded with dark material. However, if the lesion is a deeper-lying solid tumor, interstitial PDT is employed

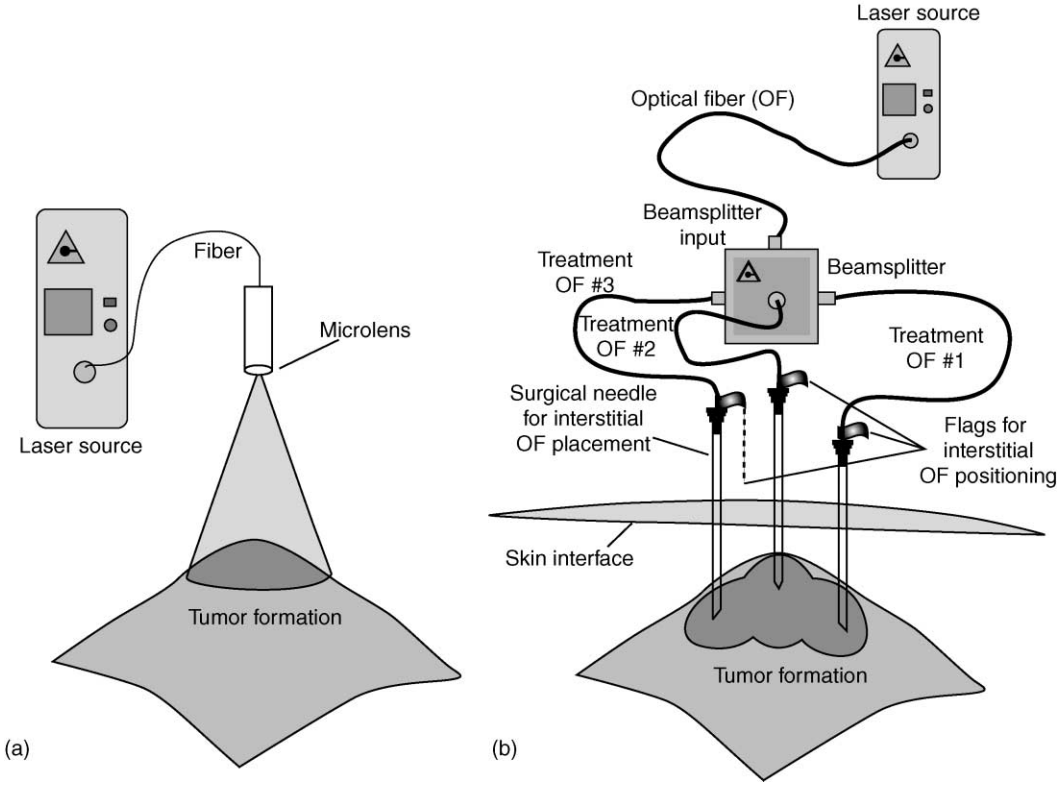

Figure 6 Clinical application of PDT. (a) Surface treatment. (b) Interstitial treatment.

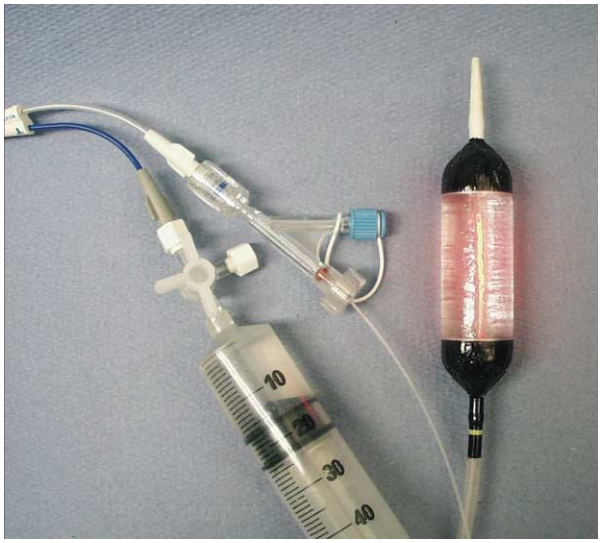

Figure 7 Balloon applicator and diffuser fiber used for PDT in Barrett's esophagus.

(Figure 6b). Surgical needles are inserted in an equidistant parallel pattern within the tumor, either freehand or under image (MRI/CT) guidance. Bare tip optical fibers are guided through the surgical needles to the lesion and flagged for position. A beamsplitter is used to divide the laser output into 2–4 components so that two to four optical fibers can be simultaneously employed. The laser power is adjusted so that the output fluence of each of the optical fibers is 100–200 mW. Even light distribution in the form of overlapping spheres approximately 1 cm diameter ensures the treatment of an equivalent volume of tissue around each fiber tip. Once each 'station' is likewise treated the fibers are repositioned accordingly, employing a pull-back technique in order for another station to be treated. Once the volume of the tumor is scanned in this manner the treatment is complete. Interstitial light delivery allows PDT to be used in the treatment of large, buried tumors and is particularly suitable for those in which surgery would involve extensive resection.

The treatment of tumors of internal hollow organs is also possible with PDT. The most representative example of this is the treatment of precancerous lesions in the esophagus, known medically as 'Barrett's esophagus'. In this case, a balloon applicator is used to house a special fiber with a light-diffusing tip or 'diffuser' (Figure 7). These diffusers are variable in length and transmit light uniformly along the whole of their length in order to facilitate treatment of circumferential lesions. The balloon applicator is endoscopically inserted into the patient. The balloon is inflated to stretch the esophageal walls and the flagged diffuser fiber is placed in position, central to the balloon optical window. In this way the whole of the lesion may be treated circumferentially at the same time.

Finally, the clinical response to PDT treatment is shown in Figure 8. The treated area becomes necrotic and inflamed within two to four days following PDT. This necrotic tissue usually sloughs off or is mechanically removed. The area eventually heals with minimal scarring (Figure 8).

Future Prospects

A major factor in the future development of PDT will be the application of relatively cheap and portable semiconductor diode lasers. High-power systems consisting of visible diode arrays coupled into multimode fibers with an output of several Watts, have recently become available which will greatly simplify the technical difficulties which have held back PDT. The use of new photosensitizers, in the treatment of certain tumors by PDT, is making steady progress, and although the toxicology testing and clinical evaluation are lengthy and costly processes, the expectation is that these compounds will become more widely available for patient use during the next five years. Regarding the current clinical status of PDT, Photofrin has recently been approved for treatment of lung and esophageal cancers in Europe, USA, and Japan. Clinical trials are in progress for several of the second-generation photosensitizers which offer significant improvements over Photofrin in terms of chemical purity, photoproperties, and skin

clearance. With the increasing clinical application of compact visible diode lasers the prospects for photodynamic therapy are therefore encouraging.

Pump and Probe Studies of Femtosecond Kinetics

G D Scholes, University of Toronto, Toronto, ON, Canada

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Pump-probe spectroscopy is a ubiquitous time-resolved optical spectroscopy that has found application to the study of all manner of ultrafast chemical processes that involve excited states. The principle of the measurement is that a 'pump pulse' – usually an intense, short laser pulse – impulsively excites a sample, thus defining the start time for the ensuing photophysical dynamics. A probe pulse interrogates the system at later times in order to capture 'snap shots' of the state of the system. Many kinds of pump-probe experiments have been devised. The present article will mainly focus on transient absorption measurements.

Femtosecond pump-probe experiments have been employed to reveal the kinetics of excited state chemical processes such as solvation, isomerization reactions, proton transfer, electron transfer, energy transfer, or photochromism. It is becoming more common to use pump-probe techniques to study systems of increasing complexity, such as photosynthetic proteins, photoreceptor proteins, molecular aggregates, nanostructured materials, conjugated polymers, semiconductors, or assemblies for artificial light harvesting. However, the underlying chemical kinetics are not always easily revealed by pump-probe signals.

The principle of the pump-probe measurement is related to the seminal flash-photolysis experiment devised by Norrish and Porter. However, in order to achieve ultrafast time resolution – beyond that attainable by electronic detection – the probe pulse is temporally short and is controlled to arrive at the sample at variable time delays after the pump pulse has excited the sample. The change in intensity of the probe pulse, as it is transmitted through the sample, is monitored at each pump-probe time delay using a 'slow' detector that integrates over the probe pulse duration. One possible xprocess that can diminish the probe transmission is transient absorption. After formation of an excited state S_1 by the pump pulse, the probe pulse can monitor a resonance with a higher excited state $S_1 \rightarrow S_n$ absorption. Figure 1 shows transient absorption spectra, corresponding to excited state absorption at various time delays, that has been probed by a white light continuum probe and monitored by a multichannel CCD detector. The transient spectrum is seen to blue-shift with

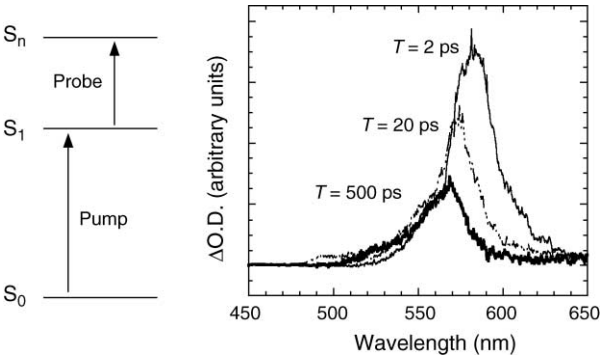

Figure 1 Excited state absorption spectra of 4′-*n*-pentyl-4-cyanoterphenyl in octanol solvent. The pump wavelength is 277 nm (100 nJ, 150 fs, 40 kHz) and the probe is a white light continuum (500 to 700 nm) generated in a sapphire crystal. The pump-probe delay T for each spectrum is indicated on the plot.

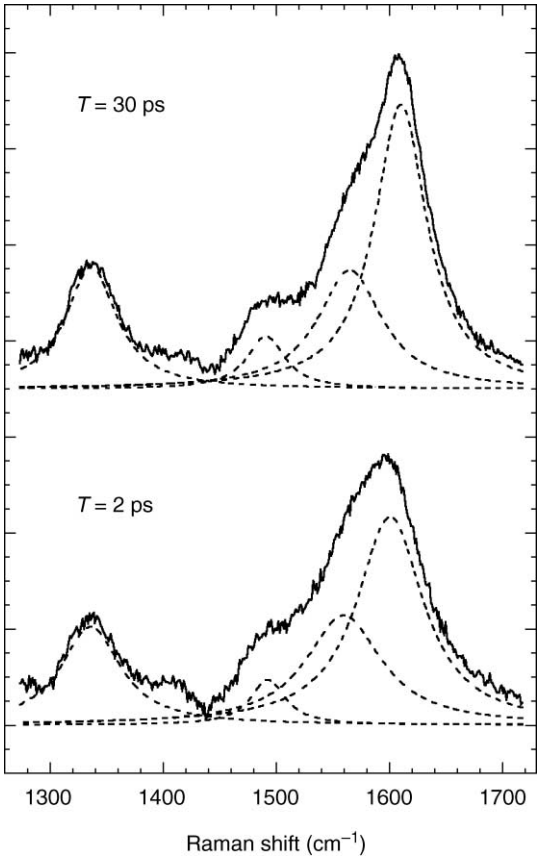

Figure 2 TR^3 spectra of 4′-*n*-pentyl-4-cyanoterphenyl in octanol solvent, recorded using the same set-up as summarized in Figure 1. The dashed lines are deconvolutions of the data to show the Raman bands.

pump-probe delay owing to solvation of the S_1 state of the molecule – the dynamic Stokes' shift. The dynamic Stokes' shift is the shift to lower energy of the emission spectrum as the solvent relaxes in response to the change in dipole moment of the excited electronic state compared to the ground state. The overall intensity of the induced absorption decays according to the lifetime of the excited state.

Although they will not be discussed in detail in the present article, various other pump-probe experiments are possible. For example, when in resonance with this transient absorption, the probe pulse can induce resonance Raman scattering, which reveals the evolution of the vibrational spectrum of the excited state. In this kind of pump-probe experiment we do not monitor the change in probe transmission through the sample. Instead, we monitor the difference between probe-induced resonance Raman scatter from the excited and ground states of the system. The resonance Raman (TR^3) scatter, time-resolved as a function of pump-probe delay, can be detected provided that it is not overwhelmed by fluorescence emission. Typical TR^3 data for different pump-probe delays are shown in Figure 2. The dashed lines show a deconvolution of the spectra to reveal the underlying vibrational bands. These bands are rather broad owing to the spectral width of the 1 ps laser pulses used in this experiment. It is clear that the time-resolution of a TR^3 experiment is limited to the picosecond regime, otherwise most of the vibrational band information is lost. TR^3 and complementary pump-probe infrared transient absorption experiments, utilizing an infrared probe beam, have been useful for observing the evolution of structural information, such as geometry changes, subsequent to photoexcitation.

In the present article we will describe the foundation of experiment and theory necessary to understand resonant ultrafast pump-probe spectroscopy applied to chemical processes in the condensed phase. By resonant, it is meant that the pump and probe pulses have frequencies (energies) resonant with electronic transitions of the molecules being studied. The implications of condensed phase are that the experiment interrogates an ensemble of molecules and the electronic transitions of these molecules are coupled to the random motions and environments of a bath, for example the solvent.

Experimental Measurement of Pump-Probe Data

The experimental setup for a one-color pump-probe experiment (i.e. pump and probe of the same color) is shown in Figure 3. The setup is easily adapted for a two-color experiment. Most of the laser intensity (70%) is transmitted through the first beam splitter so that the pump is more intense than the probe. A second beam splitter is used to split off a small amount of probe light for the reference beam. Note that the arrangement of these beam splitters results in both the pump and probe passing through the same amount of dispersive material on their way to the sample. The pump and probe beams each propagate through half-wave plates in order to control polarization. Usually the probe polarization is set to the magic angle (54.7°) relative to the pump in order to remove polarization bias. The beams are sent towards the sample by way of retroreflectors mounted on $x-y-z$ translation stages. The pump retroreflector is mounted on a precision computer-controlled translation stage such that it can be scanned in the x-direction to arrive at variable delays before and after the probe. The pump and probe beams are aligned using the $y-z$ controls on the retroreflector translation stages together with the pick-off mirrors

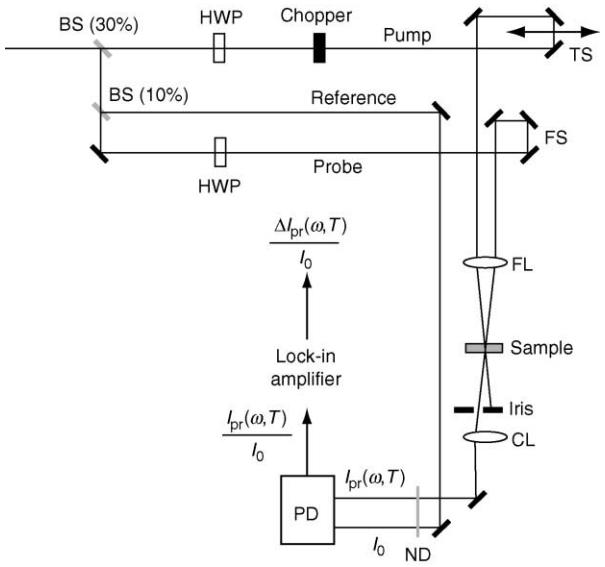

Figure 3 An experimental layout for femtosecond pump-probe spectroscopy. The reference beam ideally passes through the sample (not shown as such in aid of clarity). See text for a description. such that they travel in parallel towards the sample. The overall setup of the beams is in a box geometry so that pump and probe arms have the same path length.

The pump and probe beams are focused into the sample using a transmissive (i.e. lens) or reflective optic FL. The focal length is typically 20 to 30 cm, providing a small crossing angle to improve phase matching. The pump beam should have a larger spot size at its focal point in the sample than the probe beam, in order to avoid artifacts arising from the wandering of the pump and probe spatial overlap as a function of delay time – a potential problem, particularly for long delays. Good spatial overlap of the beams in the sample is important. It can be checked using a 50 μm pinhole. Fine adjustment of the pump-probe delay, to establish temporal overlap of the pump and probe pulses, can be dictated by autocorrelating the beams in a second harmonic generating crystal mounted at the sample position. At the same time the pulse compression is tweaked to ensure that the pulse dispersion in the experiment has been pre-compensated.

The sample is usually flowed or mounted in a spinning cell if it is liquid, in order to avoid thermal effects or photochemical bleaching. The path length of the sample is typically ≤ 1 mm. The transmitted probe beam is spatially isolated from the pump beam using an iris, is collimated, and then directed onto the photodetector.

The reference beam, which provides the relative reference intensity I_0 should preferably pass through the sample (away from the pump spot). This provides the probe-only transmission – that is, the reference beam intensity is attenuated according to sample ground state optical density. The photodetector outputs are used to ratio the pump-probe arm intensity transmitted through the sample with the reference intensity, $I_{pr}(\omega, T)/I_0$. Since the pump beam is being chopped at the lock-in reference frequency, the lock-in amplifier outputs the pump-induced fractional change in transmission intensity, $\Delta I_{pr}(\omega, T)/I_0$, usually simply written as $\Delta T/T$. When the pump-induced signal I_{pr} is small compared to the reference intensity I_0, then the detected $\Delta I_{pr}(\omega, T)/I_0$ signal is approximately equal to the change in optical density, ΔO.D.:

$$\Delta\text{O.D.} = \log\left(\frac{I_0 - \Delta I_{pr}}{I_0}\right) \approx \frac{-\Delta I_{pr}}{I_0} \equiv \frac{-\Delta T}{T} \quad [1]$$

Here we have used a Taylor expansion $\log(1 + x) \approx x$ for small x.

The power dependence of the signal in the $\chi^{(3)}$ limit should be linear in both the pump and probe intensities. It is also possible to pump the sample using two-photon absorption, then probe an excited state absorption. This is a $\chi^{(5)}$ experiment, so that the signal depends quadratically on the pump intensity.

What is Measured in a Pump-Probe Experiment?

Origin of the Signal

The pump-probe measurement is a third-order nonlinear spectroscopy. A complete calculation of the signal requires computation of the third-order polarization induced by the interaction of the pump and probe with the material sample, together with an account for the kinetic evolution of populations (e.g., excited state reactant and product states, etc.).

The pump pulse, wavevector $\mathbf{k}_1$, interacts twice with the sample, thereby creating excited state population density $|e\rangle\langle e|$ and a hole-in-the-ground state population density $|g\rangle\langle g|$. These population densities propagate until the probe pulse, with wavevector $\mathbf{k}_2$, interacts with the system to induce a polarization that depends on the state of the system at time T after the pump. This induced polarization $P_s(t)$ is radiated in the $\mathbf{k}_s = \mathbf{k}_1 - \mathbf{k}_1 + \mathbf{k}_2 = \mathbf{k}_2$ direction. Because the signal is radiated in the probe direction, the probe pulse acts as a local oscillator to heterodyne the signal. The change in probe-pulse spectral intensity after transmission through an

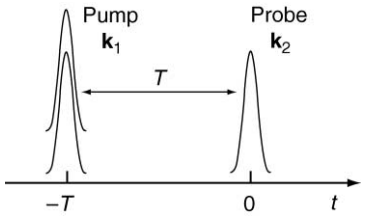

Figure 4 Labeling and time variable for the description of a pump-probe experiment. T defines the pump-probe delay.

optically thin sample of path length l, with concentration of absorbers c and refractive index n, is given by eqn [2]

$$\Delta I_{\mathrm{pr}}(\omega,T) \propto \frac{cl\omega_{\mathrm{pr}}}{n}\mathrm{Im}\left[\int dt E^{*}_{\mathrm{pr}}(t)P^{(3)}(0,T,t)e^{i\omega t}\right] \quad [2]$$

In eqn [2] $E_{\mathrm{pr}}(t)$ is the probe pulse electric field, ω is the center frequency of the probe, and * indicates complex conjugate. The time variables correspond to those indicated in Figure 4, and the signal is resolved as a function of frequency by Fourier transformation of $t \rightarrow \omega$. Experimentally this is achieved by dispersing the transmitted probe using a spectrograph. The first-time variable, the time interval between the two pump pulse interactions, is set to zero because we are interested here in the limit where the pulse duration is much shorter than T. In this regime – impulsive pump-probe – the measurement is sensitive to formation and decay of excited state species.

The induced polarization is given by eqn [3]

$$P^{(3)}(0,T,t) = \int_0^\infty \mathrm{d}t \int_0^\infty \mathrm{d}T[R^{\mathrm{SE}} - R^{\mathrm{ESA}} + R^{\mathrm{GSR}}] \times E_1^{*}(t-T)E_1(t-T)E_2(t) \quad [3]$$

where the response functions that contain information about the lineshape functions and kinetics are given by eqn [4]:

$$R^{\mathrm{SE}}(0,T,t) = |\mu_{eg}|^2|\mu_{eg}|^2 \exp(-i\omega_{eg}t) \times \exp[-g^{*}(t) + 2ig''(T+t) - 2ig''(T)] \times K^{\mathrm{SE}}(T) \quad [4a]$$

$$R^{\mathrm{ESA}}(0,T,t) = |\mu_{eg}|^2|\mu_{fe}|^2 \exp(-i\omega_{fe}t) \times \exp[-g^{*}(t) - 2ig''(T+t) + 2ig''(T)] \times K^{\mathrm{ESA}}(T) \quad [4b]$$

$$R^{\mathrm{GSR}}(0,T,t) = |\mu_{eg}|^2|\mu_{eg}|^2 \exp(-i\omega_{eg}t)\exp[-g(t)] \times K^{\mathrm{GSR}}(T) \quad [4c]$$

The overall intensity of each contribution to the signal is scaled by the transition dipole moment that connects the ground and excited state μ_{eg} or excited state and a higher excited state μ_{fe}. The intensity is further influenced by resonance of the probe-pulse spectrum with the transition frequencies ω_{eg} and ω_{fe}. These transition energies have a time-dependence owing to the relaxation of the excited state density in the condensed phase environment – the dynamic Stokes' shift. The details of the dynamic Stokes' shift depend on the bath, and are therefore contained in the imaginary part of the lineshape function $g(t) = g'(t) + ig''(t)$. The evolution of the Stokes' shift with pump-probe delay T is clearly seen in the excited state absorption spectrum shown in Figure 1. The lineshape function contains all the details of the timescales of fluctuations of the bath and the coupling of the electronic transition of the molecule to these fluctuations. The lineshape function can be cast in the simple form given by eqn [5] using the Brownian oscillator model in the high temperature, high friction limit:

$$g(t) \approx (2\lambda k_B T_B/\hbar\Lambda)[\Lambda t - 1 + \exp(-\Lambda t)] + i(\lambda/\Lambda)[1 - \exp(-\Lambda t)] \quad [5]$$

The Brownian oscillator model attributes fluctuations of the transition frequencies to coupling between electronic states and an ensemble of low-frequency bath motions. In eqn [5]; λ is the solvent reorganization energy (half the Stokes' shift) and Λ is the modulation frequency of the solvent oscillator (τ_{L}^{-1} for a Debye solvent, where τ_{L} is the longitudinal dielectric relaxation time); k_{B} is the Boltzmann constant, and T_{B} is the temperature.

Information about the kinetics of the evolution of the system initiated by the pump pulse is contained in the terms K^{SE}, K^{ESA}, and K^{GSR}. These terms will be discussed in the next section.

The evolution of the excited state density is mapped onto the response functions R^{SE} and R^{ESA}. R^{SE} is the contribution arising from the probe pulse stimulating emission from the excited state e in the probe direction, which increases the probe intensity. Thus the spectrum of the signal arising from R^{SE} resembles the fluorescence emission of the sample, as shown in Figure 5. The excited state absorption contribution to the signal R^{ESA} depletes the probe intensity, and corresponds to an e $\rightarrow$ f electronic resonance, such as that shown in Figure 1. Note that the ESA signal contributes to the overall $\Delta I_{\mathrm{pr}}(\omega, T)$ with an opposite sign to the SE and GSR contributions. The ground-state recovery term R^{GSR} arises from depletion of the ground-state population by the pump pulse, thereby increasing the transparency of the sample over the

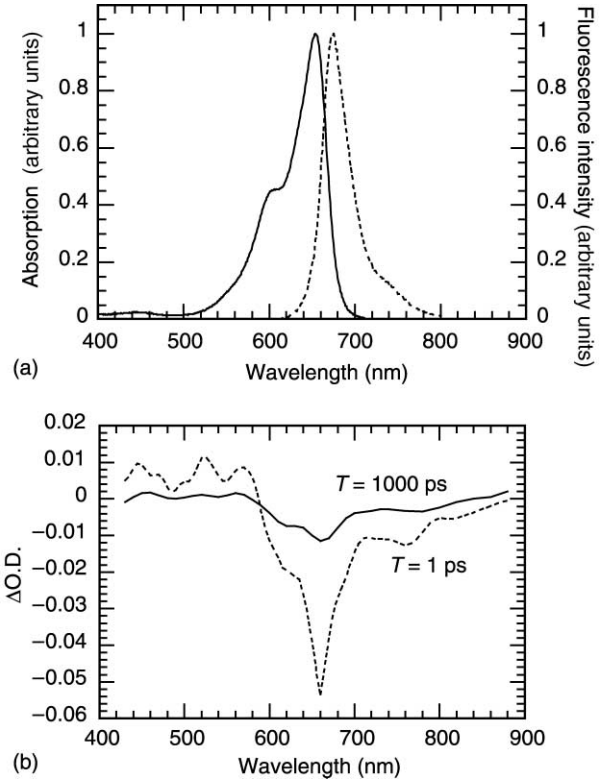

Figure 5 (a) shows the absorption and emission spectrum of a dilute solution of oxazine-1 in water. (b) shows the transient absorption spectrum of this system at various delays after pumping at 600 nm using picosecond pulses. The transient spectrum, ground state recovery and stimulated emission resemble the sum of the absorption and emission spectra.

spectrum of the ground-state absorption (see Figure 5). Thus the transmitted probe intensity is increased relative to that without the pump pulse. The GSR contribution to $\Delta I_{pr}(\omega, T)$ decreases with T according to the excited state lifetime of the photo-excited species.

The Coherent Spike

To calculate the pump-probe signal over delay times that are of the order of the pulse duration, one must calculate all possible ways that a signal can be generated with respect to all possible time orderings of the two pump interactions and the probe interactions (Liouville space pathways). Such a calculation reveals coherent as well as sequential contributions to the response of the system owing to the entanglement of time orderings that arise from the overlap of pulses of finite duration. The nonclassical, coherent, contributions dominate the signal for the time period during which pump and probe pulses overlap, leading to the coherent spike (or coherent 'artifact') (Figure 6).

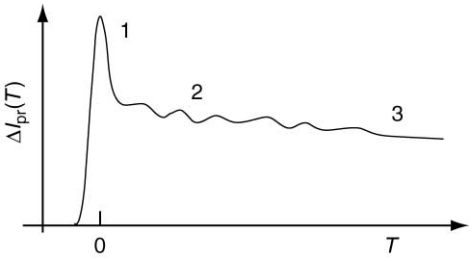

Figure 6 A schematic depiction of a pump-probe signal. The coherent spike is labeled 1. In region 2 we can see quantum beats as a sum of sinusoidal modulations of the signal. The label 3 denotes the long time decay of the signal, as determined by the population dynamics, K^{SE}, K^{GSR}, and K^{ESA}.

Nuclear Wavepackets

The electronic absorption spectrum represents a sum over all possible vibronic transitions, each weighted by a corresponding nuclear overlap factor according to the Franck–Condon principle. It was recognized by Heller and co-workers that in the time-domain representation of the electronic absorption spectrum, the sum over vibrational overlaps is replaced by the propagation of an initially excited nuclear wavepacket on the excited state according to $|i(t)\rangle = \exp(-Ht/\hbar)\,|i(0)\rangle$. Thus the absorption spectrum is written as

$$\sigma_i(\omega) = \frac{2\pi\omega}{3c}\int_{-\infty}^{\infty} \mathrm{d}t\, \exp[-i(\omega - \omega_{eg}^{i})t - g(t)] \times \langle i(0)\,|i(t)\rangle \qquad [6]$$

for mode i. The Hamiltonian H is determined by the displacement of mode i, Δ_i. A large displacement results in a strong coupling between the vibration and the electronic transition from state g to e. In the frequency domain this is seen as an intense vibronic progression. In the time domain this translates to an oscillation in the time-dependent overlap $\langle i(0)\,|i(t)\rangle$, with frequency ω_i, thereby modulating the intensity of the linear response as a function of t.

It follows that an impulsively excited coherent superposition of vibrational modes, created by an optical pulse that is much shorter than the vibrational period of each mode, propagates on the excited state as a wavepacket. The oscillations of this wavepacket then modulate the intensity of the transmitted probe pulse as a function of T to introduce features into the pump-probe signal known as quantum beats (see Figure 6). In fact, nuclear wavepackets propagate on both the ground and excited states in a pump-probe experiment. The short probe pulse interrogates the evolution of the nuclear wavepackets by projecting them onto the manifold of vibrational wavefunctions in an excited or ground state.

Femtosecond Kinetics

According to eqn [4] the kinetics of the evolution of the system initiated by the pump pulse are governed by the terms K^{SE}, K^{ESA}, and K^{GSR}. Each of these terms describes the kinetics of decay, production, or recovery of excited state and ground state populations. In the simplest conceivable case, each might be a single exponential function. The stimulated emission term K^{SE} contains information about the depopulation of the initially excited state, which for example, may occur through a chemical reaction involving the excited state species or energy transfer from that state. The excited state absorption term K^{ESA} contains information on the formation and decay of all excited state populations that give a transient absorption signal. The ground-state recovery term K^{GSR} contains information on the time-scales for return of all population to the ground state, which will occur by radiative and nonradiative processes. Usually the kinetics are assumed to follow a multi-exponential law such that

$$K^m(T, \lambda_{exc}, \omega) = \sum_{j=1}^{N} A_j(\lambda_{exc}, \omega) \exp(-t/\tau_j) \qquad [7]$$

where the amplitude A_j, but not the decay time coefficient τ_j, of each contribution in the coupled N-component system depends on the excitation wavelength λ_{exc} and the signal frequency ω. The index m denotes SE, ESA, or GSR.

In order to extract meaningful physical parameters from analysis of pump-probe data, a kinetic scheme in the form of eqn [7] needs to be constructed, based on a physical model to connect the decay of initially excited state population to formation of a product excited state and subsequent recovery of the ground-state population. An example of such a model is depicted in Figure 7. Here the stimulated emission contribution to the signal is attenuated according to the rate that state 1 goes to 2. The transient absorption appears at that same rate and decays according to the radiationless process 2 to 3. The rate of ground state recovery depends on 1 to 2 to 3 to 5 and possibly pathways involving the isomer 4.

The kinetic scheme is not easily extracted from pump-probe data because contributions from each of K^{SE}, K^{ESA}, and K^{GSR} contribute additively at each detection wavelength ω, as shown in eqns [2]–[4]. Moreover, additional, wavelength-dependent, decay or rise components may appear in the data on ultrafast time-scales owing to the time-dependent Stokes' shift (the $g''(t)$ terms indicated in eqns [4]). A spectral shift can resemble either a decay or rise component. In addition, the very fastest dynamics may be hidden beneath the coherent spike. For these reasons, simple fitting of pump-probe data usually cannot reveal the underlying kinetic model. Instead the data should be simulated according to eqns [3] and [4].

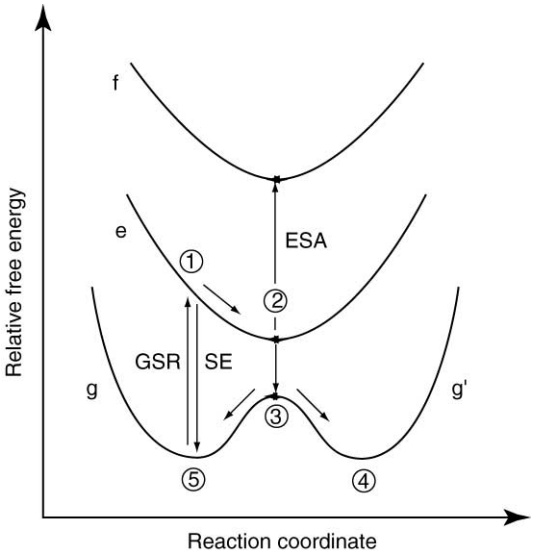

Figure 7 Free energy curves corresponding to a model for an excited state isomerization reaction, with various contributions to a pump-probe measurement indicated. See text for a description. (Courtesy of Jordanides XJ and Fleming GR.)

Alternative strategies involve global analysis of wavelength-resolved data to extract the kinetic evolution of spectral features, known as 'species associated decay spectra'. Global analysis of data effectively reduces the number of adjustable parameters in the fitting procedure and allows one to obtain physically meaningful information by associating species with their spectra. These methods are described in detail by Holzwarth.

List of Units and Nomenclature

ESA	excited state absorption
GSR	ground state recovery
SE	stimulated emission
S_n	nth singlet excited state

Time-Correlated Single-Photon Counting

A Beeby, University of Durham, Durham, UK

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Time-correlated single-photon counting, TCSPC, is a well-established technique for the determination of fluorescence lifetimes and related time-resolved fluorescence properties. Since the 1980s, there have been dramatic changes in the laser sources used for this work, which in turn have opened up the technique to a wide user base.

TCSPC: The Basics

In the TCSPC experiment, the sample is repeatedly excited by a high-repetition rate, low-intensity light source. Fluorescence from the sample is collected and may be passed though a cut-off filter or monochromator to remove scattered excitation light and to select the emission wavelength. The fluorescence is then focused onto a detector, typically a photomultiplier (PMT) or single-photon avalanche diode (SPAD) which detects single emitted photons. The 'raw' signal from the detector fluctuates considerably from event to event. In order to remove any timing error that could be induced by this, the signal is processed first by a constant fraction discriminator (CFD) in order to provide a stable and consistent timing pulse. This signal is used as an input for the time-to-amplitude converter (TAC) which determines the time interval between the excitation of the sample and the emission of the photon. The output from the TAC is a relatively slow pulse whose intensity is proportional to the time interval between the start and stop signals. A pulse height analyzer (PHA) is used to process the output from the TAC and increments a channel in its memory corresponding to a time window during which the photon was detected. As the measurement is repeated many times over, a histogram is constructed in the memory of the PHA, showing the number of photons detected as a function of the time interval. This histogram corresponds to the fluorescence decay.

As outlined below, it is desirable to have a light source with a moderately high repetition rate, typically of the order of MHz. Because it is not practical to start the TAC each time the light source 'fires', it is more usual to operate the TAC in the so-called 'reversed mode', whereby the start signal is derived from the detected photon and the stop is derived from the light source. The electronic circuitry is illustrated in Figure 1. In practice, many researchers still use modular components that are wired together manually, although there is increasingly a tendency towards the use of single PC-based cards which contain all the necessary discriminators, timing circuits, and data acquisition electronics. There are a number of commercial PC

cards that contain all the timing electronics, etc., required for TCSPC, for example, Becker and Hickl (Germany).

This approach to obtaining the fluorescence decay profile can only work if the detected photons are 'randomly selected' from the total emission from the sample. In practice, this means that the rate of detection of photons should be of the order of 1% of the excitation rate: that is, only one in a hundred excitation pulses gives rise to a detected photon. This histogram mirrors the fluorescence decay of the sample convolved with the instrument response function (IRF). The IRF is itself a convolution of the temporal response of the optical light pulse, the optical path in the collection optics, and the response of the detector and ancillary electronics. Experimentally, the IRF is usually recorded by placing a scattering material in the spectrometer.

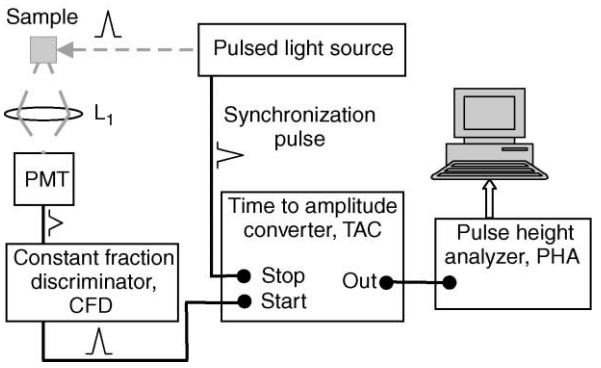

Figure 1 Schematic diagram of a TSCPC spectrometer. Fluorescence from the sample is collected by L_1, which may also include a monochromator/wavelength selection filter. A synchronization pulse is obtained either from the laser driver electronics directly, or via a photodiode and second constant fraction discriminator. The TAC is shown operating in a 'reversed mode' as is normal with a high repetition rate laser source.

In principle, the decay function of the sample can be extracted by deconvolution of the IRF from the decay function, although in practice it is more common to use the method of iterative re-convolution using a model decay function(s). Thus, the experimentally determined IRF is convolved with a model decay function and parameters within the function are systematically varied to obtain the best fit for a specific model. The most commonly used model assumes the decaying species to follow one or more exponential functions (sum of exponentials) or a distribution of exponentials. Further details regarding the mechanics of data analysis and fitting procedures can be found in the literature. A typical fit is illustrated in Figure 2.

The main aim of this review is to illustrate how recent advances in laser technology have changed the face of TCSPC and to discuss the types of laser light sources that are in use. The easiest way of approaching this topic is to define the criteria for an ideal light source for this experiment, and then to discuss the ways in which new technologies are meeting these criteria.

High Repetition Rate

A typical decay data set may contain something of the order of 0.1–5 million 'counts': it is desirable to

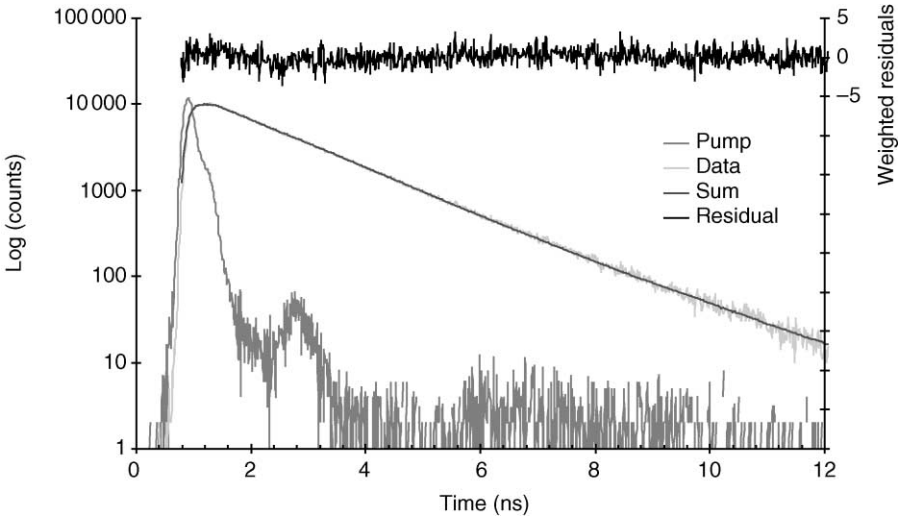

Figure 2 The fluorescence decay of Rhodamine B in water. The sample was excited using a 397 nm pulsed laser diode (1 MHz, $<$200 ps FWHM), and the emission was observed at 575 nm. Deconvolution of the IRF (dark gray trace) and observed decay (light gray trace) with a single exponential function gave a lifetime of 1.50 ns, with a $\chi^2 R = 1.07$, Durbin–Watson parameter = 1.78. The fitted curve is shown overlaid in gray, and the weighted residuals are shown offset in black.

acquire such a number of events in order that we can reliably employ statistical parameters to judge the quality of the fitted decay function(s). As stated above, the rate of photon acquisition should be of the order of 1% of the excitation rate in order to obtain reliable, good-quality data. It is clear then that a high repetition rate source is desirable in order to reduce the overall data acquisition time. However, it is important that the repetition rate of the source is not too high, otherwise the data show 'overlap' effects, caused by the fluorescence intensity from one excitation pulse not completely decaying before the next laser pulse arrives at the sample. Under these conditions the observed fluorescence decay is perturbed and extraction of complex kinetic behavior is more difficult. As a general rule of thumb, it is recommended that the inter-pulse separation is greater than five times the lifetime of the longest component of the fluorescence decay. Fluorescence lifetimes can be as long as 100 ns, indicating a maximum repetition rate of 2 MHz, although when investigating fluorophores with a shorter lifetime correspondingly higher frequencies can be selected. Clearly the ability to vary the repetition rate according to the type of sample under investigation is an advantage.

Short Pulse Duration

Typically the minimum lifetime that can be determined by a TCSPC spectrometer is limited by the instrument response function: as a general rule it is possible to extract fluorescence lifetimes of about one tenth of the full width at half maximum (FWHM) of the IRF by reconvolution methods. As discussed above, the IRF is the product of a number of factors, including the optical pulse duration, differences in the optical path traversed by the fluorescence, the response time of the detector, and the temporal response of the associated timing electronics. Ideally the excitation source should be as short as possible, and with modern laser-based TCSPC systems, it is usually the case that the time-response of the detector is the limiting factor. The introduction of high-speed microchannel plate (MCP) photomultipliers have lead to very short IRFs, which can be <50 ps FWHM. When using these detectors is it essential to keep the optical transit-time spread as low as possible: that is, the path taken by light through a monochromator should be independent of wavelength and trajectory taken through the optics. Many research groups advocate the use of a subtractive dispersive double monochromator for this purpose.

Tunability

Early TCSPC experiments were carried out using hydrogen- or nitrogen-filled flashlamps which produced broadband ns-duration pulses with low repetition rates (<100 kHz). Variable wavelength excitation is possible using these sources, but their low intensity and low repetition rates mean that data acquisition periods can be very long. The early 1980s saw the introduction of cavity-dumped ion lasers and synchronously pumped mode-locked cavity-dumped dye lasers, which provided significantly higher repetition rates, typically up to 4 MHz, and greater intensities. However, the TCSPC experiments that could be carried out using these laser-based sources were somewhat limited by the wavelengths that could be generated by the argon ion and synchronously pumped dye lasers, and their second harmonics. The dye lasers were restricted to the use of Rhodamine 6G as the gain medium, which has a limited tuning range ($\sim$580–620 nm). It is often desirable to vary the excitation wavelength as part of a photophysical study, either as a systematic study of the effects of excitation energy upon the excited state behavior, or in order to optimize excitation of a particular chromophore in a system. To some extent in the past, the wavelengths available from the laser systems dictated the science that they could be used to address. The mid- to late-1980s saw the introduction of mode-locked continuous wave (CW) Nd:YAG lasers as pump lasers and increased number of dyes that could be synchronously pumped, providing a broader range of excitation wavelengths as well as increased stability. One drawback of these complex and often fickle laser systems was the level of expertise and attention they required to keep their performance at its peak.

Since the 1990s, the introduction of two important new types of laser have had a significant impact on the use of TCSPC as an investigative method. The first is based upon the mode-locked titanium sapphire laser which offers tuneable radiation from the deep UV to the NIR, whilst the second series of laser are based upon (relatively) low-cost, turn-key solid state diode lasers. The developments and merits of these new laser sources, which now dominate the market for TCSPC sources, are discussed below.

Ti-Sapphire

The discovery of the titanium doped sapphire laser has led to a revolution in ultrafast laser sources. Coupled with efficient diode-pumped solid state

Nd:YAG pump lasers, this medium currently dominates the entire ultrafast laser market, from high repetition, low pulse energy systems through to systems generating very high pulse energies at kHz repetition rates.

Ti-sapphire is, in many respects, an ideal laser gain medium: it has a high energy storage capacity, it has a very broad-gain bandwidth, and it has good thermal properties. Following the first demonstration of laser action in a Ti-sapphire crystal, the CW Ti-sapphire laser was quickly commercialized. It proved to be a remarkable new laser medium, providing greater efficiency, with outputs of the order of 1 W. The laser also provided an unprecedented broad tuning range, spanning from just below 700 nm to 1000 nm. The most important breakthrough for time-resolved users came in 1991, when self-mode-locking in the medium was demonstrated. This self-mode-locking, sometimes referred to as Kerr-lens mode-locking, arises from the nonlinear refractive index of the material and is implemented by simply placing an aperture within the cavity at an appropriate point. The broad-gain bandwidth of the medium results in very short pulses: pulse durations of the order of tens of femtoseconds can be routinely achieved with commercial laser systems.

The mode-locked Ti-sapphire laser was quickly seized upon and commercialized. The first generation of systems used multiwatt CW argon ion lasers to pump them, making the systems unwieldy and expensive to run, but in recent years these have been replaced by diode-pumped Nd:YAG lasers, providing an all solid-state, ultrafast laser source. Equally significantly, the current generation of lasers are very efficient and do not require significant electrical power or cooling capacity. There are several commercial suppliers of pulsed Ti-sapphire lasers, including Coherent and Spectra Physics.

A typical mode-locked Ti-sapphire laser provides an 80 MHz train of pulses with a FWHM of ~100 fs, with an average power of up to 1.5 W and are tuneable from 700 nm to almost 1000 nm. The relatively high peak powers associated with these pulses means that second- or even third-harmonic generation is relatively efficient, providing radiation in the ranges 350–480 nm and 240–320 nm. The output powers of the second and third harmonics far exceeds that required for TCSPC experiments, making them an attractive source for the study of fluorescence lifetime measurements. The simple mode-locked Ti-sapphire laser has some drawbacks: the very short pulse duration provides a broad-bandwidth excitation, the repetition rate is often too high with an inter-pulse separation of ~12.5 ns, and the laser does not provide continuous tuning from the deep-UV though to the visible. Incrementally, all of these points have been addressed by the laser manufacturers.

As well as operating as a source of femtosecond pulses, with their associated bandwidths of many tens of nm, some modern commercial Ti-sapphire lasers can, by adjustment of the optical path and components, be operated in a mode that provides picosecond pulses whilst retaining their broad tuning curve. Under these conditions, the bandwidth of the output is greatly reduced, making the laser resemble a synchronously pumped mode-locked dye laser.

As stated above, a very high repetition rate can be undesirable if the system under study has a long fluorescence lifetime due to the fluorescence decay from an earlier pulse not decaying completely before the next excitation pulse. Variation of the repetition of output frequency can be addressed by two means. The first is to use a pulse-picker. This is an opto-accoustic device which is placed outside the laser cavity. An electrical signal is applied to a device, synchronized to the frequency of the mode-locked laser to provide pulses at frequencies from ~4 MHz down to single-shot. The operation of a pulse picker is somewhat inefficient, with less than half of the original pulse energy being obtained in the output, although output power is not usually an issue when using these sources. More importantly, when using pulse-pickers, it is essential to ensure that there is no pre- or post-pulse which can lead to artifacts in the observed fluorescence decays. The second means of reducing the pulse duration is cavity dumping. This is achieved by extending the laser cavity and placing an opto-acoustic device, known as a Bragg cell, at a beam-waist within the cavity. When a signal is applied to the intracavity Bragg cell, synchronized with the passage of a mode-locked pulse though the device, a pulse of light is extracted from the cavity. The great advantage of cavity-dumping is that it builds up energy within the optical cavity and when pulses are extracted these are of a higher pulse energy than the mode-locked laser alone. This in turn leads to more efficient harmonic generation. This addition of the cavity dumper system extends the laser cavity and hence reduces the overall frequency of the mode-locked laser to ~50 MHz, and can provide pulses at 9 MHz down to single shot.

The extension of the tuning range of the Ti-sapphire laser has been facilitated by the introduction of the optical parametric oscillator (OPO). In the OPO, a short wavelength pump beam passes through a nonlinear optical crystal and generates two tuneable

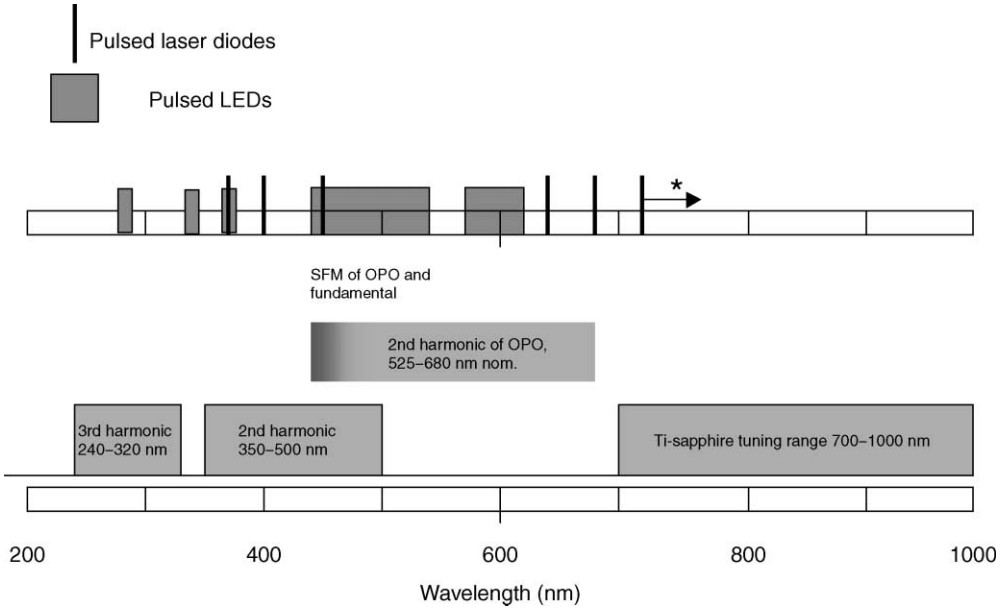

Figure 3 An illustration of the spectral coverage provided by currently available pulsed semiconductor lasers and LEDs, and a modern Ti-sapphire laser and OPO. Note that the OPO's output is frequency doubled, and the wavelengths in the range 525– ~ 440 nm may be obtained by sum frequency mixing of the Ti-sapphire's fundamental output with the output of the OPO. * denotes that there are many long wavelength pulsed laser diodes falling in the range $\lambda > 720$ nm.

beams of longer wavelengths. Synchronous pumping of the OPOs with either a fs or ps Ti-sapphire laser ensures reasonably high efficiencies. The outputs from the OPO may be frequency doubled, with the option of intracavity doubling enhancing the efficiency still further. Using an 800 nm pump wavelength, an OPO provides typical signal and idler tuning ranges of 1050– >1350 nm and 2.1–3.0 μm, respectively. The signal can be doubled to give 525–680 nm, effectively filling the visible spectrum. The average powers obtainable from Ti-sapphire pumped OPOs makes them eminently suitable for TCSPC experiments. A summary of the spectral coverage of the Ti-sapphire laser and OPO, and low-cost solid-state sources are illustrated in Figure 3.

An additional advantage of the Ti-sapphire laser is the possibility of multiphoton excitation. The combination of high average power and very short pulse duration of a mode-locked Ti-sapphire laser means that the peak-powers of the pulses can be very high. Focusing the near-IR output of the laser gives rise to exceedingly high photon densities within a sample which can lead to the simultaneous absorption of two or more photons. This is of particular significance when recording fluorescence lifetimes in conjunction with a microscope, particularly when the microscope is operated in a confocal configuration. Such systems are now being used for a derivative of TCSPC, known as fluorescence lifetime imaging (FLM).

In summary, the Ti-sapphire laser is a very versatile and flexible source that is well suited to the TCSPC experiment. Off-the-shelf systems provide broad spectral coverage and variable repetition rates. Undoubtedly this medium will be the mainstay of TCSPC for some time to come.

Diode Lasers

Low-power diode lasers, with outputs in the range 630–1000 nm, have been commercially available for some time. These devices, which are normally operated as CW sources, can be operated in a pulsed mode, providing a high frequency train of sub-ns pulses. However, the relatively long output wavelengths produced by this first generation of diode lasers severely restricted the range of chromophores that could be excited and this proved to be a limiting factor for their use as TCSPC sources. Attempts to generate shorter wavelengths from these NIR laser diodes by second harmonic generation (SHG), were never realized: the SHG process is extremely inefficient due to the very low peak output power of these lasers. Shorter wavelengths could be obtained by pulsing conventional light-emitting diodes (LEDs), which were commercially available with emission wavelengths covering the visible spectrum down to ~450 nm. However, these had the disadvantage of exhibiting longer pulse durations than those achievable from laser diodes and have

much broader emission bandwidths than a laser source.

The introduction of violet and blue diode lasers and UV-LEDs by the Nichia Corporation (Japan) in the late 1990s resulted in a renewed interest in sources utilizing these small, solid-state devices. At least three manufacturers produce ranges of commercial TCSPC light sources based upon pulsed LEDs and laser diodes and can now boast a number of pulsed laser sources in their ranges including 375, 400, 450, 473, 635, 670, and 830 nm. Currently commercial pulsed laser diodes and LEDs are manufactured by Jobin-Yvon IBH (UK), Picoquant (Germany), and Hamamatso (Japan). These small, relatively low-cost devices offer pulse durations of <100 ps and excitation repetition rates of up to tens of MHz making them ideally suited to 'routine' lifetime measurements. Although these diode laser sources are not tunable and do not span the full spectrum, they are complemented by pulsed LEDs which fill the gap in the visible spectrum. Pulsed LEDs generally have a longer pulse duration and broader, lower intensity spectral output, but are useful for some applications. At the time of writing there are no diode laser sources providing wavelengths of <350 nm, although Jobin-Yvon IBH (UK) have recently announced pulsed LEDs operating at 280 nm and 340 nm. As LEDs, and possibly diode lasers, emitting at these shorter wavelengths become more widely available, the prospects of low running costs and ease of use makes these semiconductor devices an extremely attractive option for many TCSPC experiments. Commercial TCSPC spectrometers based around these systems offer a comparatively low-cost, turnkey approach to fluorescence lifetime based experiments, opening up what was a highly specialized field to a much broader range of users.

Transient Holographic Grating Techniques in Chemical Dynamics

E Vauthey, University of Geneva, Geneva, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Over the past two decades, holographic techniques have proved to be valuable tools for investigating the dynamics of chemical processes. The aim of this chapter is to give an overview of the main applications of these techniques for chemical dynamics. The basic principle underlying the formation and the detection of elementary transient holograms, also called transient gratings, is first presented. This is followed by a brief description of a typical experimental setup. The main applications of these techniques to solve chemical problems are then discussed.

Basic Principle

The basic principle of the transient holographic technique is illustrated in Figure 1. The sample material is excited by two laser pulses at the same wavelength and crossed at an angle $2\theta_{pu}$. If the two pump pulses have the same intensity, I_{pu}, the intensity distribution at the interference region, assuming plane waves, is

$$I(x) = 2I_{pu}\left[1 + \cos\left(\frac{2\pi x}{\Lambda}\right)\right] \qquad [1]$$

where $\Lambda = \lambda_{pu}/(2\sin\theta_{pu})$ is the fringe spacing, λ_{pu} is the pump wavelength, and I_{pu} is the intensity of one pump pulse.

As discussed below, there can be many types of light–matter interactions that lead to a change in the optical properties of the material. For a dielectric material, they result in a spatial modulation of the optical susceptibility and thus of the complex refractive index, $\tilde{n}$. The latter distribution can be described as a Fourier cosine series:

$$\tilde{n}(x) = \tilde{n}_0 + \sum_{m=1}^{\infty} \tilde{n}_m \cos\left(\frac{m2\pi x}{\Lambda}\right) \qquad [2]$$

where $\tilde{n}_0$ is the average value of $\tilde{n}$. In the absence of saturation effects, the spatial modulation of $\tilde{n}$ is harmonic and the Fourier coefficients with $m > 1$ vanish. In this case, the peak to null variation of the complex refractive index, $\Delta\tilde{n}$, is equal to the Fourier coefficient $\tilde{n}_1$. The complex refractive index can be split into its real and imaginary components:

$$\tilde{n} = n + iK \qquad [3]$$

where n is the refractive index and K is the attenuation constant.

The hologram created by the interaction of the crossed pump pulses consists in periodic, one-dimensional spatial modulations of n and K. Such distributions are nothing but phase and amplitude gratings, respectively. A third laser beam at the probe wavelength, λ_{pr}, striking these gratings at Bragg angle, $\theta_B = \arcsin(\lambda_{pr}/2\Lambda)$, will thus be partially diffracted (Figure 1b). The diffraction efficiency, η, depends on the modulation amplitude of the optical properties. In the limit of small diffraction efficiency ($\eta < 0.01$), this relationship is given by

$$\eta = \frac{I_{dif}}{I_{pr}} \cong \left[\left(\frac{\ln 10 \Delta A}{4\cos\theta_B}\right)^2 + \left(\frac{\pi d \Delta n}{\lambda_{pr} \cos\theta_B}\right)^2\right] \times \exp\left(-\frac{\ln 10 A}{\cos\theta_B}\right) \qquad [4]$$

where I_{dif} and I_{pr} are the diffracted and the probe intensity respectively, d is the sample thickness, and $A = 4\pi dK/(\lambda \ln 10)$ is the average absorbance.

The first and the second terms in the square bracket describe the contribution of the amplitude and phase gratings respectively, and the exponential term accounts for the reabsorption of the diffracted beam by the sample.

The main processes responsible for the variation of the optical properties of an isotropic dielectric material are summarized in Figure 2.

The modulation of the absorbance, ΔA, is essentially due to the photoinduced concentration change,

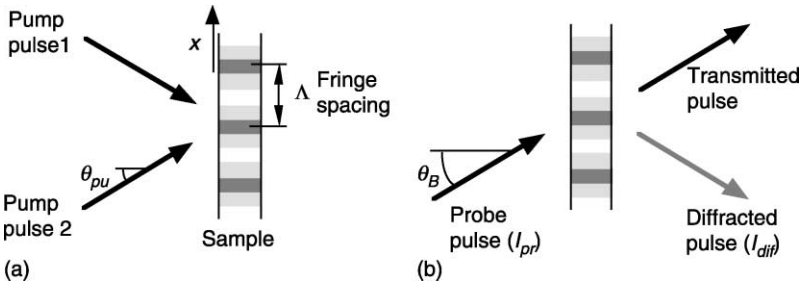

Figure 1 Principle of the transient grating technique: (a) grating formation (pumping), (b) grating detection (probing).

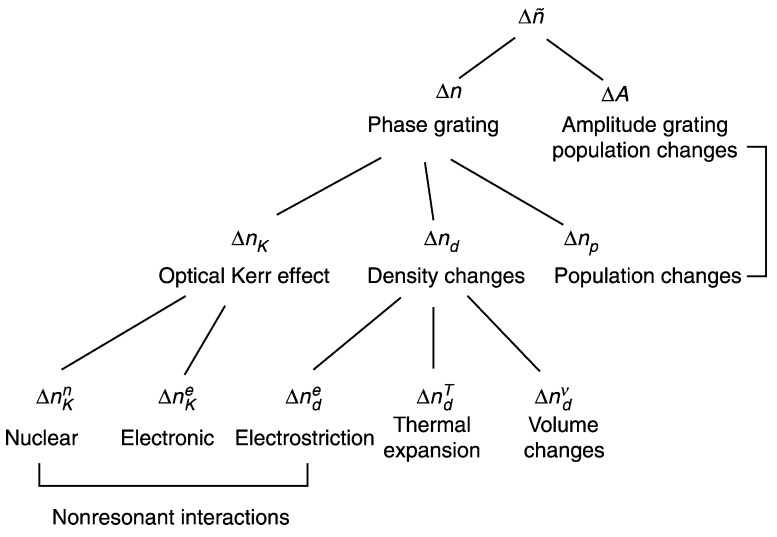

Figure 2 Classification of the possible contributions to a transient grating signal.

ΔC, of the different chemical species i (excited state, photoproduct, …):

$$\Delta A(\lambda_{pr}) = \sum_i \varepsilon_i(\lambda_{pr})\Delta C_i \qquad [5]$$

where ε_i is the absorption coefficient of the species i.

The variation of the refractive index, Δn, has several origins and can be expressed as

$$\Delta n = \Delta n_K + \Delta n_p + \Delta n_d \qquad [6]$$

Δn_K is the variation of refractive index due to the optical Kerr effect (OKE). This nonresonant interaction results in an electronic polarization (electronic OKE) and/or in a nuclear reorientation of the molecules (nuclear OKE) along the direction of the electric field associated with the pump pulses. As a consequence, a transient birefringence is created in the material. This effect is usually discussed within the framework of nonlinear optics in terms of intensity dependent refractive index or third order nonlinear susceptibility. Electronic OKE occurs in any dielectric material under sufficiently high light intensity. On the other hand, nuclear OKE is mostly observed in liquids and gases and depends strongly on the molecular shape.

Δn_p is the change of refractive index related to population changes. Its magnitude and wavelength dependence can be obtained by Kramers–Kronig transformation of $\Delta A(\lambda)$ or $\Delta K(\lambda)$:

$$\Delta n_p(\lambda) = \frac{1}{2\pi^2}\int_0^\infty \frac{\Delta K(\lambda')}{1-(\lambda'/\lambda)^2}\,\mathrm{d}\lambda' \qquad [7]$$

Δn_d is the change of refractive index associated with density changes. Density phase gratings can have essentially three origins:

$$\Delta n_d = \Delta n_d^t + \Delta n_d^v + \Delta n_d^e \qquad [8]$$

Δn_d^t is related to the temperature-induced change of density. If a fraction of the excitation energy is converted into heat, through a nonradiative transition or an exothermic process, the temperature becomes spatially modulated. This results in a variation of density, hence to a modulation of refractive index with amplitude Δn_d^t. Most of the temperature dependence of n originates from the density. The temperature-induced variation of n at constant density is much smaller than Δn_d^t.

Δn_d^v is related to the variation of volume upon population changes. This volume comprises not only the reactant and product molecules but also their environment. For example, in the case of a photodissociation, the volume of the product is larger than that of the reactant and a positive volume change can be expected. This will lead to a decrease of the density and to a negative Δn_d^v.

Finally, Δn_d^e is related to electrostriction in the sample by the electric field of the pump pulses. Like OKE, this is a nonresonant process that also contributes to the intensity dependent refractive index. Electrostriction leads to material compression in the regions of high electric field strength. The periodic compression is accompanied by the generation of two counterpropagating acoustic waves with wave vectors, $\vec{k}_{ac} = \pm(2\pi/\Lambda)\vec{i}$, where $\vec{i}$ is the unit vector along the modulation axis. The interference of these acoustic waves leads to a temporal modulation of Δn_d^e at the acoustic frequency υ_{ac}, with $2\pi\upsilon_{ac} = k_{ac}\upsilon_s$, υ_s being the speed of sound. As Δn_d^e oscillates between negative and positive values, the diffracted intensity, which is proportional to $(\Delta n_d^e)^2$, shows at temporal oscillation at twice the acoustic frequency. In most cases, Δn_d^e is weak and can be neglected if the pump pulses are within an absorption band of the sample.

The modulation amplitudes of absorbance and refractive index are not constant in time and their temporal behavior depends on various dynamic processes in the sample. The whole point of the transient grating techniques is precisely the measurement of the diffracted intensity as a function of time after excitation to deduce dynamic information on the system.

In the following, we will show that the various processes shown in Figure 2, that give rise to a diffracted signal, can in principle be separated by choosing appropriate experimental parameters, such as the timescale, the probe wavelength, the polarization of the four beams, or the crossing angle.

Experimental Setup

A typical experimental arrangement for pump–probe transient grating measurements is shown in Figure 3. The laser output pulses are split in three parts. Two parts of equal intensity are used as

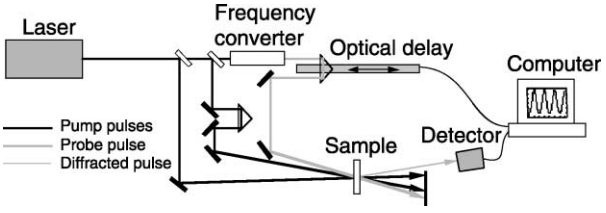

Figure 3 Schematic of a transient grating setup with pump–probe detection.

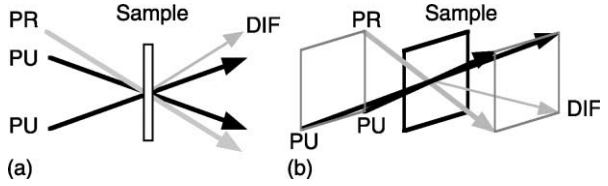

Figure 4 Beam geometry for transient grating: (a) in plane; (b) boxcars.

pump pulses and are crossed in the sample. In order to ensure time coincidence, one pump pulse travels along an adjustable optical delay line. The third part, which is used for probing, can be frequency converted using a dye laser, a nonlinear crystal, a Raman shifter, or white light continuum generation. The probe pulse is sent along a motorized optical delay line before striking the sample at the Bragg angle. There are several possible beam configurations for transient grating and the two most used are illustrated in Figure 4. When the probe and pump pulses are at different wavelengths, they can be in the same plane of incidence as shown in Figure 4a. However, if the pump and probe wavelengths are the same, the folded boxcars geometry shown in Figure 4b has to be used. The transient grating technique is background free and the diffracted signal propagates in a well-defined direction. In a pump–probe experiment, the diffracted signal intensity is measured as a function of the time delay between the pump and probe pulses. Such a setup can be used to probe dynamic processes occurring in timescales going from a few fs to a few ns, the time resolution depending essentially on the duration of the pump and probe pulses. For slower processes, the grating dynamics can be probed in real time with a *cw* laser beam and a fast photodetector.

Applications

The Transient Density Phase Grating Technique

If the grating is probed at a wavelength far from any absorption band, the variation of absorbance, $\Delta A(\lambda_{pr})$, is zero and the corresponding change of refractive index, $\Delta n_p(\lambda_{pr})$, is negligibly small. In this case, eqn [4] simplifies to

$$\eta \cong \left(\frac{\pi d}{\lambda_{pr} \cos \theta_B}\right)^2 \times \Delta n_d^2 \qquad [9]$$

In principle, the diffracted signal may also contain contributions from the optical Kerr effect, Δn_K, but we will assume here that this non-resonant and ultrafast response is negligibly small. The density change can originate from both heat releasing processes and volume differences between the products and reactants, the former contribution usually being much larger than the latter. Even if the heat releasing process is instantaneous, the risetime of the density grating is limited by thermal expansion. This expansion is accompanied by the generation of two counterpropagating acoustic waves with wave vectors, $\vec{k}_{ac} = \pm(2\pi/\Lambda)\vec{i}$. One can distinguish two density gratings: 1) a diffusive density grating, which reproduces the spatial distribution of temperature and which decays by thermal diffusion; and 2) an acoustic density grating originating from the standing acoustic wave and whose amplitude oscillates at the acoustic frequency υ_{ac}.

The amplitudes of these two gratings are equal but of opposite sign. Consequently, the time dependence of the modulation amplitude of the density phase grating is given by

$$\Delta n_d(t) = \left(\frac{\beta Q}{\rho C_v} + \Delta V\right)\rho\left(\frac{\partial n}{\partial \rho}\right)R(t) \qquad [10a]$$

with

$$R(t) = 1 - \cos(2\pi\upsilon_{ac}t) \times \exp(-\alpha_{ac}\upsilon_s t) \qquad [10b]$$

where ρ, β, C_v, and α_{ac} are the density, the volume expansion coefficient, the heat capacity, and the acoustic attenuation constant of the medium, respectively, Q is the amount of heat deposited during the photoinduced process, and ΔV is the corresponding volume change. As the standing acoustic wave oscillates, its corresponding density grating interferes with the diffusive density grating. Therefore, the total modulation amplitude of the density and thus Δn_d exhibits the oscillation at υ_{ac}. Figure 5 shows the time profile of the diffracted

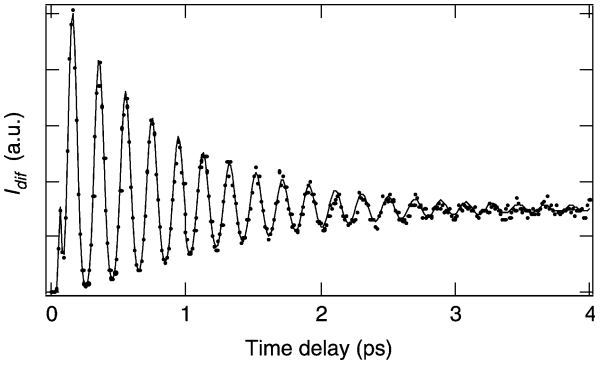

Figure 5 Time profile of the diffracted intensity measured with a solution of malachite green after excitation with two pulses with close to counterpropagating geometry.

intensity measured with a solution of malachite green. After excitation to the S_1 state, this dye relaxes nonradiatively to the ground state in a few ps. For this measurement, the sample solution was excited with two 30 ps laser pulses at 532 nm crossed with an angle close to 180°. The continuous line is the best fit of eqns [9] and [10]. The damping of the oscillation is due to acoustic attenuation. After complete damping, the remaining diffracted signal is due to the diffusive density grating only.

$R(t)$ can be considered as the response function of the sample to a prompt heat release and/or volume change. If these processes are not instantaneous compared to an acoustic period ($\tau_{ac} = \upsilon_{ac}^{-1}$), the acoustic waves are not created impulsively and the time dependence of Δn_d is

$$\Delta n_d(t) = \left(\frac{\beta Q}{\rho C_v} + \Delta V\right)\rho\left(\frac{\partial n}{\partial \rho}\right)F(t) \qquad [11a]$$

with

$$F(t) = \int_{-\infty}^{t} R(t - t') \cdot f(t')\mathrm{d}t' \qquad [11b]$$

where $f(t)$ is a normalized function describing the time evolution of the temperature and/or volume change. In many cases, $f(t) = \exp(-k_r t)$, k_r being the rate constant of the process responsible for the change. Figure 6 shows the time profile of the diffracted intensity calculated with eqns [9] and [11] for different values of k_r.

If several processes take place, the total change of refractive index is the sum of the changes due to the individual processes. In this case, Δn_d should be expressed as

$$\Delta n_d(t) = \sum_i \left(\frac{\beta Q_i}{\rho C_v} + \Delta V_i\right)\rho\left(\frac{\partial n}{\partial \rho}\right)F_i(t) \qquad [12]$$

The separation of the thermal and volume contributions to the diffracted signal is problematic. Several approaches have been proposed, the most used being the measurement in a series of solvents with different expansion coefficient β. This method requires that the other solvent properties like refractive index, dielectric constant, or viscosity, are constant or that the energetics of the system investigated does not depend on them. This separation is easier when working with water because its β value vanishes at 4 °C. At this temperature, the density variations are due to the volume changes only.

The above equations describe the growth of the density phase grating. However, this grating is not permanent and decays through diffusive processes. The phase grating originating from thermal expansion decays via thermal diffusion with a rate constant k_{th} given by

$$k_{th} = D_{th}\left(\frac{2\pi}{\Lambda}\right)^2 \qquad [13]$$

where D_{th} is the thermal diffusivity. Table 1 shows k_{th} values in acetonitrile for different crossing angles.

The decay of the phase grating originating from volume changes depends on the dynamics of the population responsible for ΔV (vide infra).

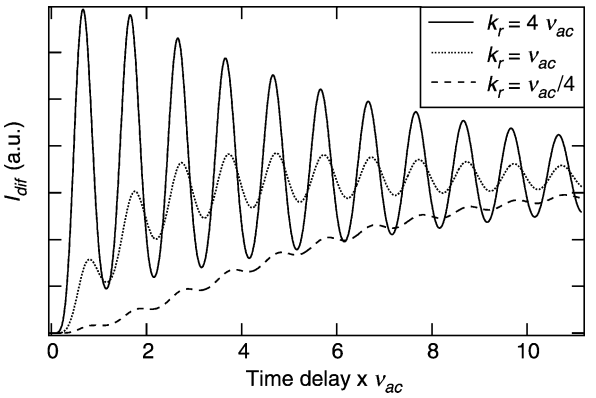

Figure 6 Time profiles of the diffracted intensity calculated using eqns [9] and [11] with various k_r values.

Time resolved optical calorimetry

A major application of the density phase grating in chemistry is the investigation of the energetics of photo-induced processes. The great advantage of this technique over other optical calorimetric methods, like the thermal lens or the photoacoustic spectroscopy, is its superior time resolution. The time constant of the fastest heat releasing process that can be time resolved with this technique is of the order of the acoustic period. The shortest acoustic period is achieved when forming the grating with two counterpropagating pump pulses ($2\theta_{pu} = 180°$). In this case the fringe spacing is

Table 1 Fringe spacing, Λ, acoustic frequency, ν_{ac}, thermal diffusion rate constant, k_{tr}, for various crossing angles of the pump pulses, 2 θ_{pu}, at 355 nm and in acetonitrile

$2\,\theta_{pu}$	Λ (μm)	$\upsilon_{ac}(s^{-1})$	k_{th} (s^{-1})
0.5°	40.7	3.2×10^7	4.7×10^3
50°	0.42	3.1×10^9	4.5×10^7
180°	0.13	9.7×10^9	4.7×10^8

$\Lambda = \lambda_{pu}/2n$ and, with UV pump pulses, an acoustic period of the order of 100 ps can be obtained in a typical organic solvent.

For example, Figure 7a shows the energy diagram for a photoinduced electron transfer (ET) reaction between benzophenone (BP) and an electron donor (D) in a polar solvent. Upon excitation at 355 nm, $^1BP^*$ undergoes intersystem-crossing (ISC) to $^3BP^*$ with a time constant of about 10 ps.

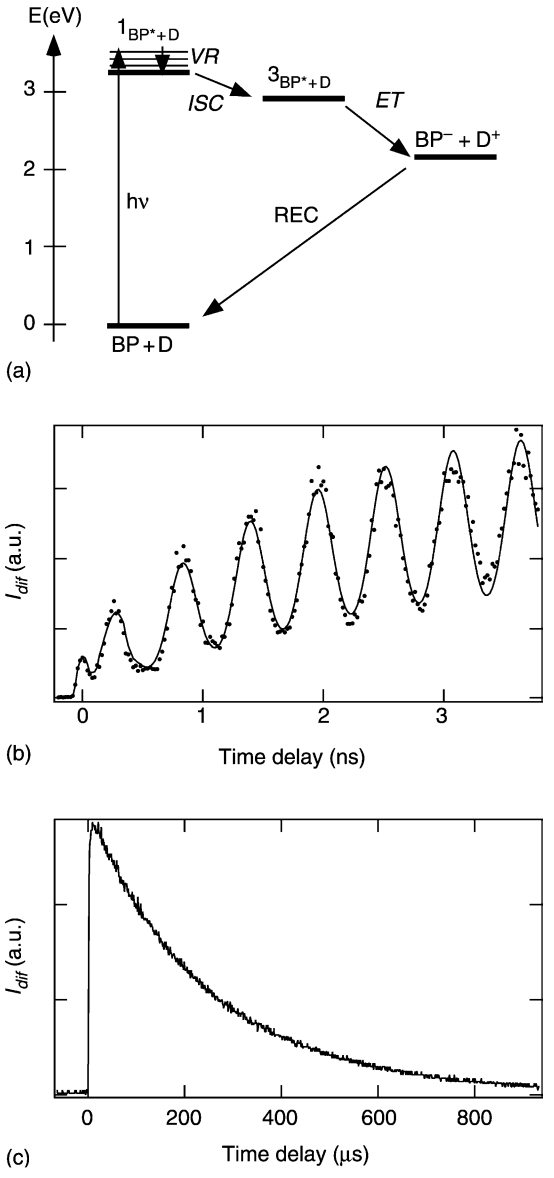

Figure 7 (a) Energy diagram of the states involved in the photoinduced electron transfer reaction between benzophenone (BP) and an electron donor (D) (VR: vibrational relaxation, ISC: intersystem crossing; ET: electron transfer; REC: charge recombination). (b) Time profile of the diffracted intensity measured at 590 nm after excitation at 355 nm of a solution of BP and 0.05 M D. (c) Same as (b) but measured at 1064 nm with a *cw* laser.

After diffusional encounter with the electron donor, ET takes place and a pair of ions is generated. With this system, the whole energy of the 355 nm photon ($E = 3.49$ eV) is converted into heat. The different heat releasing processes can be differentiated according to their timescale. The vibrational relaxation to $^1BP^*$ and the ensuing ISC to $^3BP^*$ induces an ultrafast release of 0.49 eV as heat. With donor concentrations of the order of 0.1 M, the heat deposition process due to the electron transfer is typically in the ns range. Finally, the recombination of the ions produces a heat release in the microsecond timescale. Figure 7b shows the time profile of the diffracted intensity measured after excitation at 355 nm of BP with 0.05 M D in acetonitrile. The 30 ps pump pulses were crossed at 27° ($\tau_{ac} = 565$ ps) and the 10 ps probe pulses were at 590 nm. The oscillatory behavior is due to the ultrafast heat released upon formation of $^3BP^*$, while the slow dc rise is caused by the heat dissipated upon ET. As the amount of energy released in the ultrafast process is known, the energy released upon ET can be determined by comparing the amplitudes of the fast and slow components of the time profile. The energetics as well as the dynamics of the photoinduced ET process can thus be determined. Figure 7c shows the decay of the diffracted intensity due to the washing out of the grating by thermal diffusion. As both the acoustic frequency and the thermal diffusion depends on the grating wavevector, the experimental time window in which a heat releasing process can be measured, depends mainly on the crossing angle of the pump pulses as shown in Table 1.

Determination of material properties

Another important application of the transient density phase grating technique is the investigation of material properties. Acoustics waves of various frequencies, depending on the pump wavelength and crossing angle, can be generated without physical contact with the sample. Therefore, acoustic properties, such as the speed of sound and the acoustic attenuation of the material, can be easily obtained from the frequency and the damping of the oscillation of the transient grating signal.

Similarly, the optoelastic constant of a material, $\rho\partial n/\partial\rho$, can be determined from the amplitude of the signal (see eqn [11]). This is done by comparing the signal amplitude of the material under investigation with that obtained with a known standard.

Finally, the thermal diffusivity, D_{th}, can be easily obtained from the decay of the thermal density

phase grating, such as that shown in Figure 7c. This technique can be used with a large variety of bulk materials as well as films, surfaces and interfaces.

Investigation of Population Dynamics

The dynamic properties of a photogenerated species can be investigated by using a probe wavelength within its absorption or dispersion spectrum. As shown by eqn [4], either ΔA or Δn_p has to be different from zero. For this application, Δn_K and Δn_d should ideally be equal to zero. Unless working with ultrashort pulses (< 1 ps) and a weakly absorbing sample, Δn_K can be neglected. Practically, it is almost impossible to find a sample system for which some fraction of the energy absorbed as light is not released as heat. However, by using a sufficiently small crossing angle of the pump pulses, the formation of the density phase grating, which depends on the acoustic period, can take as much as 30 to 40 ns. In this case, Δn_d is negligible during the first few ns after excitation and the diffracted intensity is due to the population grating only:

$$I_{dif}(t) \propto \sum_i \Delta C_i^2(t) \qquad [14]$$

where ΔC_i is the modulation amplitude of the concentration of every species i whose absorption and/or dispersion spectrum overlaps with the probe wavelength.

The temporal variation of ΔC_i can be due either to the dynamics of the species i in the illuminated grating fringes or to processes taking place between the fringes, such as translational diffusion, excitation transport, and charge diffusion. In liquids, the decay of the population grating by translational diffusion is slow and occurs in the microsecond to millisecond timescale, depending on the fringe spacing. As thermal diffusion is typically hundred times faster, eqn [14] is again valid in this long timescale. Therefore if the population dynamics is very slow, the translational diffusion coefficient of a chemical species can be obtained by measuring the decay of the diffracted intensity as a function of the fringe spacing. This procedure has also been used to determine the temperature of flames. In this case however, the decay of the population grating by translational diffusion occurs typically in the sub-ns timescale.

In the condensed phase, these interfringe processes are of minor importance when measuring the diffracted intensity in the short timescale, i.e., before the formation of the density phase grating. In this case, the transient grating technique is similar to transient absorption, and it thus allows the measurement of population dynamics. However, because holographic detection is background free, it is at least a hundred times more sensitive than transient absorption.

The population gratings are usually probed with monochromatic laser pulses. This procedure is well suited for simple photoinduced processes, such as the decay of an excited state population to the ground state. For example, Figure 8 shows the decay of the diffracted intensity at 532 nm measured after excitation of a cyanine dye at the same wavelength. These dynamics correspond to the ground state recovery of the dye by non-radiative deactivation of the first singlet excited state. Because the diffracted intensity is proportional to the square of the concentration changes (see eqn [14]), its decay time is twice as short as the ground state recovery time. If the reaction is more complex, or if several intermediates are involved, the population grating has to be probed at several wavelengths. Instead of repeating many single wavelength experiments, it is preferable to perform multiplex transient grating. In this case, the grating is probed by white light pulses generated by focusing high intensity fs or ps laser pulses in a dispersive medium. If the crossing angle of the pump pulses is small enough ($< 1°$), the Bragg angle for probing is almost independent on the wavelength. A transient grating spectrum is obtained by dispersing the diffracted signal in a spectrograph. This spectrum consists in the sum of the square of the transient absorption and transient dispersion spectra. Practically, it is very similar to a transient absorption spectrum, but with a much superior signal to noise ratio. Figure 9 shows the transient grating spectra measured at various time delays after excitation of a solution of chloranil (CA) and

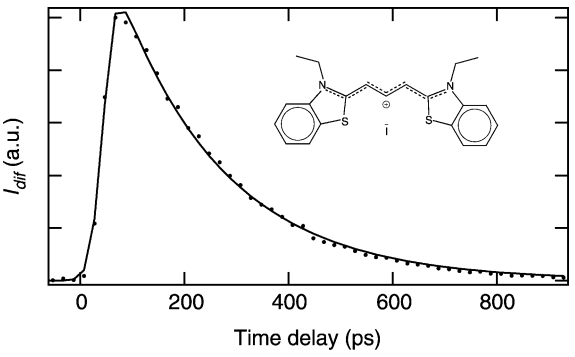

Figure 8 Time profile of the diffracted intensity at 532 nm measured after excitation at the same wavelength of a cyanine dye (inset) in solution and best fit assuming exponential ground state recovery.

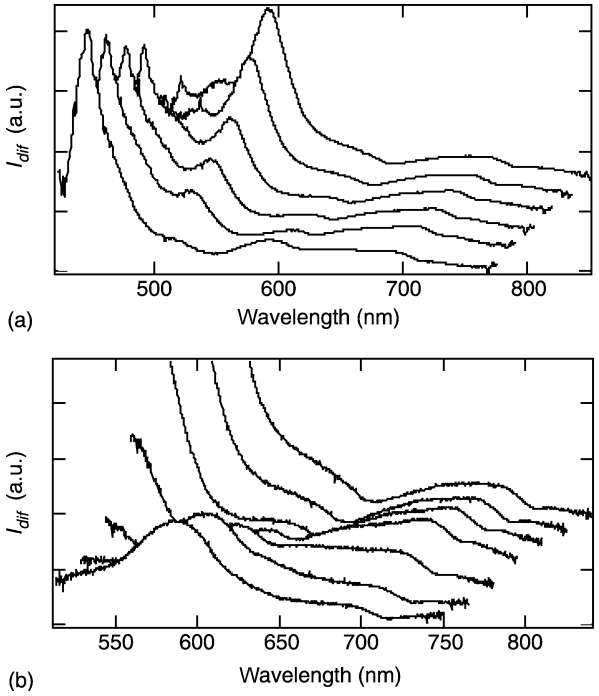

Figure 9 Transient grating spectra obtained at various time delays after excitation at 355 nm of a solution of chloranil and 0.25 M methylnaphthalene (a): from top to bottom: 60, 100, 180, 260, 330 and 600 ps; (b): from top to bottom: 100, 400, 750, 1100, 1500 ps).

methylnaphthalene (MNA) in acetonitrile. The reaction that takes place is

$$^3CA^* \cdot MNA \xrightarrow{\text{diffusion}} (^3CA^* \cdot MNA) \xrightarrow{ET}$$
$$^3(CA^- \cdot MNA^+) \xrightarrow{MNA} {}^3(CA^- \cdot MNA^+)$$

After its formation upon ultrafast ISC, $^3CA^*$, which absorbs around 510 nm, decays upon ET with MNA to generate CA^-(450 nm) and MNA^+ (690 nm). The ion pair reacts further with a second MNA molecule to form the dimer cation (580 nm).

The time profile of the diffracted intensity reflects the population dynamics as long as these populations follow first- or pseudo-first order kinetics. Higher order kinetics leads to inharmonic gratings and in this case the time dependence of the diffracted intensity is no longer a direct measure of the population dynamics.

Polarization Selective Transient Grating

In the above applications, the selection between the different contributions to the diffracted signal was essentially made by choosing the probe wavelength and the crossing angle of the pump pulses. However, this approach is not always sufficient. Another important parameter is the polarization of the four waves involved in a transient grating experiment. For example, when measuring population dynamics, the polarization of the probe beam has to be at magic angle (54.7°) relatively to that of the pump pulses. This ensures that the observed time profiles are not distorted by the decay of the orientational anisotropy of the species created by the polarized pump pulses.

The magnitude of ΔA and Δn depends on the pump pulses intensity, and therefore the diffracted intensity can be expressed by using the formalism of nonlinear optics:

$$I_{dif}(t) = C \int_{-\infty}^{+\infty} \mathrm{d}t\, I_{pr}(t - t'') \times \left[\int_{-\infty}^{t} \mathrm{d}t' |R_{ijkl}(t'' - t')| I_{pu}(t') \right]^2 \quad [15]$$

where C is a constant and R_{ijkl} is an element of the fourth rank tensor $\mathbf{R}$ describing the nonlinear response of the material to the applied optical fields. In isotropic media, this tensor has only 21 nonzero elements, which are related as follows:

$$R_{1111} = R_{1122} + R_{1212} + R_{1221} \quad [16]$$

where the subscripts are the Cartesian coordinates. Going from right to left, they design the direction of polarization of the pump, probe, and signal pulses. The remaining elements can be obtained by permutation of these indices ($R_{1122} = R_{1133} = R_{2211} = \ldots$). In a conventional transient grating experiment, the two pump pulses are at the same frequency and are time coincident and therefore their indices can be interchanged. In this case, $R_{1212} = R_{1221}$ and the number of independent tensor elements is further reduced:

$$R_{1111} = R_{1122} + 2R_{1212} \quad [17]$$

The tensor $\mathbf{R}$ can be decomposed into four tensors according to the origin of the sample response: population and density changes, electronic and nuclear optical Kerr effects:

$$\mathbf{R} = \mathbf{R}(p) + \mathbf{R}(d) + \mathbf{R}(K, e) + \mathbf{R}(K, n) \quad [18]$$

As they describe different phenomena, these tensors do not have the same symmetry properties. Therefore, the various contributions to the diffracted intensity can, in some cases, be measured selectively by choosing the appropriate polarization of the four waves.

Table 2 shows the relative amplitude of the most important elements of these four tensors.

The tensor $\mathbf{R}(p)$ depends on the polarization anisotropy of the sample, r, created by excitation with polarized pump pulses:

$$r(t) = \frac{N_{\parallel}(t) - N_{\perp}(t)}{N_{\parallel}(t) + 2N_{\perp}(t)} = \frac{2}{5}\mathrm{P}_2[\cos(\gamma)]\exp(-k_{re}t) \qquad [19]$$

where $N_{\parallel}$ and $N_{\perp}$ are the number of molecules with the transition dipole oriented parallel and perpendicular to the polarization of the probe pulse, respectively, γ is the angle between the transition dipoles involved in the pump and probe processes, P_2 is the second Legendre polynomial, and k_{re} is the rate constant for the reorientation of the transition dipole, for example, by rotational diffusion of the molecule or by energy hopping.

The table shows that $R_{1212}(d) = 0$, i.e., the contribution of the density grating can be eliminated with the set of polarization $(0°, 90°, 0°, 90°)$, the so-called crossed grating geometry. In this geometry, the two pump pulses have orthogonal polarization, the polarization of the probe pulse is parallel to that of one pump pulse and the polarization component of the signal that is orthogonal to the polarization of the probe pulse is measured. In this geometry, $R_{1212}(p)$ is nonzero as long as there is some polarization anisotropy, ($r \neq 0$). In this case, the diffracted intensity is

$$I_{dif}(t) \propto |R_{1212}(p)|^2 \propto [\Delta C(t) \times r(t)]^2 \qquad [20]$$

The crossed grating technique can thus be used to investigate the reorientational dynamics of molecules, through $r(t)$, especially when the dynamics of r is faster than that of ΔC. For example, Figure 10 shows the time profile of the diffracted intensity measured in the crossed grating geometry with rhodamine 6G in ethanol. The decay is due to the reorientation of the molecule by rotational diffusion, the excited lifetime of rhodamine being about 4 ns.

On the other hand, if the decay of r is slower than that of ΔC, the crossed grating geometry can be used to measure the population dynamics without any interference from the density phase grating. For example, Figure 11 shows the time profile of the diffracted intensity after excitation of a suspension of TiO_2 particles in water. The upper profile was measured with the set of polarization $(0°, 0°, 0°, 0°)$ and thus reflects the time dependence of $R_{1111}(p)$ and $R_{1111}(d)$. $R_{1111}(p)$ is due to the trapped electron population, which decays by charge recombination, and $R_{1111}(d)$ is due to the heat dissipated upon both charge separation and recombination. The lower time profile was measured in the crossed grating geometry and thus reflects the time dependence of R_{1212} and in particular that of $R_{1212}(p)$.

Each contribution to the signal can be selectively eliminated by using the set of geometry $(\zeta, 45°, 0°, 0°)$ where the value of the 'magic angle' ζ for each

Table 2 Relative value of the most important elements of the response tensors $\mathbf{R}(i)$ and polarization angle ζ of the signal beam, where the contribution of the corresponding process vanishes for the set of polarization $(\zeta, 45°, 0°, 0°)$.

Process	R_{1111}	R_{1122}	R_{1212}	ζ
Electronic OKE	1	1/3	1/3	−71.6°
Nuclear OKE	1	−1/2	3/4	63.4°
Density	1	1	0	−45°
Population:				
$\gamma = 0°$	1	1/3	1/3	−71.6°
$\gamma = 90°$	1	2	−1/2	−26.6°
No correlation: $r = 0$	1	1	0	−45°

contribution is listed in Table 2. This approach allows for example the nuclear and electronic contributions to the optical Kerr effect to be measured separately.

Concluding Remarks

The transient grating techniques offer a large variety of applications for investigating the dynamics of chemical processes. We have only discussed the cases where the pump pulses are time coincident and at the same wavelength. Excitation with pump pulses at different wavelengths results to a moving grating. The well-known CARS spectroscopy is such a moving grating technique. Finally, the three pulse photon echo can be considered as a special case of transient grating where the sample is excited by two pump pulses, which are at the same wavelength but are not time coincident.

List of Units and Nomenclature

C	concentration [mol L^{-1}]
C_v	heat capacity [J K^{-1} kg^{-1}]
d	sample thickness [m]
D_{th}	thermal diffusivity [m^2 s^{-1}]
I_{dif}	diffracted intensity [W m^{-2}]
I_{pr}	intensity of the probe pulse [W m^{-2}]
I_{pu}	intensity of a pump pulse [W m^{-2}]
k_{ac}	acoustic wavevector [m^{-1}]
k_r	rate constant of a heat releasing process [s^{-1}]
k_{re}	rate constant of reorientation [s^{-1}]
k_{th}	rate constant of thermal diffusion [s^{-1}]
K	attenuation constant
n	refractive index
$\tilde{n}$	complex refractive index
N	number of molecule per unit volume [m^{-3}]
r	polarization anisotropy
$\mathbf{R}$	fourth rank response tensor [m^2 V^{-2}]
v_s	speed of sound [m s^{-1}]
V	volume [m^3]
α_{ac}	acoustic attenuation constant [m^{-1}]
β	cubic volume expansion coefficient [K^{-1}]
γ	angle between transition dipoles
Λ	fringe spacing [m]
Δn_d	variation of refractive index due to density changes
Δn_d^e	Δn_d due to electrostriction
Δn_K	variation of refractive index due to optical Kerr effect
Δn_d^p	Δn_d due to volume changes
Δn_p	variation of refractive index due to population changes
Δn_d^t	Δn_d due to temperature changes
Δx	peak to null variation of the parameter x
ε	molar decadic absorption coefficient [cm L mol^{-1}]
ζ	angle of polarization of the diffracted signal
η	diffraction efficiency
θ_B	Bragg angle (angle of incidence of the probe pulse)
θ_{pu}	angle of incidence of a pump pulse
λ_{pr}	probe wavelength [m]
λ_{pu}	pump wavelength [m]
ρ	density [kg m^{-3}]
τ_{ac}	acoustic period [s]
υ_{ac}	acoustic frequency [s^{-1}]

Introduction

Coherence refers to the characteristic of a wave that indicates whether different parts of the wave oscillate in tandem, or in a definite phase relationship. In other words, it refers to the degree of confidence by which one can predict the amplitude and phase of a wave at a point, from the knowledge of these at another point at the same or a different instant of time. Emission from a thermal source, such as a light bulb, is a highly disordered process and the emitted light is incoherent. A well-stabilized laser source, on the other hand, generates light in a highly ordered manner and the emitted light is highly coherent. Incoherent and coherent light represent two extreme cases. While describing the phenomena of physical optics and diffraction theory, light is assumed to be perfectly coherent in both spatial as well as temporal senses, whereas in radiometry it is generally assumed to be incoherent. However, practical light sources and the fields generated by them are in between the two extremes and are termed as partially coherent sources and fields. The degree of order that exists in an optical field produced by a source of any kind may be described in terms of various correlation functions. These correlation functions are the basic theoretical tools for the analyses of statistical properties of partially coherent light fields.

Light fields generated from real physical sources fluctuate randomly to some extent. On a microscopic level quantum mechanical fluctuations produce randomness and on macroscopic level the randomness occurs as a consequence of these microscopic fluctuations, even in free space. In real physical sources, spontaneous emission causes random fluctuations and even in the case of lasers, spontaneous emission cannot be suppressed completely. In addition to spontaneous emission, there are many other processes that give rise to random fluctuations of light fields. Optical coherence theory was developed to describe the random nature of light and it deals with the statistical similarity between light fluctuations at two (or more) space–time points.

As mentioned earlier, in developing the theory of interference or diffraction, light is assumed to be perfectly coherent, or, in other words, it is taken to be monochromatic and sinusoidal for all times. This is, however, an idealization since the wave is obviously generated at some point of time by an atomic or molecular transition. Furthermore, a wavetrain generated by such a transition is of a finite duration, which is related to the finite lifetime of the atomic or molecular levels involved in the transition. Thus, any wave emanating from a source is an ensemble of a large number of such wavetrains of finite duration, say τ_c. A simplified visualization of such an ensemble is shown in Figure 1 where a wave is shown as a series of wavetrains of duration τ_c. It is evident from the figure that the fields at time t and $t + \Delta t$ will have a definite phase relationship if $\Delta t \ll \tau_c$ and will have no or negligible phase relationship when $\Delta t \gg \tau_c$. The time τ_c is known as the coherence time of the

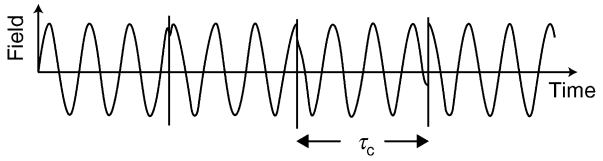

Figure 1 Typical variation of the radiation field with time. The coherence time $\sim \tau_c$.

radiation and the field is said to remain coherent for time $\sim \tau_c$. This property of waves is referred to as the time coherence or the temporal coherence and is related to the spectral purity of the radiation. If one obtains the spectrum of the wave shown in Figure 1 by taking the Fourier transform of the time variation, it would have a width of $\Delta\nu$ around ν_0 which is the frequency of the sinusoidal variation of individual wavetrains. The spectral width $\Delta\nu$ is related to the coherence time as

$$\Delta\nu \sim 1/\tau_c \qquad [1]$$

For thermal sources such as a sodium lamp, $\tau_c \sim 100$ ps, whereas for a laser beam it could be as large as a few milliseconds. A related quantity is the coherence length l_c, which is the distance covered by the wave in time τ_c,

$$l_c = c\tau_c \sim \frac{c}{\Delta\nu} = \frac{\lambda_0^2}{\Delta\lambda} \qquad [2]$$

where λ_0 is the central wavelength ($\lambda_0 = c/\nu_0$) and $\Delta\lambda$ is the wavelength spread corresponding to the spectral width $\Delta\nu$. In a two-beam interference experiment (e.g., Michelson interferometer, Figure 2), the interfering beam derived from the same source will produce good interference fringes if the path difference between the two interfering beams is less than the coherence length of the radiation given out by the source.

It must be added here that for the real fields, generated by innumerable atoms or molecules, the individual wavetrains have different lengths around an average value τ_c. Furthermore, several wavetrains in general are propagating simultaneously, overlapping in space and time, to produce an ensemble whose properties are best understood in a statistical sense as we shall see in later sections.

Another type of coherence associated with the fields is the space coherence or the spatial coherence, which is related to the size of the source of radiation. It is evident that when the source is an ideal point source, the field at any two points (within the coherence length) would have definite phase relationship. However, the field from a thermal source of finite area S can be thought as resultant of the fields

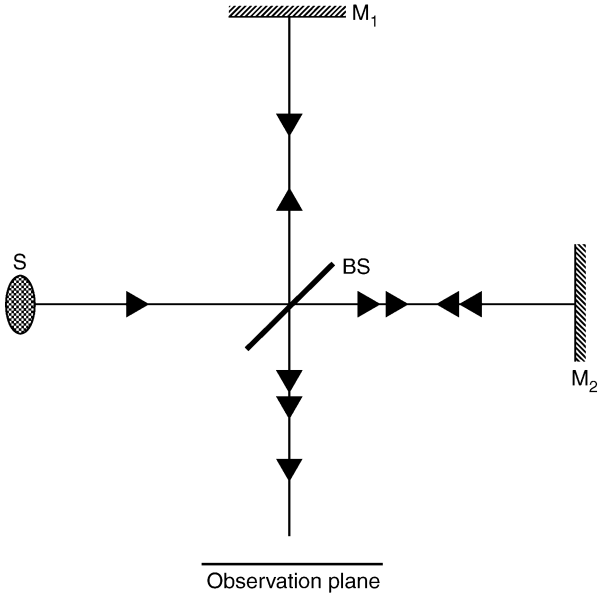

Figure 2 Michelson interferometer to study the temporal coherence of radiation from source S; M_1 and M_2 are mirrors and BS is a 50%–50% beamsplitter.

from each point on the source. Since each point source would usually be independent of the other, the phase relationship between the fields at any two points would depend on their position and size of the source. It can be shown that two points will have a strong phase relationship if they lie within the solid angle $\Delta\Omega$ from the source (Figure 3) such that

$$\Delta\Omega \sim \frac{\lambda_0^2}{S} \qquad [3]$$

Thus, on a plane R distance away from the source, one can define an area $A_c = R^2\Delta\Omega$ over which the field remains spatially coherent. This area A_c is called the coherence area of the radiation and its square root is sometimes referred to as the transverse coherence length. It is trivial to show that

$$A_c \sim \frac{\lambda_0^2}{\Delta\Omega_S} \qquad [4]$$

where $\Delta\Omega_S$ is the solid angle subtended by the source on the plane at which the coherence area is defined. In Young's double-hole experiment, if the two pinholes lie within the coherence area of the radiation from the primary source, good contrast in fringes would be observed.

Combining the concepts of coherence length and the coherence area, one can define a coherence volume as $V_c = A_c l_c$. For the wavefield from a thermal source, this volume represents that portion of the space in which the field is coherent and any

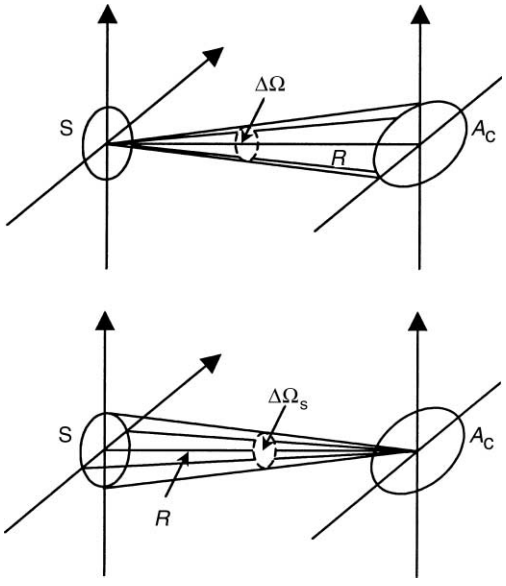

Figure 3 Spatial coherence and coherence area.

interference produced using the radiation from points within this volume will produce fringes of good contrast.

Mathematical Description of Coherence

Analytical Field Representation

Coherence properties associated with fields are best analyzed in terms of complex representation for optical fields. Let the real function $V^{(r)}(\mathbf{r},t)$ represent the scalar field, which could be one of the transverse Cartesian components of the electric field associated with the electromagnetic wave. One can then define a complex analytical signal $V(\mathbf{r},t)$ such that

$$V^{(r)}(\mathbf{r},t) = \mathrm{Re}[V(\mathbf{r},t)],$$
$$V(\mathbf{r},t) = \int_0^\infty \tilde{V}^{(r)}(\mathbf{r},\nu)\mathrm{e}^{-2\pi i\nu t}\,\mathrm{d}\nu \qquad [5]$$

where the spectrum $\tilde{V}^{(r)}(\mathbf{r},\nu)$ is the Fourier transform of the scalar field $V^{(r)}(\mathbf{r},t)$ and the spectrum for negative frequencies has been suppressed as it does not give any new information since $\tilde{V}^{(r)^*}(\mathbf{r},\nu) = \tilde{V}^{(r)}(\mathbf{r},-\nu)$.

In general, the radiation from a quasi-monochromatic thermal source fluctuates randomly as it is made of a large number of mutually independent contributions from individual atoms or molecules in the source. The field from such a source can be regarded as an ensemble of a large number of randomly different analytical signals such as $V(\mathbf{r},t)$. In other words, $V(\mathbf{r},t)$ is a typical member of an ensemble, which is the result of a random process representing the radiation from a quasi-monochromatic source. This process is assumed to be stationary and ergodic so that the ensemble average is equal to the time average of a typical member of the ensemble and that the origin of time is unimportant. Thus, the quantities of interest in the theory of coherence are defined as time averages:

$$\langle f(t)\rangle = \underset{T\to\infty}{\mathrm{Lim}}\,\frac{1}{2T}\int_{-T}^{T} f(t)\mathrm{d}t \qquad [6]$$

Mutual Coherence

In order to define the mutual coherence, the key concept in the theory of coherence, we consider Young's interference experiment, as shown in Figure 4, where the radiation from a broad source of size S is illuminating a screen with two pinholes P_1 and P_2. The light emerging from the two pinholes produces interference, which is observed on another screen at a distance R from the first screen. The field at point P, due to the pinholes, would be $K_1V(\mathbf{r}_1,t-t_1)$ and $K_2V(\mathbf{r}_2,t-t_2)$ respectively, where $\mathbf{r}_1$ and $\mathbf{r}_2$ define the positions of P_1 and P_2, t_1 and t_2 are the times taken by the light to travel to P from P_1 and P_2, and K_1 and K_2 are imaginary constants that depend on the geometry and size of the respective pinhole and its distance from the point P. Thus, the resultant field at point P would be given by

$$V(\mathbf{r},t) = K_1V(\mathbf{r}_1,t-t_1) + K_2V(\mathbf{r}_2,t-t_2) \qquad [7]$$

Since the optical periods are extremely small as compared to the response time of a detector, the detector placed at point P will record only the time-averaged intensity:

$$I(P) = \langle V^*(\mathbf{r},t)V(\mathbf{r},t)\rangle \qquad [8]$$

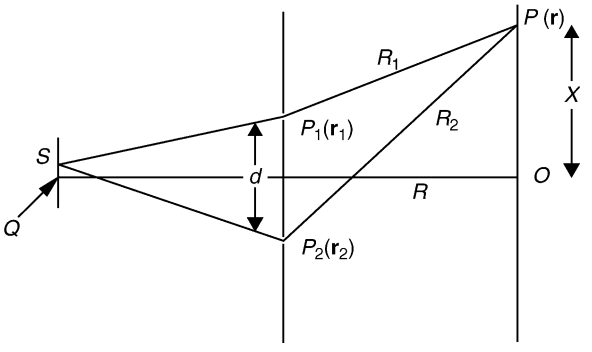

Figure 4 Schematic of Young's double-hole experiment.

where some constants have been ignored. With eqn [7], the intensity at point P would be given by

$$I(P) = I_1 + I_2 + 2\,\mathrm{Re}\{K_1 K_2^* \Gamma(\mathbf{r}_1, \mathbf{r}_2, t - t_1, t - t_2)\} \quad [9]$$

where I_1 and I_2 are the intensities at point P, respectively, due to radiations from pinholes P_1 and P_2 independently (defined as $I_i = \langle |K_i V(\mathbf{r}_i, t)|^2 \rangle$) and

$$\Gamma(\mathbf{r}_1, \mathbf{r}_2, t - t_1, t - t_2) \equiv \Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = \langle V^*(\mathbf{r}_1, t) V(\mathbf{r}_2, t + \tau) \rangle \quad [10]$$

is the mutual coherence function of the fields at P_1 and P_2, and it depends on the time difference $\tau = t_2 - t_1$, since the random process is assumed to be stationary. This function is also sometimes denoted by $\Gamma_{12}(\tau)$. The function $\Gamma_{ii}(\tau) \equiv \Gamma(\mathbf{r}_i, \mathbf{r}_i, \tau)$ defines the self-coherence of the light from the pinhole at P_i, and $|K_i|^2 \Gamma_{ii}(0)$ defines the intensity I_i at point P, due to the light from pinhole P_i.

Degree of Coherence and the Visibility of Interference Fringes

One can define a normalized form of the mutual coherence function, namely:

$$\gamma_{12}(\tau) \equiv \gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = \frac{\Gamma_{12}(\tau)}{\sqrt{\Gamma_{11}(0)}\sqrt{\Gamma_{22}(0)}} = \frac{\langle V^*(\mathbf{r}_1, t) V(\mathbf{r}_2, t + \tau) \rangle}{\left[\langle |V(\mathbf{r}_1, t)|^2 \rangle \langle |V(\mathbf{r}_2, t)|^2 \rangle \right]^{1/2}} \quad [11]$$

which is called the complex degree of coherence. It can be shown that $0 \leq |\gamma_{12}(\tau)| \leq 1$. The intensity at point P, given by eqn [9], can now be written as

$$I(P) = I_1 + I_2 + 2\sqrt{I_1 I_2}\,\mathrm{Re}[\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)] \quad [12]$$

Expressing $\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)$ as

$$\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = |\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| \exp[i\alpha(\mathbf{r}_1, \mathbf{r}_2, \tau) - 2\pi i \nu_0 \tau] \quad [13]$$

where $\alpha(\vec{r}_1, \vec{r}_2, \tau) = \arg[\gamma(\vec{r}_1, \vec{r}_2, \tau)] + 2\pi\nu_0\tau$, and ν_0 is the mean frequency of the light, the intensity in eqn [12] can be written as

$$I(P) = I_1 + I_2 + 2\sqrt{I_1 I_2}|\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| \times \cos[\alpha(\mathbf{r}_1, \mathbf{r}_2, \tau) - 2\pi\nu_0\tau] \quad [14]$$

Now, if we assume that the source is quasi-monochromatic, i.e., its spectral width $\Delta\nu \ll \nu_0$, the quantities $\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)$ and $\alpha(\mathbf{r}_1, \mathbf{r}_2, \tau)$ vary slowly on the observation screen, and the interference fringes are mainly obtained due to the cosine term. Thus, defining the visibility of fringes as $v = (I_{\max} - I_{\min})/(I_{\max} + I_{\min})$, we obtain

$$v = \frac{2(I_1 I_2)^{1/2}}{I_1 + I_2} |\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| \quad [15]$$

which shows that for maximum visibility, the two interfering fields must be completely coherent ($|\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| = 1$). On the other hand, if the fields are completely incoherent ($|\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| = 0$), no fringes are observed ($I_{\max} = I_{\min}$). The fields are said to be partially coherent when $0 < |\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| < 1$. When $I_1 = I_2$, the visibility is the same as $|\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)|$. The relation in eqn [15] shows that in an interference experiment, one can obtain the modulus of the complex degree of coherence by measuring I_1, I_2, and the visibility. Similarly, eqn [14] shows that from the measurement the positions of maxima, one can obtain the phase of the complex degree of coherence, $\alpha(\mathbf{r}_1, \mathbf{r}_2, \tau)$.

Temporal and Spatial Coherence

If the source illuminating the pinholes is a point source of finite spectral width situated at point Q, the fields at point P_1 and P_2 (Figure 4) at any given instant are the same and the mutual coherence function becomes

$$\Gamma_{11}(\tau) = \Gamma(\mathbf{r}_1, \mathbf{r}_1, \tau) = \langle V^*(\mathbf{r}_1, t) V(\mathbf{r}_1, t + \tau) \rangle = \langle V^*(\mathbf{r}_2, t) V(\mathbf{r}_2, t + \tau) \rangle = \Gamma_{22}(\tau) \quad [16]$$

The self-coherence, $\Gamma_{11}(\tau)$, of the light from pinhole P_1, is a direct measure of the temporal coherence of the source. On the other hand, if the source is of finite size and we observe the interference at point O which corresponds to $\tau = 0$, the mutual coherence function would be

$$\Gamma_{12}(0) = \Gamma(\mathbf{r}_1, \mathbf{r}_2, 0) = \langle V^*(\mathbf{r}_1, t) V(\mathbf{r}_2, t) \rangle \equiv J_{12} \quad [17]$$

which is called the mutual intensity and is a direct measure of the spatial coherence of the source. In general, however, the function $\Gamma_{12}(\tau)$ measures, for a source of finite size and spectral width, a combination of the temporal and spatial coherence, and in only some limiting cases, the two types of coherence can be separated.

Spectral Representation of Mutual Coherence

One can also analyze the correlation between two fields in the spectral domain. In particular, one can define the cross-spectral density function $W(\mathbf{r}_1, \mathbf{r}_2, \nu)$ which defines the correlation between the amplitudes of the spectral components of frequency ν of the light

at the points P_1 and P_2. Thus:

$$W(\mathbf{r}_1, \mathbf{r}_2, \nu)\delta(\nu - \nu') = \left\langle V^*(\mathbf{r}_1, \nu)V(\mathbf{r}_2, \nu')\right\rangle \qquad [18]$$

Using the generalized Wiener–Khintchine theorem, the cross-spectral density function can be shown to be the Fourier transform of the mutual coherence function:

$$\Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau) = \int_0^\infty W(\mathbf{r}_1, \mathbf{r}_2, \nu)\mathrm{e}^{-2\pi\mathrm{i}\nu t}\,\mathrm{d}\nu \qquad [19]$$

$$W(\mathbf{r}_1, \mathbf{r}_2, \nu) = \int_{-\infty}^\infty \Gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)\mathrm{e}^{2\pi\mathrm{i}\nu t}\,\mathrm{d}\tau \qquad [20]$$

If the two points P_1 and P_2 coincide (i.e., there is only one pinhole), the cross-spectral density function reduces to the spectral density function of the light, which we denote by $S(\mathbf{r}, \nu)[\equiv W(\mathbf{r}, \mathbf{r}, \nu)]$. Thus, it follows from eqn [20] that the spectral density of light is the inverse Fourier transform of the self-coherence function. This leads to the Fourier transform spectroscopy, as we shall see later. One can also define spectral degree of coherence at frequency ν as

$$\mu(\mathbf{r}_1, \mathbf{r}_2, \nu) = \frac{W(\mathbf{r}_1, \mathbf{r}_2, \nu)}{\sqrt{W(\mathbf{r}_1, \mathbf{r}_1, \nu)W(\mathbf{r}_2, \mathbf{r}_2, \nu)}} = \frac{W(\mathbf{r}_1, \mathbf{r}_2, \nu)}{\sqrt{S(\mathbf{r}_1, \nu)S(\mathbf{r}_2, \nu)}} \qquad [21]$$

It is easy to see that $0 \le |\mu(\mathbf{r}_1, \mathbf{r}_2, \nu)| \le 1$. It is also sometimes referred to as the complex degree of coherence at frequency ν. It may be noted here that in the literature the notation $G^{(1,1)}(\nu) \equiv G(\mathbf{r}_1, \mathbf{r}_2, \gamma)$ has also been used for $W(\mathbf{r}_1, \mathbf{r}_2, \nu)$.

Propagation of Coherence

The van Cittert–Zernike Theorem

Perfectly coherent waves propagate through diffraction formulae, which have been discussed in this volume elsewhere. However, incoherent and partially coherent waves would evidently propagate somewhat differently. The earliest treatment of propagation noncoherent light is due to van Cittert, which was later generalized by Zernike to obtain what is now the van Cittert–Zernike theorem. The theorem deals with the correlations developed between fields at two points, which have been generated by a quasi-monochromatic and spatially incoherent planar source. Thus, as shown in Figure 5, we consider a quasi-monochromatic ($\Delta\nu \ll \nu_0$) planar source σ, which has an intensity distribution $I(\mathbf{r}')$ on its plane and is spatially incoherent, i.e., there is no correlation between the fields at any two points on the source.

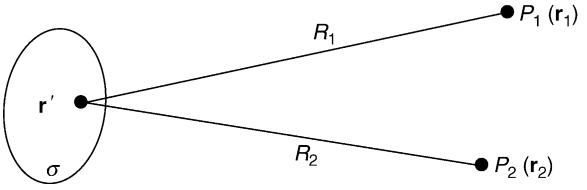

Figure 5 Geometry for the van Cittert–Zernike theorem.

The field, due to this source, would develop finite correlations after propagation, and the theorem states that

$$\gamma(\mathbf{r}_1, \mathbf{r}_2, 0) = \frac{\Gamma_{12}(0)}{\sqrt{\Gamma_{11}(0)}\sqrt{\Gamma_{12}(0)}} = \frac{1}{\sqrt{I(\mathbf{r}_1)I(\mathbf{r}_2)}}\int\int_\sigma I(\mathbf{r}')\frac{\mathrm{e}^{2\pi\mathrm{i}\nu_0(R_2-R_1)/c}}{R_1R_2}\mathrm{d}^2r' \qquad [22]$$

where $R_i = |\mathbf{r}_i - \mathbf{r}'|$ and $I(\mathbf{r}_i)$ is the intensity at point P_i. This relation is similar to the diffraction pattern produced at point P_1 due to a wave, with a spherical wavefront converging towards P_2 and with an amplitude distribution $I(\mathbf{r}')$ when it is diffracted by an aperture of the same shape, size, and the intensity distribution as those of the incoherent source σ. Thus, the theorem shows that a radiation, which was incoherent at the source, becomes partially coherent as it propagates.

Generalized Propagation

The expression $\mathrm{e}^{-2\pi\mathrm{i}\nu_0R_1/c}/R_1$ can be interpreted as the field obtained at P_1 due to a point source located at the point $\mathbf{r}'$ on the planar source. Thus, this expression is simply the point spread function of the homogeneous space between the source and the observation plane containing the points P_1 and P_2. Hopkins generalized this to include any linear optical system characterized by a point spread function $h(\mathbf{r}_i - \mathbf{r}')$ and obtained the formula for the complex degree of coherence of a radiation emerging from an incoherent, quasi-monochromatic planar source after it has propagated through such a linear optical system:

$$\gamma(\mathbf{r}_1,\mathbf{r}_2,0)=\frac{1}{\sqrt{I(\mathbf{r}_1)I(\mathbf{r}_2)}}\int\int_\sigma I(\mathbf{r}')h(\mathbf{r}_1-\mathbf{r}')h^*(\mathbf{r}_2-\mathbf{r}')\mathrm{d}^2r' \qquad [23]$$

It would thus seem that the correlations propagate in much the same way, as does the field. Indeed, Wolf showed that the mutual correlation function

$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)$ satisfies the wave equations:

$$\nabla_1^2\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\frac{1}{c^2}\frac{\partial^2}{\partial\tau^2}\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)$$
$$\nabla_2^2\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\frac{1}{c^2}\frac{\partial^2}{\partial\tau^2}\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau) \qquad [24]$$

where ∇_i^2 is the Laplacian with respect to the point $\mathbf{r}_i$. Here the first of eqns [24], for instance, gives the variation of the mutual coherence function with respect to $\mathbf{r}_1$ and τ for fixed $\mathbf{r}_2$. Further, the variable τ is the time difference defined through the path difference, since $\tau=(R_2-R_1)/c$, and the actual time does not affect the mutual coherence function (as the fields are assumed to be stationary).

Using the relation in eqn [20], one can also obtain from eqn [24], the propagation equations for the cross-spectral density function $W(\mathbf{r}_1,\mathbf{r}_2,\nu)$:

$$\nabla_1^2 W(\mathbf{r}_1,\mathbf{r}_2,\nu)+k^2W(\mathbf{r}_1,\mathbf{r}_2,\nu)=0$$
$$\nabla_2^2 W(\mathbf{r}_1,\mathbf{r}_2,\nu)+k^2W(\mathbf{r}_1,\mathbf{r}_2,\nu)=0 \qquad [25]$$

where $k=2\pi\nu/c$.

Thompson and Wolf Experiment

One of the most elegant experiments for studying various aspects of coherence theory was carried out by Thompson and Wolf by making slight modifications in the Young's double-hole experiment. The experimental set-up shown in Figure 6 consists of a quasi-monochromatic broad incoherent source S of diameter $2a$. This was obtained by focusing filtered narrow band light from a mercury lamp (not shown in the figure) on to a hole of size $2a$ in an opaque screen A. A mask consisting of two pinholes, each of diameter $2b$ with their axes separated by a distance d, was placed symmetrically about the optical axis of the experimental setup at plane B between two lenses L_1 and L_2, each having focal length f. The source was at the front focal plane of the lens L_1 and the observations were made at the plane C at the back focus of the lens L_2. The separation d was varied to study the spatial coherence function on the mask plane by measuring the visibility and the phase of the fringes formed in plane C.

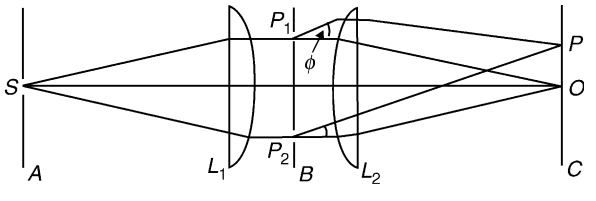

Figure 6 Schematic of the Thompson and Wolf experiment.

Using the van Cittert–Zernike theorem, the complex degree of coherence at the pinholes P_1 and P_2 on the mask after the lens L_1 is

$$\gamma_{12}=|\gamma_{12}|e^{i\beta_{12}}=\frac{2J_1(v)}{v} \text{ with } v=\left(\frac{2\pi vad}{cf}\right) \qquad [26]$$

for symmetrically placed pinholes about the optical axis. Here β_{12} is the phase of the complex degree of coherence and in this special case where the two holes are equidistant from the axis, β_{12} is either zero or π, respectively, for positive or negative values of $2J_1(v)/v$. Let us assume that the intensities at two pinholes P_1 and P_2 are equal. The interference pattern observed at the back focal plane of lens L_2 is due to the superposition of the light diffracted from the pinholes. The beams are partially coherent with degree of coherence given by eqn [26]. Since the pinholes are symmetrically placed, the intensity due to either of the pinholes at a point P at the back focal plane of the lens L_2 is the same and is given by the Fraunhofer formula for diffraction from circular apertures, i.e.:

$$I_1(P)=I_2(P)=\left|\frac{2J_1(u)}{u}\right|^2, \text{ with } u=\frac{2\pi\nu}{c}b\sin\phi \qquad [27]$$

and ϕ is the angle that the diffracted beam makes from normal to the plane of the pinholes. The intensity of the interference pattern produced at the back focal plane of the lens L_2 is:

$$I(P)=2I_1(P)\left[1+\left|\frac{2J_1(v)}{v}\right|^2\cos(\delta+\beta_{12})\right] \qquad [28]$$

where $\delta=\mathrm{d}\sin\phi$ is the phase difference between the two beams reaching P from P_1 and P_2. For the on-axis point O, the quantity δ is zero.

The maximum and minimum values of $I(P)$ are given by

$$I_{\max}(P)=2I_1(P)\left[1+|2J_1(v)/v|^2\right] \qquad [29(a)]$$

$$I_{\max}(P)=2I_1(P)\left[1-|2J_1(v)/v|^2\right] \qquad [29(b)]$$

Figure 7 shows an example of the observed fringe patterns obtained by Thompson (1958) in a subsequent experiment.

Types of Fields

As mentioned above, $\gamma_{12}(\tau)$ is a measure of the correlation of the complex field at any two points P_1

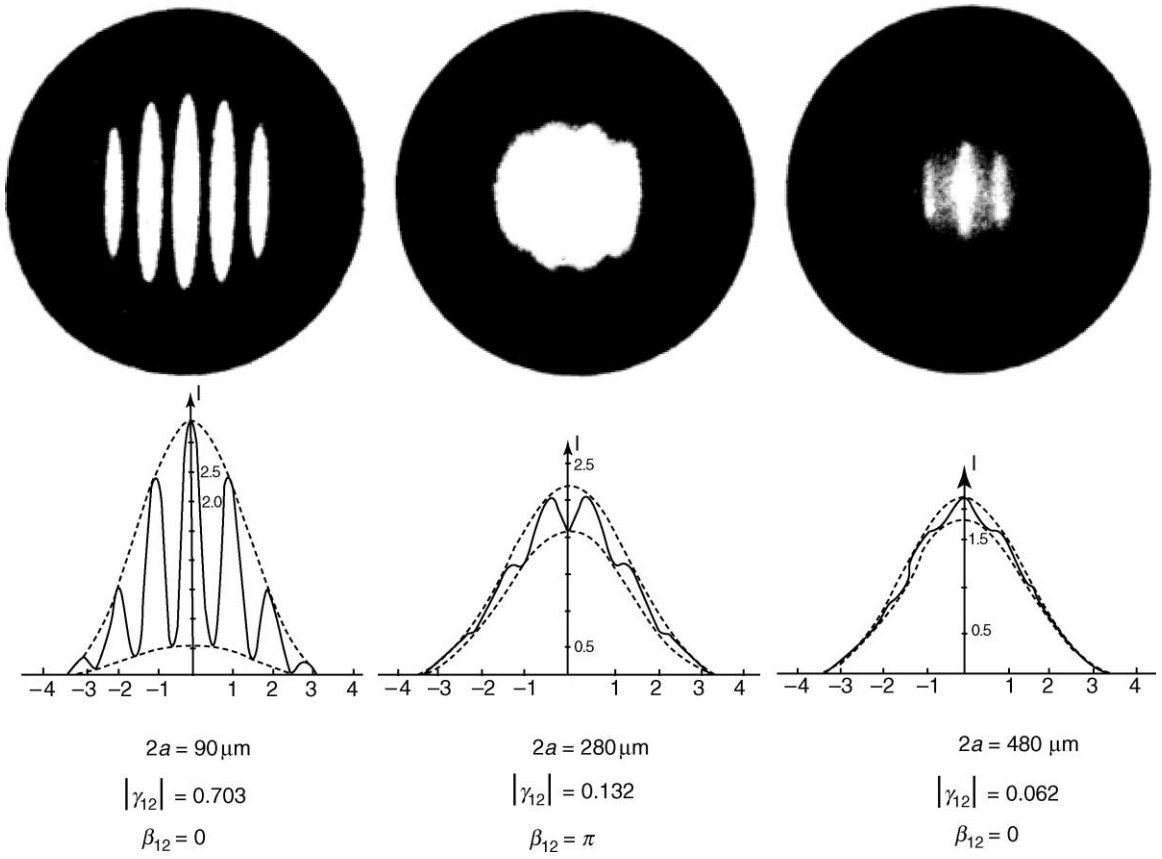

Figure 7 Two beam interference patterns obtained by using partially coherent light. The wavelength of light used was 0.579 μm and the separation *d* of the pinholes in the screen at B was 0.5 cm. The figure shows the observed fringe pattern and the calculated intensity variation for three sizes of the secondary source. The dashed lines show the maximum and minimum intensity. The values of the diameter, 2*a*, of the source and the corresponding values of the magnitude, $|\gamma_{12}|$, and the phase, β_{12}, are also shown in each case. Reproduced with permission from Thompson BJ (1958) Illustration of phase change in two-beam interference with partially coherent light. *Journal of the Optical Society of America* 48: 95–97.

and P_2 at specific time delay τ. Extending this definition, an optical field may be coherent or incoherent, if $|\gamma_{12}(\tau)| = 1$ or $|\gamma_{12}(\tau)| = 0$, respectively, for all pairs of points in the field and for all time delays. In the following, we consider some specific cases of fields and their properties.

Perfectly Coherent Fields

A field would be termed as perfectly coherent or self-coherent at a fixed point, if it has the property that $|\gamma(\mathbf{R}, \mathbf{R}, \tau)| = 1$ at some specific point $\mathbf{R}$ in the domain of the field for all values of time delay τ. It can also be shown that $\gamma(\mathbf{R}, \mathbf{R}, \tau)$ is periodic in time, i.e.:

$$\gamma(\mathbf{R}, \mathbf{R}, \tau) = \mathrm{e}^{-2\pi \mathrm{i} \nu_0 \tau} \quad \text{for} \quad \nu_0 > 0 \qquad [30]$$

For any other point $\mathbf{r}$ in the domain of the field, $\gamma(\mathbf{R}, \mathbf{r}, \tau)$ and $\gamma(\mathbf{r}, \mathbf{R}, \tau)$ are also unimodular and also periodic in time.

A perfectly coherent optical field at two fixed points has the property that $|\gamma(\mathbf{R}_1, \mathbf{R}_2, \tau)| = 1$ for any two fixed points $\mathbf{R}_1$ and $\mathbf{R}_2$ in the domain of the field for all values of time delay τ. For such a field, it can be shown that $\gamma(\mathbf{R}_1, \mathbf{R}_2, \tau) = \exp[\mathrm{i}(\beta - 2\pi\nu_0\tau)]$ with ν_0 (> 0) and β are real constants. Further, as a corollary, $|\gamma(\mathbf{R}_1, \mathbf{R}_1, \tau)| = 1$ and $|\gamma(\mathbf{R}_2, \mathbf{R}_2, \tau)| = 1$ for all τ, i.e., the field is self-coherent at each of the field points $\mathbf{R}_1$ and $\mathbf{R}_2$, and

$$\gamma(\mathbf{R}_1, \mathbf{R}_1, \tau) = \gamma(\mathbf{R}_2, \mathbf{R}_2, \tau) = \exp(-2\pi \mathrm{i} \nu_0 \tau) \text{ for } \nu_0 > 0$$

It can be shown that for any other point $\mathbf{r}'$ within the field

$$\begin{aligned} &\gamma(\mathbf{r}, \mathbf{R}_2, \tau) = \gamma(\mathbf{R}_1, \mathbf{R}_2, 0)\gamma(\mathbf{r}, \mathbf{R}_1, \tau) = \gamma(\mathbf{r}, \mathbf{R}_1, \tau)\mathrm{e}^{\mathrm{i}\beta} \\ &\gamma(\mathbf{R}_1, \mathbf{R}_2, \tau) = \gamma(\mathbf{R}_1, \mathbf{R}_2, 0) \exp[-2\pi \mathrm{i} \nu_0 \tau] \end{aligned} \qquad [31]$$

A perfectly coherent optical field for all points in the domain of the field has the property that $|\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)| = 1$ for all pairs of points $\mathbf{r}_1$ and $\mathbf{r}_2$ in the domain of the field, for all values of time delay τ.

It can then be shown that $\gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\exp\{i[\alpha(\mathbf{r}_1)-\alpha(\mathbf{r}_2)]-2\pi i\nu_0\tau\}$, where $\alpha(\mathbf{r}')$ is real function of a single position $\mathbf{r}'$ in the domain of the field. Further, the mutual coherence function $\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)$ for such a field has a factorized periodic form as

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=U(\mathbf{r}_1)U^*(\mathbf{r}_2)\ \exp(-2\pi i\nu_0\tau) \qquad [32]$$

which means the field is monochromatic with frequency ν_0 and $U(\mathbf{r})$ is any solution of the Helmholtz equation:

$$\nabla^2U(\mathbf{r})+k_0^2U(\mathbf{r})=0, \quad k_0=2\pi\nu_0/c \qquad [33]$$

The spectral and cross-spectral densities of such fields are represented by Dirac δ-functions with their singularities at some positive frequency ν_0. Such fields, however, can never occur in nature.

Quasi-Monochromatic Fields

Optical fields are found in practice for which spectral spread $\Delta\nu$ is much smaller than the mean frequency $\bar{\nu}$. These are termed as quasi-monochromatic fields. The cross-spectral density $W(\mathbf{r}_1,\mathbf{r}_2,\nu)$ of the quasi-monochromatic fields attains an appreciable value only in the small region $\Delta\nu$, and falls to zero outside this region.

$$W(\mathbf{r}_1,\mathbf{r}_2,\nu)=0, \quad |\nu-\bar{\nu}|>\Delta\nu \ \text{ and } \ \Delta\nu\ll\bar{\nu} \qquad [34]$$

The mutual coherence function $\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)$ can be written as the Fourier transform of cross-spectral density function as

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=e^{-2\pi i\bar{\nu}\tau}\int_0^\infty W(\mathbf{r}_1,\mathbf{r}_2,\nu)e^{-2\pi i(\nu-\bar{\nu})\tau}\,d\nu \qquad [35]$$

If we limit our attention to small τ such that $\Delta\nu|\tau|\ll1$ holds, the exponential factor inside the integral is approximately equal to unity and eqn [35] reduces to

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\exp(-2\pi i\bar{\nu}\tau)\int_0^\infty[W(\mathbf{r}_1,\mathbf{r}_2,\nu)]\,d\nu \qquad [36]$$

which gives

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\Gamma(\mathbf{r}_1,\mathbf{r}_2,0)\exp(-2\pi i\bar{\nu}\tau) \qquad [37]$$

Equation [37] describes the behavior of $\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)$ for a limited range of τ values for quasi-monochromatic fields and in this range it behaves as a monochromatic field of frequency $\bar{\nu}$. However, due to the factor $\Gamma(\mathbf{r}_1,\mathbf{r}_2,0)$, the quasi-monochromatic field may be coherent, partially coherent, or even incoherent.

Cross-Spectrally Pure Fields

The complex degree of coherence, if it can be factored into a product of a component dependent on spatial coordinates and a component dependent on time delay, is called reducible. In the case of perfectly coherent light, the complex degree of coherence is reducible, as we have seen above, e.g., in eqn [32], and in the case of quasi-monochromatic fields, this is reducible approximately as shown in eqn [37]. There also exists a very special case of a cross-spectrally pure field for which the complex degree of coherence is reducible. A field is called a cross-spectrally pure field if the normalized spectrum of the superimposed light is equal to the normalized spectrum of the component beams, a concept introduced by Mandel. In the space-frequency domain, the intensity interference law is expressed as the so-called spectral interference law:

$$S(\mathbf{r},\nu)=S^{(1)}(\mathbf{r},\nu)+S^{(2)}(\mathbf{r},\nu)+2\left[\sqrt{S^{(1)}(\mathbf{r},\nu)}\sqrt{S^{(2)}(\mathbf{r},\nu)}\right]\mathrm{Re}[\mu(\mathbf{r}_1,\mathbf{r}_2,\nu)e^{-2\pi i\nu\tau}] \qquad [38]$$

where $\mu(\mathbf{r}_1,\mathbf{r}_2,\nu)$ is the spectral degree of coherence, defined in eqn [21] and τ is the relative time delay that is needed by the light from the pinholes to reach any point on the screen; $S^{(1)}(\mathbf{r},\nu)$ and $S^{(2)}(\mathbf{r},\nu)$ are the spectral densities of the light reaching P from the pinholes P_1 and P_2, respectively (see **Figure 4**) and it is assumed that the spectral densities of the field at pinholes P_1 and P_2 are the same [$S(\mathbf{r}_1,\nu)=CS(\mathbf{r}_2,\nu)$]. Now, if we consider a point for which the time delay is τ_0, then it can be seen that the last term in eqn [38] would be independent of frequency, provided that

$$\mu(\mathbf{r}_1,\mathbf{r}_2,\nu)\ \exp(-2\pi i\nu\tau_0)=f(\mathbf{r}_1,\mathbf{r}_2,\tau_0) \qquad [39]$$

where $f(\mathbf{r}_1,\mathbf{r}_2,\tau_0)$ is a function of $\mathbf{r}_1$, $\mathbf{r}_2$ and τ_0 only and the light at this point would have the same spectral density as that at the pinholes. If a region exists around the specified point on the observation plane, such that the spectral distribution of the light in this region is of the same form as the spectral distribution of the light at the pinholes, the light at the pinholes is cross-spectrally pure light.

In terms of the spectral distribution of the light $S(\mathbf{r}_1,\nu)$ at pinhole P_1 and $S(\mathbf{r}_2,\nu)[=CS(\mathbf{r}_1,\nu)]$ at pinhole P_2, the mutual coherence function at the pinholes can be written as

$$\Gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\sqrt{C}\int S(\mathbf{r}_1,\nu)\mu(\mathbf{r}_1,\mathbf{r}_2,\nu)\ \exp(-2\pi i\nu\tau)d\nu \qquad [40]$$

and using eqn [39], we get the very important condition for the field to be cross-spectrally pure, i.e.:

$$\gamma(\mathbf{r}_1,\mathbf{r}_2,\tau)=\gamma(\mathbf{r}_1,\mathbf{r}_2,\tau_0)\gamma(\mathbf{r}_1,\mathbf{r}_1,\tau-\tau_0) \qquad [41]$$

The complex degree of coherence $\gamma(\mathbf{r}_1, \mathbf{r}_2, \tau)$ is thus expressible as the product of two factors: one factor characterizes the spatial coherence at the two pinholes at time delay τ_0 and the other characterizes the temporal coherence at one of the pinholes. Equation [41] is known as the reduction formula for cross-spectrally pure light. It can further be shown that

$$\mu(\mathbf{r}_1, \mathbf{r}_2, \nu) = \gamma(\mathbf{r}_1, \mathbf{r}_2, \tau_0)\ \exp(2\pi i \nu \tau_0) \qquad [42]$$

Thus, the absolute value of the spectral degree of coherence is the same for all frequencies and is equal to the absolute value of the degree of coherence for the point specified by τ_0. It has been shown that cross-spectrally pure light can be generated, for example, by linear filtering of light that emerges from the two pinholes in Young's interference experiments.

Types of Sources

Primary Sources

A primary source is a set of radiating atoms or molecules. In a primary source the randomness comes from true source fluctuations, i.e., from the spatial distributions of fluctuating charges and currents. Such a source gives rise to a fluctuating field. Let $Q(\mathbf{r}, t)$ represent the fluctuating source variable at any point $\mathbf{r}$ at time t, then the field generated by the source is represented by fluctuating field variable $V(\mathbf{r}, t)$. The source is assumed to be localized in some finite domain such that $Q(\mathbf{r}, t) = 0$ at any time $t > 0$ outside the domain. Assuming that field variable $V(\mathbf{r}, t)$ and the source variable $Q(\mathbf{r}, t)$ are scalar quantities, they are related by an inhomogeneous equation as

$$\nabla^2 V(\mathbf{r}, t) - \frac{1}{c^2}\frac{\partial^2}{\partial t^2} V(\mathbf{r}, t) = -4\pi Q(\mathbf{r}, t) \qquad [43]$$

The mutual coherence functions of the source $\Gamma_Q(\mathbf{r}_1, \mathbf{r}_2, \tau) = \langle Q^*(\mathbf{r}_1, t) Q(\mathbf{r}_2, t + \tau)\rangle$ and of the field $\Gamma_V(\mathbf{r}_1, \mathbf{r}_2, \tau) = \langle V^*(\mathbf{r}_1, t) V(\mathbf{r}_2, t + \tau)\rangle$ characterize the statistical similarity of the fluctuating quantities at the points $\mathbf{r}_1$ and $\mathbf{r}_2$. Following eqn [20], one can define, respectively, the cross-spectral density function of the source and the field as

$$W_Q(\mathbf{r}_1, \mathbf{r}_2, \nu) = \int_{-\infty}^{\infty} \Gamma_Q(\mathbf{r}_1, \mathbf{r}_2, \tau) e^{-2\pi i \nu t}\, d\tau \qquad [44]$$

$$W_V(\mathbf{r}_1, \mathbf{r}_2, \nu) = \int_{-\infty}^{\infty} \Gamma_V(\mathbf{r}_1, \mathbf{r}_2, \tau) e^{-2\pi i \nu t}\, d\tau$$

The cross-spectral density functions of the source and of the field are related as

$$(\nabla_2^2 + k^2)(\nabla_1^2 + k^2) W_V(\mathbf{r}_1, \mathbf{r}_2, \nu) = 4\pi^2 W_Q(\mathbf{r}_1, \mathbf{r}_2, \nu) \qquad [45]$$

The solution of eqn [45] is represented as

$$W_V(\mathbf{r}_1, \mathbf{r}_2, \nu) = \int_S \int_S W_Q(\mathbf{r}'_1, \mathbf{r}'_2, \nu) \frac{e^{ik(R_2 - R_1)}}{R_1 R_2} d^3 r'_1\, d^3 r'_2 \qquad [46]$$

where $R_1 = |\mathbf{r}_1 - \mathbf{r}'_1|$ and $R_2 = |\mathbf{r}_2 - \mathbf{r}'_2|$ (see Figure 8). Using eqn [46], one can then obtain an expression for the spectrum at a point ($\mathbf{r}_1 = \mathbf{r}_2 = \mathbf{r} = r\mathbf{u}$) in the far field ($r \gg r'_1, r'_2$) of a source as

$$S^{\infty}(r\mathbf{u}, \nu) = \frac{1}{r^2} \int_S \int_S W_Q(\mathbf{r}'_1, \mathbf{r}'_2, \nu) e^{-ik\mathbf{u}\cdot(\mathbf{r}'_1 - \mathbf{r}'_2)} d^3 r'_1\, d^3 r'_2 \qquad [47]$$

where $\mathbf{u}$ is the unit vector along $\mathbf{r}$. The integral in eqn [47], i.e., the quantity defined by $r^2 S^{\infty}(r\mathbf{u}, \nu)$, is also defined as the radiant intensity, which represents the rate of energy radiated at the frequency ν from the source per unit solid angle in the direction of $\mathbf{u}$.

Secondary Sources

Sources used in a laboratory are usually secondary planar sources. A secondary source is a field, which arises from the primary source in the region outside the domain of the primary sources. This kind of source is an aperture on an opaque screen illuminated either directly or via an optical system by primary sources. Let $V(\boldsymbol{\rho}, t)$ represent the fluctuating field in a secondary source plane σ at $z = 0$ (Figure 9) and $W_0(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \nu)$ represent its cross-spectral density (the subscript 0 refers to $z = 0$). One can then solve eqn [25] to obtain the propagation of the cross-spectral density from this planar source. For two points P_1 and P_2 located at distances which are large compared to wavelength, the cross-spectral density is

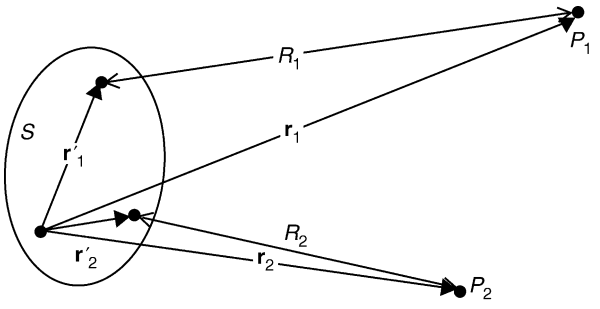

Figure 8 Geometry of a 3-dimensional primary source S and the radiation from it.

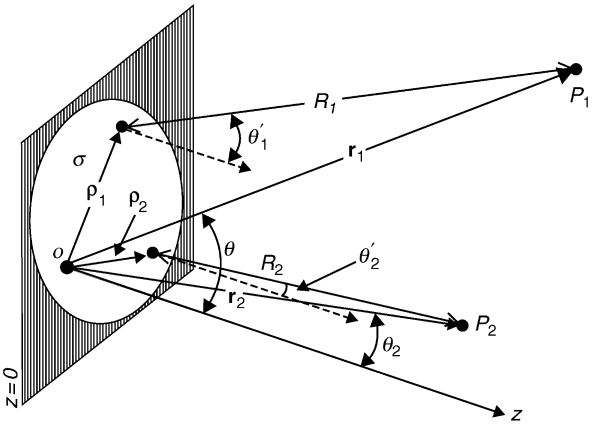

Figure 9 Geometry of a planar source σ and the radiation from it.

then given by

$$W(\mathbf{r}_1, \mathbf{r}_2, \nu) = \left(\frac{k}{2\pi}\right)^2 \int_\sigma \int_\sigma W_0(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \nu) \times \frac{e^{ik(R_2 - R_1)}}{R_1 R_2} \cos\theta'_1 \cos\theta'_2 \, d^2\rho_1 \, d^2\rho_2 \quad [48]$$

where $R_j = |\mathbf{r}_j - \boldsymbol{\rho}_j|$, $(j = 1, 2)$, θ'_1 and θ'_2 are the angles that R_1 and R_2 directions make with the z-axis (Figure 9). Using eqn [48], one can then obtain an expression for the spectrum at a point $(\mathbf{r}_1 = \mathbf{r}_2 = \mathbf{r} = r\mathbf{u})$ in the far field $(r \gg \rho_1, \rho_2)$ of a planar source as

$$S^\infty(r\mathbf{u}, \nu) = \frac{k^2}{2\pi^2} \frac{\cos^2\theta}{r^2} \int_\sigma \int_\sigma W_0(\boldsymbol{\rho}_1, \boldsymbol{\rho}_2, \nu) \times e^{-ik\mathbf{u}_\perp \cdot (\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2)} d^2\rho_1 \, d^2\rho_2 \quad [49]$$

where $\mathbf{u}_\perp$ is the projection of the unit vector $\mathbf{u}$ on the plane σ of the source.

Schell-Model Sources

In the framework of coherence theory in space–time domain, two-dimensional planar model sources of this kind were first discussed by Schell. Later, the model was adopted for formulation of coherence theory in space–frequency domain. Schell-model sources are the sources whose degree of spectral coherence $\mu_A(\mathbf{r}_1, \mathbf{r}_2, \nu)$ (for either primary or secondary source) is stationary in space. It means that $\mu_A(\mathbf{r}_1, \mathbf{r}_2, \nu)$ depends on $\mathbf{r}_1$ and $\mathbf{r}_2$ only through the difference $\mathbf{r}_2 - \mathbf{r}_1$, i.e., of the form:

$$\mu_A(\mathbf{r}_1, \mathbf{r}_2, \nu) \equiv \mu_A(\mathbf{r}_2 - \mathbf{r}_1, \nu) \quad [50]$$

for each frequency ν present in the source spectrum. Here A stands for field variables V, in the case of a Schell-model secondary source and for source variables Q, in the case of a Schell-model primary source. The cross-spectral density function of a Schell-model source is of the form:

$$W_A(\mathbf{r}_1, \mathbf{r}_2, \nu) = [S_A(\mathbf{r}_1, \nu)]^{1/2} [S_A(\mathbf{r}_2, \nu)]^{1/2} \mu_A(\mathbf{r}_2 - \mathbf{r}_1, \nu) \quad [51]$$

where $S_A(\mathbf{r}, \nu)$ is the spectral density of the light at a typical point in the primary source or on the plane of a secondary source. Schell model sources do not assume low coherence, and therefore, can be applied to spatially stationary light fields of any state of coherence. The Schell-model of the form given in eqn [51] has been used to represent both three-dimensional primary sources and two-dimensional secondary sources.

Quasi-Homogeneous Sources

Useful models of partially coherent sources that are frequently encountered in nature or in the laboratory are the so-called quasi-homogeneous sources. These are an important sub-class of Schell-model sources. A Schell-model source is called quasi-homogeneous if the intensity of a Schell model source is essentially constant over any coherence area. Under these approximations, the cross-spectral density function for a quasi-homogeneous source is given by

$$W_A(\mathbf{r}_1, \mathbf{r}_2, \nu) = S_A\left[\tfrac{1}{2}(\mathbf{r}_1 + \mathbf{r}_2), \nu\right] \mu_A(\mathbf{r}_2 - \mathbf{r}_1, \nu) = S_A[\mathbf{r}, \nu] \mu_A(\mathbf{r}', \nu) \quad [52]$$

where $\mathbf{r} = (\mathbf{r}_1 + \mathbf{r}_2)/2$, and $\mathbf{r}' = \mathbf{r}_2 - \mathbf{r}_1$. The subscript A stands for either V or Q for the field variable or a source variable, respectively. It is clear that for a quasi-homogeneous source the spectral density $S_A(\mathbf{r}, \nu)$ varies so slowly with position that it is approximately constant over distances across the sources that are of the order of the correlation length Λ, which is a measure of the effective width of $|\mu_A(\mathbf{r}', \nu)|$. Therefore, $S_A(\mathbf{r}, \nu)$ is a slowly varying function of $\mathbf{r}$ (Figure 10b) and $|\mu_A(\mathbf{r}', \nu)|$ is a fast varying function of $\mathbf{r}'$ (Figure 10a). In addition, the linear dimensions of the source are large compared with the wavelength of light and with the correlation length Δ (Figure 10c).

Quasi-homogeneous sources are always spatially incoherent in the 'global' sense, because their linear dimensions are large compared with the correlation length. This model is very good for representing two-dimensional secondary sources with sufficiently low coherence such that the intensity does not vary over the coherence area on the input plane. It has also been applied to three-dimensional primary sources,

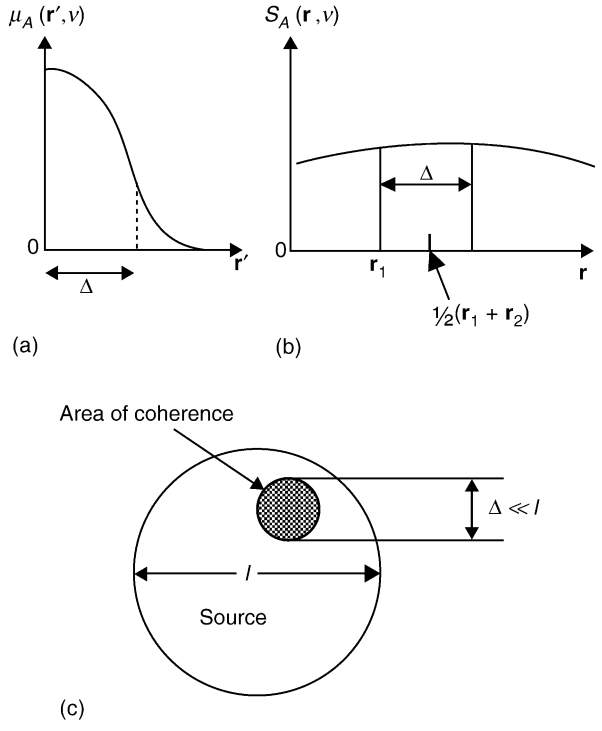

Figure 10 Concept of quasi-homogeneous sources.

three-dimensional scattering potentials, and two-dimensional primary and secondary sources.

Equivalence Theorems

The study of partially coherent sources led to the formulations of a number of equivalence theorems, which show that sources of any state of coherence can produce the same distribution of the radiant intensity as a fully spatially coherent laser source. These theorems provide conditions under which sources of different spatial distribution of spectral density and of different state of coherence will generate fields, which have the same radiant intensity. It has been shown, by taking examples of Gaussian–Schell model sources, that sources of completely different coherence properties and different spectral distributions across the source generate identical distribution of radiant intensity. Experimental verifications of the results of these theorems have also been carried out. For further details on this subject, the reader is referred to Mandel and Wolf (1995).

Correlation-Induced Spectral Changes

It was assumed that spectrum is an intrinsic property of light that does not change as the radiation propagates in free-space, until studies on partially coherent sources and radiations from them in 1980s, revealed that this was true only for specific type of sources. It was discovered on general grounds that the spectrum of light, which originates in an extended source, either a primary source or a secondary source, depends not only on the source spectrum but also on the spatial coherence properties of the source. It was also predicted theoretically by Wolf that the spectrum of light would, in general, be different from the spectrum of the source, and be different at different points in space on propagation in free space.

For a quasi-homogeneous planar secondary source defined by eqn [52], whose normalized spectrum is the same at each source point, one can write the spectral density as

$$S_0(\boldsymbol{\rho}, \nu) = I_0(\boldsymbol{\rho}) g_0(\nu) \quad \text{with} \quad \int_0^\infty g_0(\nu) \mathrm{d}\nu = 1 \qquad [53]$$

where $I_0(\boldsymbol{\rho})$ is the intensity of light at point $\boldsymbol{\rho}$ on the plane of the source, $g_0(\nu)$ is the normalized spectrum of the source and the subscript 0 refers to the quantities of the source plane. Using eqn [49], one can obtain an expression for the far-field spectrum due to this source as

$$S^{\infty}(r\mathbf{u}, \nu) = \frac{k^2}{2\pi^2} \frac{\cos^2 \theta}{r^2} \int_\sigma \int_\sigma I_0(\boldsymbol{\rho}) g_0(\nu) \mu_0(\boldsymbol{\rho}', \nu) \times \mathrm{e}^{-\mathrm{i}k\mathbf{u}_\perp \cdot (\boldsymbol{\rho}_1 - \boldsymbol{\rho}_2)} \, \mathrm{d}^2\rho_1 \, \mathrm{d}^2\rho_2 \qquad [54]$$

Noting that $\boldsymbol{\rho} = (\boldsymbol{\rho}_1 + \boldsymbol{\rho}_2)/2$ and $\boldsymbol{\rho}' = \boldsymbol{\rho}_2 - \boldsymbol{\rho}_1$, one can transform the variables of the integration and obtain after some manipulation:

$$S^{(\infty)}(r\mathbf{u}, \nu) = \frac{k^2 \cos^2 \theta}{(2\pi r)^2} \tilde{I}_0 \tilde{\mu}_0(k\mathbf{u}_\perp, \nu) g_0(\nu) \qquad [55]$$

where

$$\tilde{\mu}_0(k\mathbf{u}_\perp, \nu) = \int_\sigma \mu_0(\boldsymbol{\rho}', \nu) \mathrm{e}^{-\mathrm{i}k\mathbf{u}_\perp \cdot \boldsymbol{\rho}'} \, \mathrm{d}^2\rho' \qquad [56]$$

and

$$\tilde{I}_0 = \int_\sigma I_0(\boldsymbol{\rho}) \mathrm{d}^2\rho \qquad [57]$$

Equation [55] shows that the spectrum of the field in the far-zone depends on the coherence properties of the source through its spectral degree of coherence $\mu_0(\boldsymbol{\rho}', \nu)$ and on the normalized source spectrum $g_0(\nu)$.

Scaling Law

The reason why coherence-induced spectral changes were not observed until recently is that the usual thermal sources employed in laboratories or

commonly encountered in nature have special coherence properties and the spectral degree of coherence has the function form:

$$\mu^{(0)}(\boldsymbol{\rho}_2-\boldsymbol{\rho}_1,\nu)=f[k(\boldsymbol{\rho}_2-\boldsymbol{\rho}_1)] \quad \text{with} \quad k=\frac{2\pi\nu}{c} \qquad [58]$$

which shows that the spectral degree of coherence depends only on the product of the frequency and space coordinates. This formula expresses the so-called scaling law, which was enunciated by Wolf. Commonly used sources satisfy this property. For example, the spectral degree of coherence of Lambertian sources and black-body sources can be shown to be

$$\mu_0(\boldsymbol{\rho}_2-\boldsymbol{\rho}_1,\nu)=\frac{\sin(k|\boldsymbol{\rho}_2-\boldsymbol{\rho}_1|)}{k|\boldsymbol{\rho}_2-\boldsymbol{\rho}_1|} \qquad [59]$$

This expression evidently satisfies the scaling law. If the spectral degree of coherence does not satisfy the scaling law, the normalized far-field spectrum will, in general, vary in different directions in the far-zone and will differ from the source spectrum.

Spectral Changes in Young's Interference Experiment

Spectral changes in Young's interference experiment with broadband light are not as well understood as in experiments with quasi-monochromatic, probably because in such experiments no interference fringes are formed. However, if one were to analyze the spectrum of the light in the region of superposition, one would observe changes in the spectrum of light in the region of superposition in the form of a shift in the spectrum for narrowband spectrum and spectral modulation for broadband light. One can readily derive an expression for the spectrum of light in the region of superposition. Let $S^{(1)}(P,\nu)$ be the spectral density of the light at P which would be obtained if the small aperture at P_1 alone was open; $S^{(2)}(P,\nu)$ has a similar meaning if only the aperture at P_2 was open (Figure 4).

Let us assume, as is usually the case, that $S^{(2)}(P,\nu)\approx S^{(1)}(P,\nu)$ and let d be the distance between the two pinholes. Consider the spectral density at the point P, at distance x from the axis of symmetry in an observation plane located at distance of R from the plane containing the pinholes. Assuming that $x/R \ll 1$, one can make the approximation $R_2 - R_1 \approx xd/R$. The spectral interference law (eqn [38]) can then be written as

$$S(P,\nu)\approx 2S^{(1)}(P,\nu)\{1+|\mu(P_1,P_2,\nu)| \times\cos[\beta(P_1,P_2,\nu)+2\pi\nu xd/cR]\} \qquad [60]$$

where $\beta(P_1,P_2,\nu)$ denotes the phase of the spectral degree of coherence. Equation [60] implies the two results:

(i) at any fixed frequency ν, the spectral density varies sinusoidally with the distance x of the point from the axis, with the amplitude and the phase of the variation depending on the (generally complex) spectral degree of coherence $\mu(P_1,P_2,\nu)$; and
(ii) at any fixed point P in the observation plane the spectrum $S(P,\nu)$ will, in general, differ from the spectrum $S^{(1)}(P,\nu)$, the change also depending on the spectral degree of coherence $\mu(P_1,P_2,\nu)$ of the light at the two pinholes.

Experimental Confirmations

Experimental tests of the theoretical prediction of spectral invariance and noninvariance due to correlation of fluctuations across the source were performed just after the theoretical predictions. Figure 11 shows results of one such experiment in which spectrum changes in the Young's experiment were studied. Several other experiments also reported confirmation of the source correlation-dependent spectral changes. One of the important applications of these observations has been to explain the discrepancies in the maintenance of the spectroradiometric scales by national laboratories in different countries. These studies also have potential application in determining experimentally the spectral degree of coherence of partially coherent fields. The knowledge of spectral degree of coherence is often important in remote sensing, e.g., for determining angular diameters of stars.

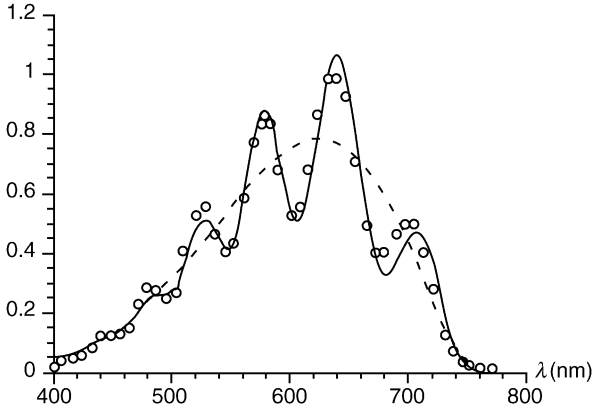

Figure 11 Correlation-induced changes in spectrum in Young's interference. Dashed line represents the spectrum when only one of the slits is open, the continuous curve shows the spectrum when both the slits are open and the circles are the measured values in the latter case. Applications of Optical Coherence

Stellar Interferometry

The Michelson stellar interferometer, named after Albert Michelson, was used to determine the angular diameters of stars and also the intensity distribution across the star. The method was devised by Michelson without using any concept of coherence, although subsequently the full theory of the method was developed on the basis of propagation of correlations. A schematic of the experiment is shown in Figure 12. The interferometer is mounted in front of a telescope, a reflecting telescope in this case. The light from a star is reflected from mirrors M_1 and M_2 and is directed towards the primary mirror (or the objective lens) of the telescope. The two beams thus collected superpose in the focal plane F of telescope where an image crossed with fringes is formed. The outer mirrors M_1 and M_2 can be moved along the axis defined as $M_1M_3M_4M_2$ while the inner mirrors M_3 and M_4 remain fixed. The fringe spacing depends on the position of mirrors M_3 and M_4 and hence is fixed, while the visibility of the fringes depends on the separation of the mirrors M_1 and M_2 and hence, can be varied. Michelson showed that from the measurement of the variation of the visibility with the separation of the two mirrors, one could obtain information about the intensity distribution of the stars, which are rotationally symmetric. He also showed that if the stellar disk is circular and uniform, the visibility curve as a function of the separation d of the mirrors M_1 and M_2 will have zeros for certain values of d, and that the smallest of these d values for which zero occurs is given by $d_0 = 0.61\lambda_a/\alpha$, where α is the semi-angular diameter of the star and λ_a is the mean wavelength of the filtered quasi-monochromatic light from the star. Angular diameters of several stars down to 0.02 second of an arc were determined.

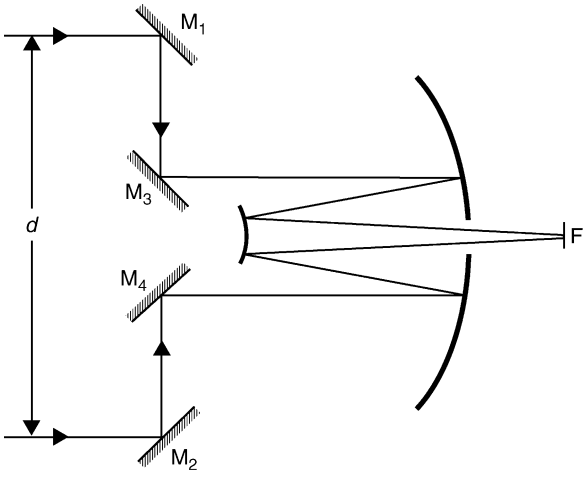

Figure 12 Schematic of the Michelson stellar interferometer.

From the standpoint of second-order coherence theory the principles of the method can be readily understood. The star is considered an incoherent source and according to the van Cittert–Zernike theorem, the light reaching the outer mirrors M_1 and M_2 of the interferometer will be partially coherent. This coherence would depend on the size of and the intensity distribution across the star. Let (x_1, y_1) and (x_2, y_2) be the coordinates of the positions of the mirrors M_1 and M_2, respectively, and (ξ, η) the coordinates of a point on the surface plane of the star which is assumed to be at a very large (astronomical) distance R from the mirrors. The complex degree of coherence at the mirrors would then be given by eqn [22] which can now be written as

$$\gamma(\Delta x, \Delta y, 0) = \frac{\int_\sigma I(u,v)\mathrm{e}^{-\mathrm{i}k_a(u\Delta x + v\Delta y)}\,\mathrm{d}u\,\mathrm{d}v}{\int_\sigma I(u,v)\mathrm{d}u\,\mathrm{d}v} \qquad [61]$$

where $I(u, v)$ is the intensity distribution across the star disk σ as a function of the angular coordinates $u = \xi/R$, $v = \eta/R$, $\Delta x = x_1 - x_2$, $\Delta y = y_1 - y_2$, and $k_a = 2\pi/\lambda_a$, λ_a being the mean wavelength of the light from the star. Equation [61] shows that the equal-time ($\tau = 0$) complex degree of coherence of the light incident at the outer mirrors of the interferometer is the normalized Fourier-transform of the intensity distribution across the stellar disk. Further, eqn [15] shows that the visibility of the interference fringes is the absolute value of γ, if the intensity of the two interfering beams is equal, as in the present case. The phase of γ can be determined by the position of the intensity maxima of the fringe pattern (eqn [14]). If one is interested in determining only the angular size of the star and the star is assumed to be a circularly symmetric disk of angular diameter 2α and of uniform intensity [$I(u, v)$ is constant across the disk], then eqn [61] reduces to

$$\gamma(\Delta x,\Delta y)=\frac{2J_1(v)}{v}, \quad v=\frac{2\pi\alpha}{\lambda_a}d, \quad d=\sqrt{(\Delta x)^2+(\Delta y)^2} \qquad [62]$$

The smallest separation of the mirrors for which the visibility γ vanishes corresponds to $v = 3.832$, i.e., $d_0 = 0.61\lambda_a/\alpha$, which is in agreement with Michelson's result.

Interference Spectroscopy

Another contribution of Michelson, which was subsequently identified as an application of the

coherence theory, was the use of his interferometer (Figure 2) to determine the energy distribution in the spectral lines. The method he developed is capable to resolving spectral lines that are too narrow to be analyzed by the spectrometer. The visibility of the interference fringes depends on the energy distribution in the spectrum of the light and its measurement can give information about the spectral lines. In particular, if the energy distribution in a spectral line is symmetric about some frequency ν_0, its profile is simply the Fourier transform of the visibility variation as a function of the path difference between the two interfering beams. This method is the basis of interference spectroscopy or the Fourier transform spectroscopy.

Within the framework of second-order coherence theory, if the mean intensity of the two beams in a Michelson's interferometer is the same, then the visibility of the interference fringes in the observation plane is related to the complex degree of coherence of light at a point at the beamsplitter where the two beams superimpose (eqn [15]). The two quantities are related as $v(\tau) = |\gamma(\tau)|$ where $\gamma(\tau) \equiv \gamma(\mathbf{r}_1, \mathbf{r}_1, \tau)$ is the complex degree of self-coherence at the point $\mathbf{r}_1$ on the beamsplitter. Following eqn [19], $\gamma(\tau)$ can be represented by a Fourier integral as

$$\gamma(\tau) = \int_0^\infty s(\nu)\exp(-\mathrm{i}2\pi\nu\tau)\mathrm{d}\nu \qquad [63]$$

where $s(\nu)$ is the normalized spectral density of the light defined as $s(\nu) = S(\nu)/\int_0^\infty S(\nu)\mathrm{d}\nu$ and $S(\nu) \equiv S(\mathbf{r}_1, \nu) = W(\mathbf{r}_1, \mathbf{r}_1, \nu)$ is the spectral density of the beam at the point $\mathbf{r}_1$. The method is usually applied to very narrow spectral lines for which one can assume that the peak that occurs at ν_0, and $\gamma(\tau)$ can be represented as

$$\begin{aligned} \gamma(\tau) &= \bar{\gamma}(\tau)\exp(-2\pi\mathrm{i}\nu_0\tau) \quad \text{with} \\ \bar{\gamma}(\tau) &= \int_{-\infty}^\infty \bar{s}(\mu)\exp(-\mathrm{i}2\pi\mu\tau)\mathrm{d}\mu \end{aligned} \qquad [64]$$

where $\bar{s}(\mu)$ is the shifted spectrum such that

$$\begin{aligned} \bar{s}(\mu) &= s(\nu_0 + \mu) \quad \mu \geq -\nu_0 \\ &= 0 \qquad\qquad \mu < -\nu_0 \end{aligned}$$

From the above one readily gets

$$v(\tau) = |\gamma(\tau)| = \left| \int_{-\infty}^\infty \bar{s}(\mu)\,\exp(-\mathrm{i}2\pi\mu\tau)\mathrm{d}\mu \right| \qquad [65]$$

If the spectrum is symmetric about ν_0, then $v(\tau)$ would be an even function of τ and the Fourier inversion would give:

$$\bar{s}(\mu) = s(\nu_0 + \mu) = 2\int_0^\infty v(\tau)\cos(2\pi\mu\tau)\mathrm{d}\tau \qquad [66]$$

which can be used to calculate the spectral energy distribution for a symmetric spectrum about ν_0 from the visibility curve. However, for an asymmetric spectral distribution, the visibility and the phase of the complex degree of coherence must be determined as the Fourier transform of the shifted spectrum is no longer real everywhere.

Higher-Order Coherence

So far we have considered correlations of the fluctuating field variables at two space–time $(\mathbf{r}, t)$ points, as defined in eqn [10]. These are termed as second-order correlations. One can extend the concept of correlations to more than two space–time points, which will involve higher-order correlations. For example, one can define the space–time cross correlation function of order (M, N) of the random field $V(\mathbf{r}, t)$, represented by $\Gamma^{(M,N)}$, as an ensemble average of the product of the field $V(\mathbf{r}, t)$ values at N space–time points and $V^*(\mathbf{r}, t)$ at other M points. In this notation, the mutual coherence function as defined in eqn [10] would now be $\Gamma^{(1,1)}$. Among higher-order correlations, the one with $M = N = 2$, is of practical significance and is called the fourth-order correlation function, $\Gamma^{(2,2)}(\mathbf{r}_1, t_1, \mathbf{r}_2, t_2; \mathbf{r}_3, t_3, \mathbf{r}_4, t_4)$. The theory of Gaussian random variables tells us that any higher correlation can be written in terms of second-order correlations over all permutations of pairs of points. In addition, if we assume that $(\mathbf{r}_3, t_3) = (\mathbf{r}_1, t_1)$ and $(\mathbf{r}_4, t_4) = (\mathbf{r}_2, t_2)$, and that the field is stationary, then $\Gamma^{(2,2)}$ is called the intensity–intensity correlation and is given as

$$\begin{aligned} &\Gamma^{(2,2)}(\mathbf{r}_1, \mathbf{r}_2, t_2 - t_1) \\ &= \left\langle V(\mathbf{r}_1, t_1)V(\mathbf{r}_2, t_2)V^*(\mathbf{r}_1, t_1)V^*(\mathbf{r}_2, t_2)\right\rangle \\ &= \left\langle I(\mathbf{r}_1, t_1)I(\mathbf{r}_2, t_2)\right\rangle \\ &= \left\langle I(\mathbf{r}_1, t_1)\right\rangle\left\langle I(\mathbf{r}_2, t_2)\right\rangle\left(1 + |\gamma^{(1,1)}(\mathbf{r}_1, \mathbf{r}_2, t_2 - t_1)|^2\right) \end{aligned} \qquad [67]$$

where

$$\gamma^{(1,1)}(\mathbf{r}_1, \mathbf{r}_2, t_2 - t_1) = \frac{\Gamma^{(1,1)}(\mathbf{r}_1, \mathbf{r}_2, t_2 - t_1)}{[\langle I(\mathbf{r}_1, t_1)\rangle]^{1/2}[\langle I(\mathbf{r}_2, t_2)\rangle]^{1/2}} \qquad [68]$$

We now define fluctuations in intensity at $(\mathbf{r}_j, t_j)$ as

$$\Delta I_j = I(\mathbf{r}_j, t_j) - \langle I(\mathbf{r}_j, t_j)\rangle$$

and then the correlation of intensity fluctuations becomes

$$\begin{aligned}\langle \Delta I_1 \Delta I_2 \rangle &= \langle I(\mathbf{r}_1,t_1) I(\mathbf{r}_2,t_2)\rangle - \langle I(\mathbf{r}_1,t_1)\rangle\langle I(\mathbf{r}_2,t_2)\rangle \\ &= \langle I(\mathbf{r}_1,t_1)\rangle\langle I(\mathbf{r}_2,t_2)\rangle |\gamma^{(1,1)}(\mathbf{r}_1,\mathbf{r}_2,t_2-t_1)|^2\end{aligned} \quad [69]$$

where we have used eqn [67]. Equation [69] forms the basis for intensity interferometry.

Hanbury-Brown and Twiss Experiment

In this landmark experiment conducted both on the laboratory scale and astronomical scale, Hanbury-Brown and Twiss demonstrated the existence of intensity–intensity correlations in terms of the correlations in the photocurrents in the two detectors and thus measured the squared modulus of complex degree of coherence. In the laboratory experiment, the arc of a mercury lamp was focused onto a circular hole to produce a secondary source. The light from this source was then divided equally into two parts through a beamsplitter. Each part was, respectively, detected by two photomultiplier tubes, which had identical square apertures in front. One of the tubes could be translated normally to the direction of propagation of light and was so positioned that its image through the splitter could be made to coincide with the other tube. Thus, by suitable translation a measured separation d between the two square apertures could be introduced. The output currents from the photomultiplier tubes were taken by cables of equal length to a correlator. In the path of each cable a high-pass filter was inserted, so that only the current fluctuations could be transmitted to the correlator. Thus, the normalized correlations between the two current fluctuations:

$$C(d) = \frac{\langle \Delta J_1(t) \Delta J_2(t)\rangle}{\langle [\Delta J_1(t)]^2\rangle^{1/2}\langle [\Delta J_2(t)]^2\rangle^{1/2}} \quad [70]$$

as a function of detector separation d could be measured. Now when the detector response time is much larger than the time-scale of the fluctuations in intensity, then it can be shown that the correlations in the fluctuations of the photocurrent are proportional to the correlations of the fluctuations in intensity of the light being detected. Thus, we would have

$$C(d) \approx \delta |\gamma^{(1,1)}(\mathbf{r}_1,\mathbf{r}_2,0)|^2 \quad [71]$$

where δ is the average number of photocounts of the light of one polarization during the time-scale of the fluctuations (for general thermal sources, this is much less than one). Equation [71] represents the Hanbury-Brown–Twiss effect.

Stellar Intensity Interferometry

Michelson stellar interferometry can resolve stars which have angular sizes of the order of $0.01''$, since for smaller stars, the separation between the primary mirrors runs into several meters and maintaining stability of mirrors such that the optical paths do not change, even by fraction of a wavelength, is extremely difficult. The atmospheric turbulence further adds to this problem and obtaining stable fringe pattern becomes next to impossible for very small stars. Hanbury-Brown and Twiss applied the intensity interferometry based on their photoelectric correlation technique for determining the angular sizes of such stars. Two separate parabolic mirrors collected light from the star and the output of the photodetectors placed at the focus of each mirror was sent to a correlator. The cable lengths were made unequal so as to compensate for the time difference of the light arrival at the two mirrors. The normalized correlation of the fluctuations of the photocurrents was determined as described above. This would give the variation of the modulus-squared degree of coherence as a function of the mirror separation d from which the angular size of the stars can be estimated. The advantage of the stellar intensity interferometer over the stellar (amplitude) interferometer is that the light need not interfere as in the latter, since the photodetectors are mounted directly at the focus of the primary mirrors of the telescope. Thus, the constraint on the large path difference between the two beams is removed and large values of d can now be used. Moreover, the atmosphere turbulence and the mirror movements have very small effect. Stellar angular diameters as small as $0.0004''$ of arc with resolution of $0.00003''$ could be measured by such interferometers.

Introduction

Optical imaging systems are strongly affected by the coherence of the light that illuminates the object of interest. In many cases, the light is approximately coherent or incoherent. These approximations lead to simple mathematical models for the image formation process and allow straightforward analysis and design of such systems. When the light is partially coherent, the mathematical models are more complicated and system analysis and design is more difficult. Partially coherent illumination is often used in microscopy, machine vision, and optical lithography. The intent of this article is to provide the reader with a basic understanding of the effects of coherence on imaging. The information should enable the reader to recognize when coherence effects are present in an imaging system and give insight into when coherence can be modified to improve imaging performance. The material relies mostly on concepts drawn from the Fourier optics perspective of imaging and a rigorous coherence theory treatment is avoided. We encourage the reader to consult the Further Reading list at the end of this article, for more complete definitions of terms for coherence theory. A number of experimental results highlight the effects of spatial coherence of the illumination on image formation. Discussions of the role of coherence in such key applications are interspersed throughout the article.

Image Formation – Ideal and Optimal

An image is typically defined as the reproduction or likeness of the form of an object. An image that is indistinguishable from the original object is generally considered to be ideal. In a general context, the sound of a voice coming from a loudspeaker can be thought of as the image of the sound coming directly from the original speaker's mouth. In optical imaging, the ideal image replicates the light emanating from the object. Taken to the extreme, the ideal image replicates the light leaving the object in terms of intensity, wavelength, polarization, and even coherence. When the final image is viewed by the eye, the ideal image only needs to replicate the spatial distribution of the light leaving the object in terms of color and relative intensity at each point on the object. (In this article, intensity is defined as optical power per unit area (watts per meter squared).)

A general diagram of a direct view image formation system is shown in Figure 1. The condenser optics gathers light from a primary source and illuminates a transmissive object having a complex wave amplitude

transmission of $O(x, y)$. The imaging optics produce an optical image that is viewed directly by the viewer. A growing number of image formation systems now include a solid-state image detector as shown in Figure 2. The raw intensity optical image is converted to an electronic signal that can be digitally processed and then displayed on a monitor. In this system, the spatial intensity distribution emanating from the monitor is the final image. The task of the optical system to the left of the detector is to gather spatial information about the light properties of the object. In fact, the information gathered by the detector includes information about the object, the illumination system, and the image formation optics. If the observer is only interested in the light transmission properties of the object, the effects of the illumination and image formation optics must be well understood. When the light illuminating the object is known to be coherent or incoherent, reasonably simple models for the overall image formation process can be used. More general, partially coherent illumination can produce optically formed images that differ greatly from the intensity pattern leaving the object. Seen from this perspective, partially coherent illumination is an undesirable property that creates nonideal images and complicates the image analysis.

The ideal image as described above is not necessarily the optimum image for a particular task. Consider the case of object recognition when the object has low optical contrast. Using the above definition, an ideal image would mimic the low contrast and render recognition difficult. An image formation system that alters the contrast to improve the recognition task would be better than the so-called ideal image. The image formation system that maximized the appropriate performance metric for a particular recognition task would be considered optimal. In optimizing the indirect imaging system of Figure 2, the designer can adjust the illumination, the imaging optics, and the post-detection processing. In fact, research microscopes often include an adjustment that modifies illumination coherence and often alters the image contrast. Darkfield and phase contrast imaging microscopes usually employ partially coherent illumination combined with pupil modification to view otherwise invisible objects. Seen from this perspective, partially coherent illumination is a desirable property that provides more degrees of freedom to the imaging system designer. Quite often, partially coherent imaging systems provide a compromise between the performance of coherent and incoherent systems.

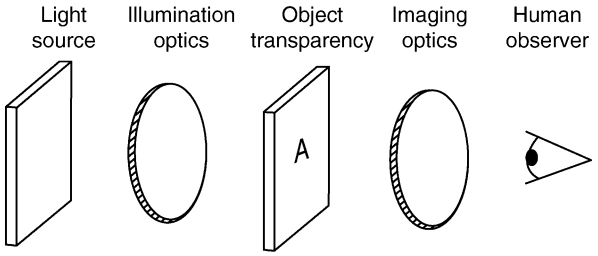

Figure 1 Direct view optical system. Imaging optics conveys the light from an illuminated object directly to the human viewer.

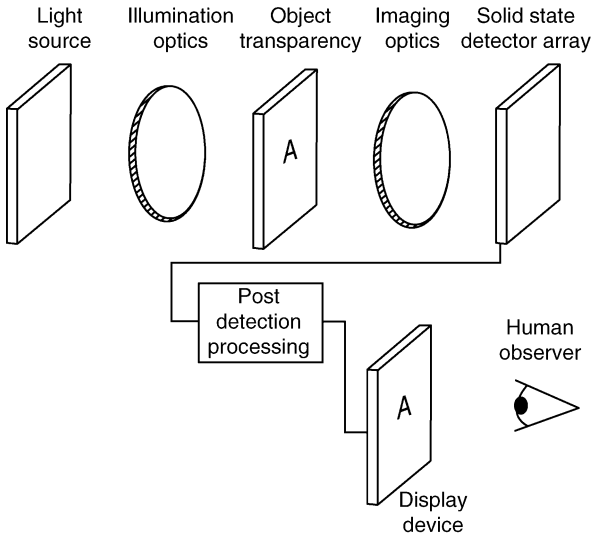

Figure 2 Indirect view optical system. The raw intensity optical image is detected electronically, processed and a final image is presented to the human observer on a display device.

Elementary Coherence Concepts

Most readers are somewhat familiar with the concept of temporal coherence. In Figure 3, a Michelson interferometer splits light from a point source into two paths and recombines the beams to form interference fringes. The presence of interference fringes indicates that the wave amplitude fluctuations of the two beams are highly correlated so the light adds in wave amplitude. If the optical path difference between the two paths can be made large without reducing the fringe contrast, the light is said to be

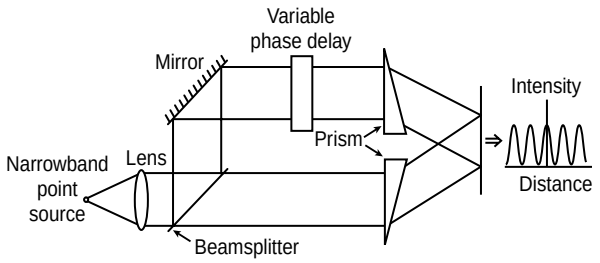

Figure 3 The presence of high contrast fringes in a Michelson interferometer indicates high temporal coherence.

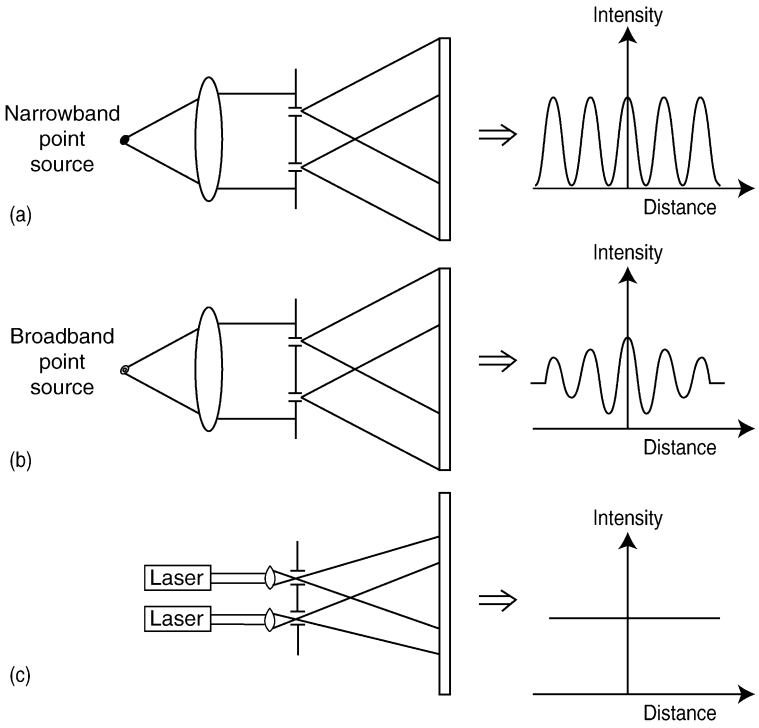

Figure 4 A Young's two pinhole interferometer produces: (a) a uniform high contrast fringe pattern for light that is highly spatially and temporally coherent; (b) high contrast fringes only near the axis for low temporal coherence and high spatial coherence light; and (c) no fringe pattern for high temporal coherence, low spatial coherence light.

highly temporally coherent. Light from very narrowband lasers can maintain coherence over very large optical path differences. Light from broadband light sources requires very small optical path differences to add in wave amplitude.

Spatial coherence is a measure of the ability of two separate points in a field to interfere. The Young's two pinhole experiment in Figure 4 measures the coherence between two points sampled by the pinhole mask. Only a one-dimensional pinhole mask is shown for simplicity. Figure 4a shows an expanded laser beam illuminating two spatially separated pinholes and recombining to form an intensity fringe pattern. The high contrast of the fringe indicates that the wave amplitude of the light from the two pinholes is highly correlated. Figure 4b shows a broadband point source expanded in a similar fashion. The fringe contrast is high near the axis because the optical path difference between the two beams is zero on the axis and relatively low near the axis. For points far from the axes, the fringe pattern disappears because the low temporal coherence from the broadband source results in a loss in correlation of the wave amplitudes.

A final Young's experiment example in Figure 4c shows that highly temporally coherent light can be spatially incoherent. In the figure, the light illuminating the two pinholes comes from two separate and highly temporally coherent lasers that are designed to have the same center frequency. Since the light from the lasers is not synchronized in phase, any fringes that might form for an instant will move rapidly and average to a uniform intensity pattern over the integration time of a typical detector. Since the fringe contrast is zero over a practical integration time, the light at the two pinholes is effectively spatially incoherent.

Two-point Imaging

In a typical partially coherent imaging experiment we need to know how light from two pinholes adds at the optical image plane, as shown in Figure 5. Diffraction and system aberrations cause the image of a single point to spread so that the images of two spatially separated object points overlap in the image plane. The wave amplitude image of a single pinhole is called the coherent point spread function (CPSF). Since the CPSF is compact, two CPSFs will only overlap when the corresponding object points are closely spaced. When the two points are sufficiently close, the relevant optical path differences will be small so full temporal coherence can be assumed. Spatial coherence will be the critical factor in determining how to add the responses to pairs of

point images. We assume full temporal coherence in the subsequent analyses and the light is said to be *quasimonochromatic*.

Coherent Two-Point Imaging

Consider imaging a two-point object illuminated by a spatially coherent plane wave produced from a point source, as depicted in Figure 6a. In the figure, the imaging system is assumed to be space-invariant. This means that the spatial distribution of the CPSF is the same regardless of position of the input pinhole. The CPSF in the figure is broad enough such that the image plane point responses overlap for this particular pinhole spacing. Since the wave amplitudes from the two pinholes are correlated, the point responses add in wave amplitude, resulting in a two-point image intensity given by

$$I_{2\text{coh}}(x) = I_0|h(x - x_1)|^2 + I_0|h(x - x_2)|^2 \qquad [1]$$

where $h(x)$ is the normalized CPSF and I_0 is a scaling factor that determines the absolute image intensity value. Since the CPSF has units of wave amplitude, the magnitude squaring operation accounts for the square law response of the image plane detector.

More generally, the image intensity for an arbitrary object distribution can be found by breaking the object into a number of points and adding the CPSFs due to each point on the object. The resultant image plane intensity is the spatial convolution of the object amplitude transmittance with the CPSF and is given by

$$I_{\text{coh}}(x) = I_0\left|\int O(\xi)h(\xi - x)\mathrm{d}\xi\right|^2 \qquad [2]$$

where $O(x)$ is the object amplitude transmittance.

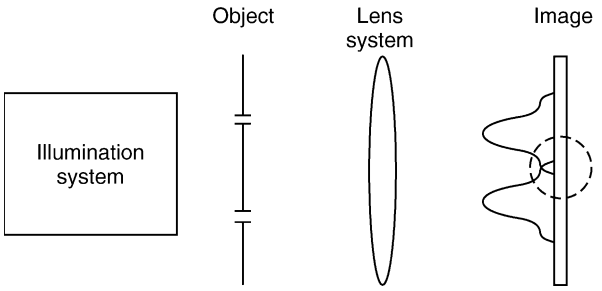

Figure 5 Imaging of two points. The object plane illumination coherence determines how the light adds in the region of overlap of the two image plane points.

Incoherent Two-Point Imaging

Two pinhole imaging with spatially incoherent light is shown in Figure 6b, where a spatially extended blackbody radiator is placed directly behind the pinholes. Once again the imaging optics are assumed to be space-invariant and have the same CPSF as the system in Figure 6a. Since the radiation is originating from two completely different physical points on the source, no correlation is expected between the wave amplitude of the light leaving the pinholes and the light is said to be spatially incoherent. The resultant image intensity corresponding to the two pinhole object with equal amplitude transmittance values is calculated by adding the individual intensity responses to give

$$I_{2\text{inc}}(x) = I_0|h(x - x_1)|^2 + I_0|h(x - x_2)|^2 \qquad [3]$$

For more general object distributions, the image intensity is the convolution of the object intensity transmittance with the incoherent PSF, and is given by

$$I_{\text{inc}}(x) = I_0\int |o(\xi)|^2|h(x - \xi)|^2\mathrm{d}\xi \qquad [4]$$

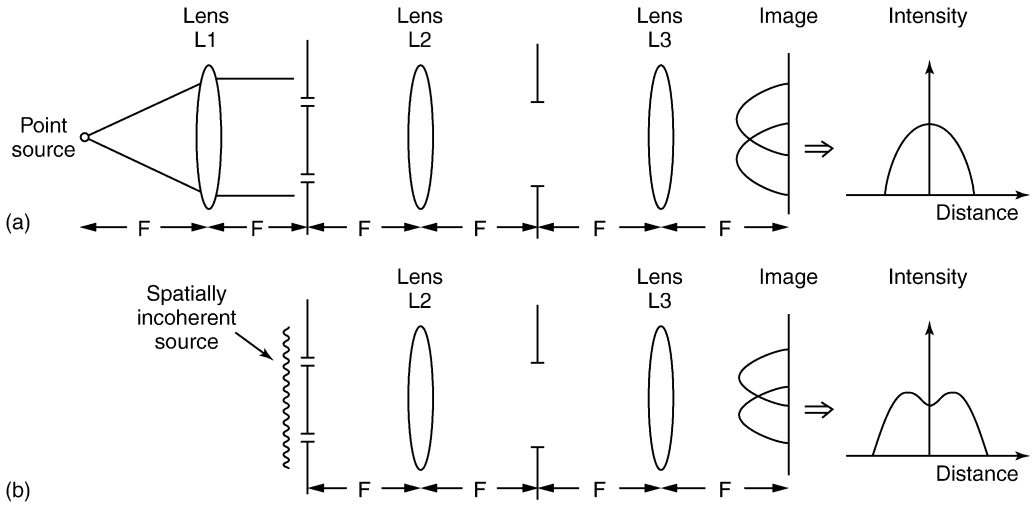

Figure 6 Imaging of two points for (a) spatially coherent illumination and (b) spatially incoherent imaging.

where the intensity transmittance is the squared magnitude of the amplitude transmittance and the incoherent PSF is the squared magnitude of the CPSF.

Partially Coherent Two-Point Imaging

Finally we consider two pinhole imaging illuminated by partially spatially coherent light. Now the two-point responses do not add simply in amplitude or intensity. Rather, the image intensity is given by the more general equation:

$$I_{2pc}(x) = I_0[|h(x-x_1)^2 + |h(x-x_2)|^2 + 2\mathrm{Re}\{\mu(x_1;x_2)h(x-x_1)h^*(x-x_2)\}] \quad [5]$$

where the $*$ denotes complex conjugations and $\mu(x_1;x_2)$ is the normalized form of the mutual intensity of the object illumination evaluated at the object points in question. The mutual intensity function is often denoted as $J_0(x_1;x_2)$ and is a measure of the cross correlation of the wave amplitude distributions leaving the two pinholes. Rather than providing a rigorous definition, we note that the magnitude of $J_0(x_1;x_2)$ corresponds to the fringe contrast that would be produced if the two object pinholes were placed at the input of a Young's interference experiment. The phase is related to the relative spatial shift of the fringe pattern. When the light is uncorrelated, $J_0(x_1;x_2) = 0$ and eqn [5] collapses to the incoherent limit of eqn [4]. When the light is coherent, $J_0(x_1;x_2) = 1$ and eqn [5] reduces to the coherent form of eqn [2].

Image formation for a general object distribution is given by the bilinear equation:

$$I_{pc}(x) = I_0 \int o(\xi_1)o^*(\xi_2)h(x-\xi_1)h^*(x-\xi_2) \times J_o(\xi_1-\xi_2)\mathrm{d}\xi_1\,\mathrm{d}\xi_2 \quad [6]$$

Note that, in general, $J_0(x_1;x_2)$ must be evaluated for all pairs of object points. Close examination of this equation reveals that just as a linear system can be evaluated by considering all possible single point responses, a bilinear system requires consideration of all possible pairs of points. This behavior is much more complicated and does not allow the application of the well-developed linear system theory.

Source Distribution and Object Illumination Coherence

According to eqn [6], the mutual intensity of all pairs of points at the object plane must be known, to calculate a partially coherent image. Consider the telecentric Kohler illumination imaging system shown in Figure 7. The primary source is considered to be spatially incoherent and illuminates the object after passing through lens L1 located one focal distance away from the source and one focal distance away from the object. Even though the primary source is spatially incoherent, the illumination at the object plane is partially coherent. The explicit mutual intensity function corresponding to the object plane illumination is given by applying the van Cittert Zernike theorem:

$$J_0(\Delta x) = \int S(\xi)\exp[\mathrm{j}2\pi\Delta x\xi/\lambda F]\mathrm{d}\xi \quad [7]$$

where $S(x)$ is the intensity distribution of the spatially incoherent primary source, F is the focal length of the lens, λ is the illumination wavelength, and $\Delta x = x_1 - x_2$. The van Cittert Zernike theorem reflects a Fourier transform relationship between the source image intensity distribution and the mutual intensity at the object plane. When the source plane is effectively spatially incoherent, the object plane mutual intensity is only a function of separation distance. For a two-dimensional object, the mutual intensity needs to be characterized for all pairs of unique spacings in x and y. In Figure 7, the lens arrangement ensures that the object plane is located in the far field of the primary source plane. In fact, the van Cittert Zernike theorem applies more generally, even in the Fresnel propagation regime, as long as the standard paraxial approximation for optics is valid.

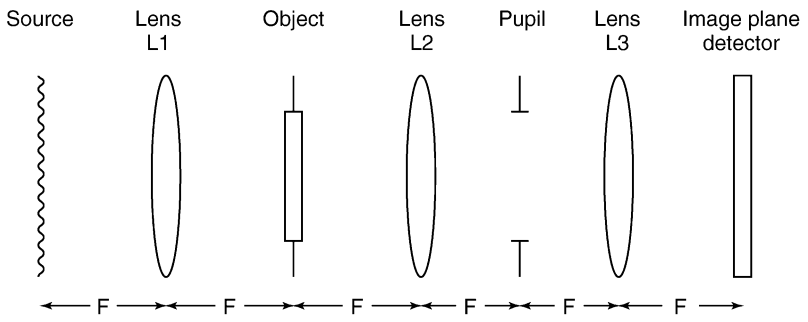

Figure 7 A telecentric Kohler illumination system with a spatially incoherent primary source imaged onto the pupil.

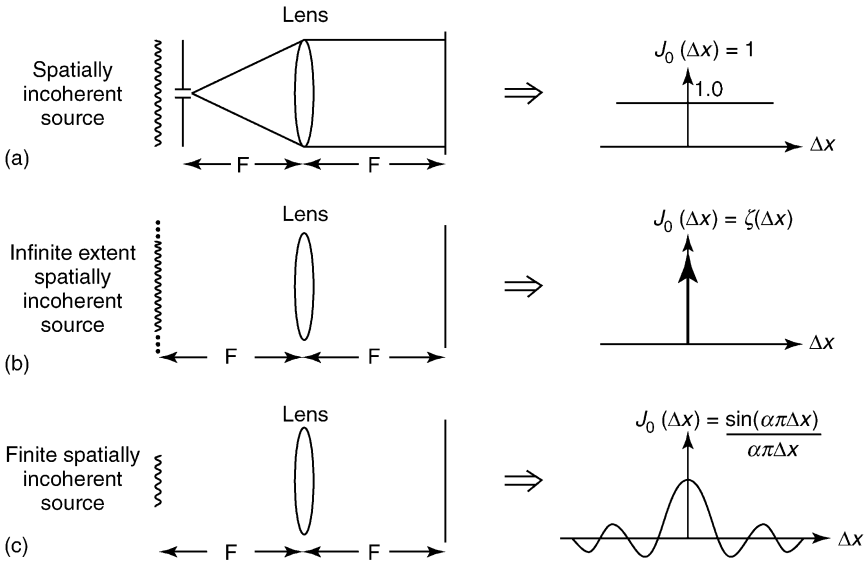

Figure 8 Light propages from the source plane to the object plane and produces (a) coherent illumination from a single source point; (b) incoherent illumination from an infinite extent source; and (c) partially coherent illumination from a finite extent primary source.

Figure 8 shows some simple examples of primary source distributions and the corresponding object plane mutual intensity function. Figure 8a assumes an infinitesimal point source and the corresponding mutual intensity is 1.0 for all possible pairs of object points. Figure 8b assumes an infinite extent primary source and results in a dirac delta function for the mutual intensity function. This means that there is no correlation between any two object points having a separation greater than zero so the object plane illumination is spatially incoherent. In Figure 5c, a finite extent uniform source gives a mutual intensity function of the form $\sin(\alpha\pi\Delta x)/(\alpha\Delta x)$. The finite-sized source corresponds to partially coherent imaging and shows that the response to pairs of points is affected by the spatial distribution of the source in a complicated way. Note that a large primary source corresponds to a large range of angular illumination at the object plane.

Varying the size of the source in the imaging system of Figure 8 will affect the spatial coherence of the illumination and hence the optical image intensity. Many textbook treatments discuss the imaging of two points separated by the Rayleigh resolution criterion which corresponds to the case where the first minimum of one point image coincides with the maximum of the adjacent point image. With a large source that provides effectively incoherent light, the two point image has a modest dip in intensity between the two points, as shown in Figure 9a. Fully coherent illumination of two points separated by the Rayleigh resolution produces a single large spot with no dip in intensity, as shown in Figure 9b. Varying the source size and hence the illumination spatial coherence produces a dip that is less than the incoherent intensity dip. This result is often used to suggest that coherent imaging gives poorer resolution than incoherent imaging. In fact, generalizations about two-point resolution can be misleading.

Recent developments in optical lithography have shown that coherence can be used to effectively increase two-point resolution beyond traditional diffraction limits. In Figure 9c, one of the pinholes in a coherent two-point imaging experiment has been modified with a phase shift corresponding to one half of a wavelength of the illuminating light. The two images add in wave amplitude and the phase shift creates a distinct null at the image plane and effectively enhances the two-point resolution. This approach is termed phase screen lithography and has been exploited to produce finer features in lithography by purposely introducing small phase shift masks at the object mask. In practice, the temporal and spatial coherence of the light is engineered to give sufficient coherence to take advantage of the two-point enhancement while maintaining sufficient incoherence to avoid speckle-like artifacts associated with coherent light.

Spatial Frequency Modeling of Imaging

Spatial frequency models of image formation are also useful in understanding how coherence affects image formation. A spatially coherent imaging system has a particularly simple spatial frequency model. In the

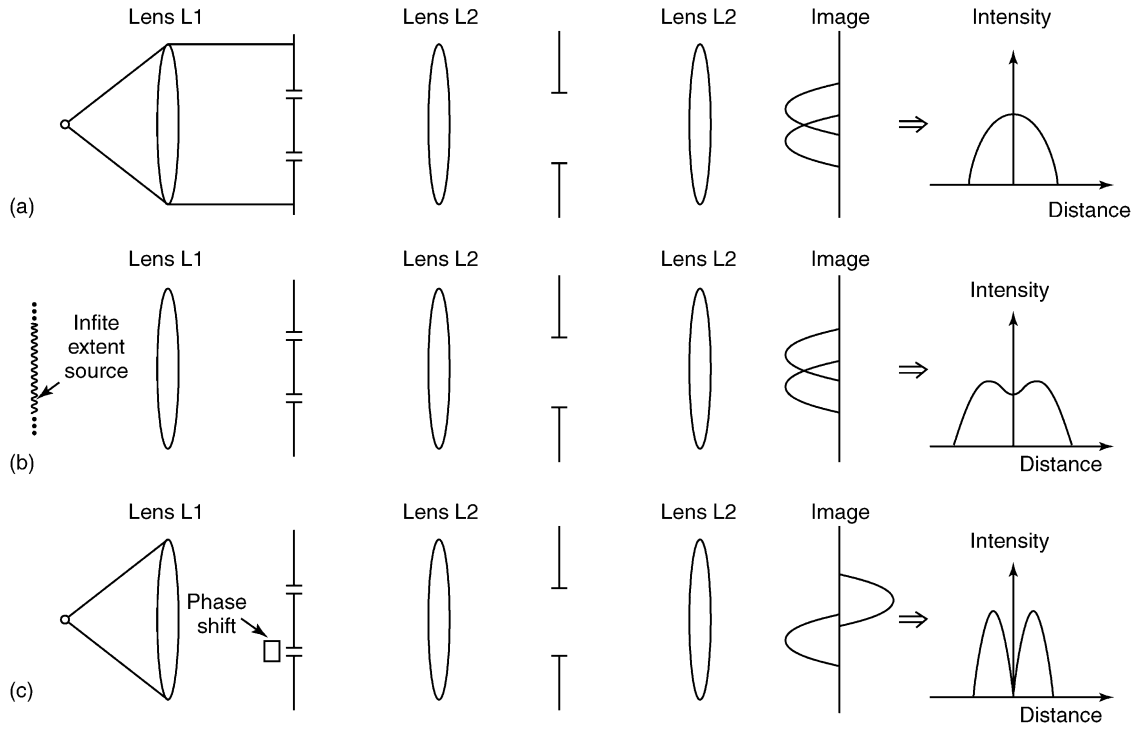

Figure 9 Comparison of coherent and two point imaging of two pinholes separated by the Rayleigh distance. (a) Coherent image cannot resolve the two points. (b) Incoherent image barely resolves the two points. (c) Coherent illumination with a phase shifting plate at one pinhole produces a null between the two image points.

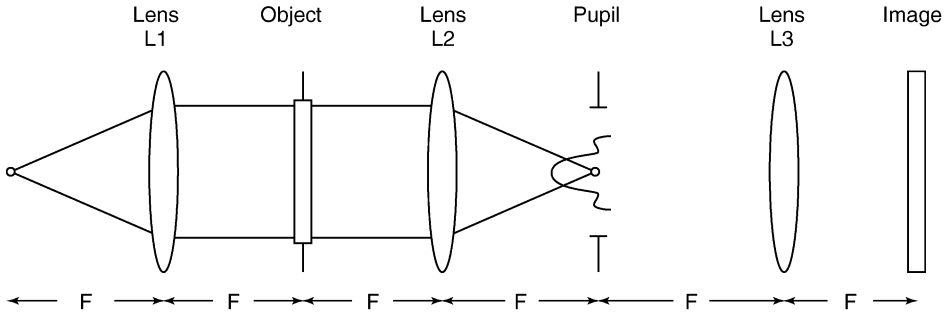

Figure 10 The object Fourier transform is filtered by the pupil function in a coherent imaging system.

spatially coherent imaging system shown in Figure 10, the on-axis plane wave illumination projects the spatial Fourier transform of the object, or Fraunhofer pattern, onto the pupil plane of the imaging system. The pupil acts as a frequency domain filter that can be modified to perform spatial frequency filtering. The complex transmittance of the pupil is the wave amplitude spatial frequency transfer function of the imaging system. It follows that the image plane wave amplitude frequency spectrum, $\tilde{U}_c(f_x)$, is given by

$$\tilde{U}_c(f_x) = \tilde{O}(f_x)H(f_x) \qquad [8]$$

where $\tilde{O}(f_x)$ is the spatial Fourier transform of the object amplitude transmittance function and $H(f_x)$ is proportional to the pupil plane amplitude transmittance. Equation [8] is the frequency domain version of the convolution representation given by eqn [2], but does not account for the squared magnitude response of the detector.

In the previous section, we learned that an infinite extent source is necessary to achieve fully incoherent imaging for the imaging system of Figure 7. As a thought experiment, one can start with a single point source on the axis and keep adding mutually incoherent source points to build up from a coherent imaging system to an incoherent imaging system. Since the individual source points are assumed to be incoherent with each other, the images from each point source can be added in intensity. In Figure 11,

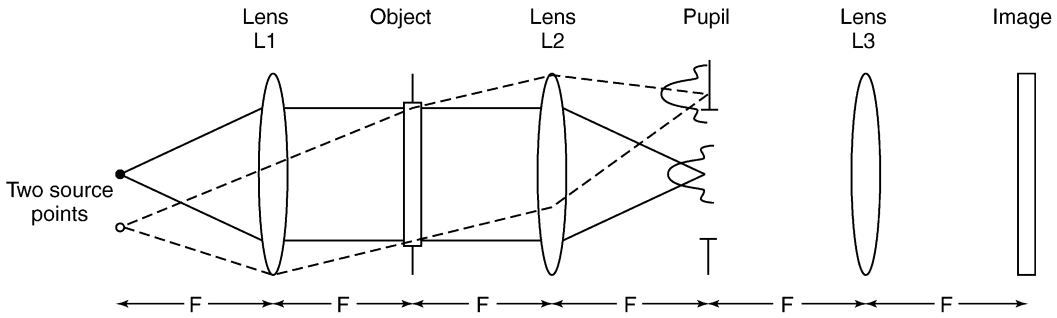

Figure 11 A second source point projects a second object Fourier transform onto the pupil plane. The images produced by the two source points add in intensity at the image plane.

only two point sources are shown. Each point source projects an object Fraunhofer pattern onto the pupil plane. The centered point source will result in the familiar coherent image. The off-axis point source projects a displaced object Fraunhofer pattern that is also filtered by the pupil plane before forming an image of the object. The image formed from this second point source can be modeled with the same coherent imaging model with a shifted pupil plane filter. Since the light from the two source points is uncorrelated, the final image is calculated by adding the intensities of the two coherently formed images.

The two source point model of Figure 11 can be generalized to an arbitrary number of source points. The final image is an intensity superposition of a number of coherent images. This suggests that partially coherent imaging systems behave as a number of redundant coherent imaging systems, each having a slightly different amplitude spatial frequency transfer function due to the relative shift of the pupil filter with respect to the object Fraunhofer pattern. As the number of point sources is increased to infinity, the primary source approaches an infinite extent spatially incoherent source. In practice, the source need not be infinite. When the source is large enough to effectively produce linear-in-intensity imaging, the imaging system is effectively spatially incoherent. The corresponding image intensity in the spatial frequency domain, $\tilde{I}_{\text{inc}}(f_x)$, is given by

$$\tilde{I}_{\text{inc}}(f_x) = \tilde{I}_{\text{obj}}(f_x)\text{OTF}(f_x) \qquad [9]$$

where $\tilde{I}_{\text{obj}}(f_x)$ is the spatial Fourier transform of the object intensity transmittance and $\text{OTF}(f_x)$ is the incoherent optical transfer function which is proportional to the spatial autocorrelation of the pupil function.

Many texts include detailed discussions comparing the coherent transfer function and the OTF and attempt to make comparisons about the relative performance of coherent and incoherent systems. These comparisons are often misleading since one transfer function describes the wave amplitude spatial frequency transfer function and the other describes the intensity spatial frequency transfer function. Here we note that incoherent imaging systems do indeed allow higher object amplitude spatial frequencies to participate in the image formation process. This argument is often used to support the claim that incoherent systems have higher resolution. However, both systems have the same image intensity spatial frequency cutoff. Furthermore, the nature of the coherent transfer function tends to produce high contrast images that are typically interpreted as higher-resolution images than their incoherent counterparts. Perhaps the real conclusion is that the term resolution is not well defined and direct comparisons between coherent and incoherent imaging must be treated carefully.

The frequency domain treatment for partially coherent imaging of two-dimensional objects involves a four-dimensional spatial frequency transfer function that is sometimes called the bilinear transfer function or the transmission cross-coefficient model. This model describes how constituent object wave amplitude spatial frequencies interact to form image plane intensity frequencies. The utility of this approach to analysis is limited for someone new to the field, but is often used in numerical simulations of partially coherent imaging systems used in optical lithography.

Experimental Examples of Important Coherence Imaging Phenomena

Perhaps the best way to gain an understanding of coherence phenomena in imaging is to examine experimental results. In the following section we use experimental data to see how coherence affects edge response, noise immunity, and depth of field. Several experimental configurations were used to collect

the image data, but all of the systems can be represented generically by the Kohler illumination system shown in Figure 12. Kohler illumination is often employed in many projection illumination systems. In order to obtain Kohler illumination, the primary spatially incoherent source is imaged onto the pupil plane of the imaging portion of the system and the object is placed at the pupil plane of the condenser optics.

Primary Source Generation

Figure 13 shows a highly coherent illumination system produced by focusing a laser beam to a point and imaging the focused spot onto the pupil of the imaging system to produce spatially coherent illumination. The use of a laser produces highly temporally coherent light.

Two methods were used to create an extended spatially incoherent primary source with control over the spatial intensity distribution. Figure 14a shows a collimated laser beam with a 633 nm center wavelength illuminating a rotating diffuser. A photographically produced mask defines the spatial shape of the primary source. The laser provides highly temporally coherent light and the diffuser destroys the spatial coherence of the light. Consider the thought experiment of two pinholes placed immediately to the right of the moving diffuser. Without the diffuser, the two wave amplitudes would be highly correlated. Assuming that the diffuser can be modeled as a spatially random phase plate, a fixed diffuser would only introduce a fixed phase difference between the amplitudes leaving the two pinholes and would not destroy the coherence. When the diffuser is rotated, the light from each pinhole encounters a different phase modulation that is changing over time. This random modulation destroys the effective correlation between the wave amplitude of the light leaving the two pinholes provided that the rotation speed is sufficiently fast.

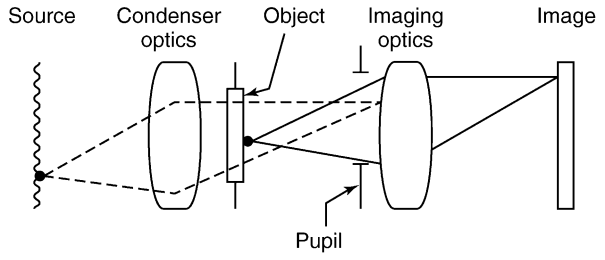

Figure 12 General representation of the Kohler illumination imaging systems used in the experimental result section. The primary incoherent source is imaged onto the imaging system pupil plane and the object resides in the pupil of the condenser optics.

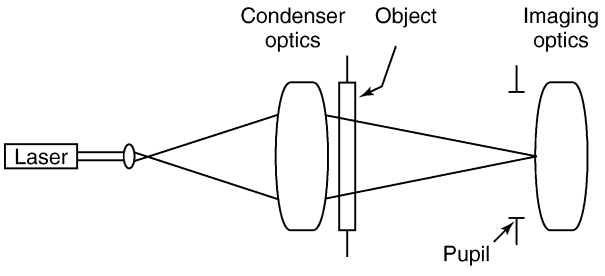

Figure 13 Highly spatially and temporally coherent illumination produced by imaging a focused laser beam into the imaging system pupil.

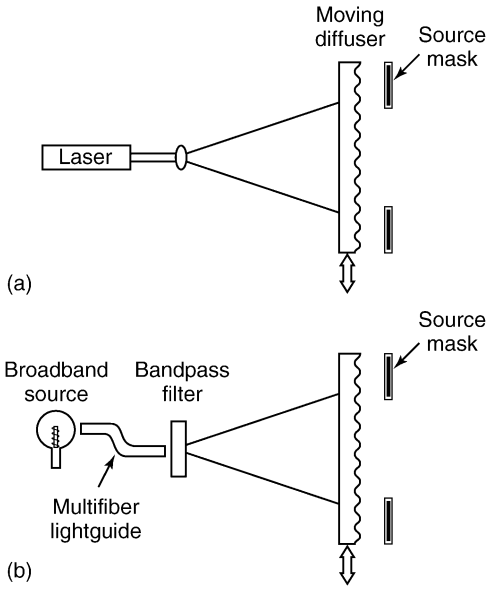

Figure 14 Two methods for generating a spatially incoherent primary source. (a) An expanded laser beam passes through a moving diffuser followed by a mask to define the extent and shape of the source. (b) A broadband source exits a multifiber lightguide and propagates to a moving diffuser followed by a source mask.

The moving diffuser method is light inefficient but is a practical way of exploring coherence in imaging in a laboratory environment. The choice of the diffuser is critical. The diffuser should spread light out uniformly over an angular subtense that overfills the object of interest. Many commercially available diffusers tend to pass too much light in the straight through direction. Engineered diffusers can be purchased to produce an optimally diffused beam. When quick and inexpensive results are required, thin plastic sheets used in day-to-day packaging often serve as excellent diffusers. When the diffusion angles are not high enough, a number of these plastic sheets can be layered on top of each other to achieve the appropriate angular spread.

The second method for producing a spatially incoherent source is shown in Figure 14b. Broadband

light is delivered through a large multifiber lightguide and illuminates a moving diffuser. The main purpose of the diffuser is to ensure that the entire object is illuminated uniformly. The low temporal coherence of the source and the long propagation distances are usually enough to destroy any spatial coherence at the plane of the diffuser. The rotation further ensures that no residual spatial coherence exists at the primary source plane. A chromatic filter centered around 600 nm, with a spectral width of approximately 100 nm, is shown in the light path. The filter was used to minimize the effects of chromatic aberrations in the system. The wide spectral width certainly qualifies as a broadband source in relation to a laser. High-contrast photographically defined apertures determine the spatial intensity distribution at the plane of the primary source. In the following results, the primary source distributions were restricted to circular sources of varying sizes as well as annular sources. These shapes are representative of most of the sources employed in microscopy, machine vision, and optical lithography.

Noise Immunity

Coherent imaging systems are notorious for introducing speckle-like noise artifacts at the image. Dust and optically rough surfaces within an optical system result in a complicated textured image plane intensity distribution that is often called speckle noise. We refer to such effects as coherent artifact noise. **Figure 15a** shows the image of a standard binary target as imaged by a benchtop imaging system, with the highly coherent illumination method shown in **Figure 13**. Some care was taken to clean individual lenses and optical surfaces within the system and no dust was purposely introduced. The image is corrupted by a complicated texture that is due in

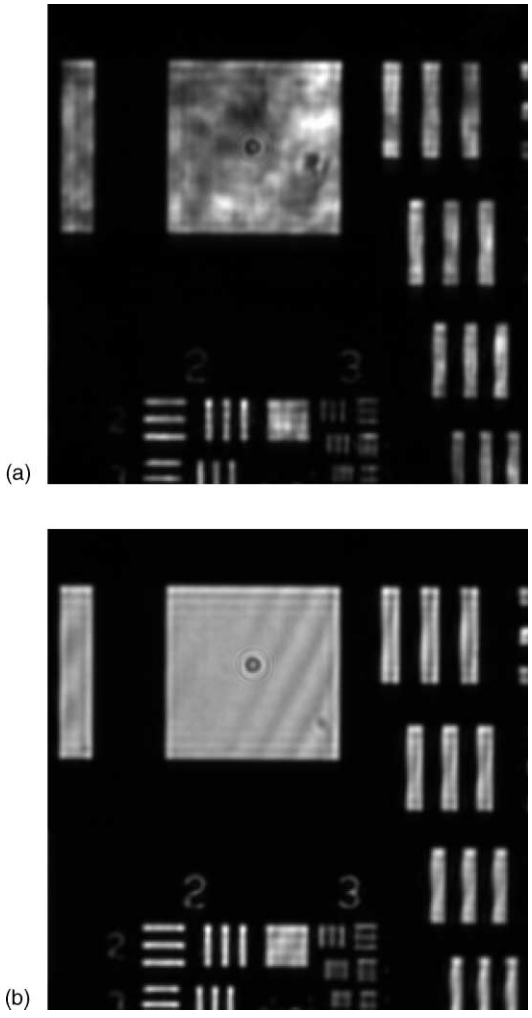

Figure 15 High temporal coherence imaging with disk sources corresponding to (a) extremely high spatial coherence ($K = 0.05$) and (b) slightly reduced but high spatial coherence ($K = 0.1$).

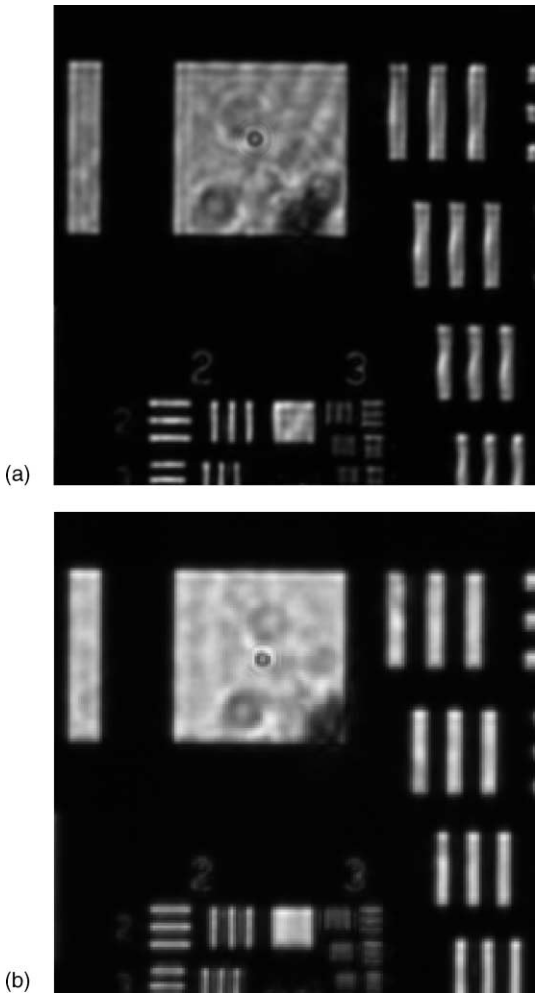

Figure 16 High spatial coherence disk illumination ($K = 0.1$) imaging through a dust covered surface with (a) narrowband laser illumination and (b) with broadband illumination.

part to imperfections in the laser beam itself and in part to unwanted dust and optically rough surfaces. Certainly, better imaging performance can be obtained with more attention to surface cleanliness and laser beam filtering, but the result shows that it can be difficult to produce high-quality coherent images in a laboratory setting.

Lower temporal coherence and lower spatial coherence will reduce the effect of speckle noise. The image of Figure 15b was obtained with laser illumination according to Figure 14a with a source mask corresponding to a source to pupil diameter ratio of $K = 0.1$. The object plane illumination is still highly temporally coherent and the spatial coherence has been reduced but is still very high. The artifact noise has been nearly eliminated by the modest reduction of spatial coherence. The presence of diagonal fringes in some regions is a result of multiple reflections produced by the cover glass in front of the CCD detector. The reflections produce a weak secondary image that is slightly displaced from the main image and the high temporal coherence allows the two images to interfere.

The noise performance was intentionally perturbed in the image of Figure 16a by inserting a slide with a modest sprinkling of dust at an optical surface in between the object and the pupil plane. The illumination conditions are the same as for the image of Figure 15b. The introduction of the dust has further degraded the image. The image of Figure 16b maintains the same spatial coherence ($K = 0.1$) but employs the broadband source. The lower temporal coherence eliminates the unwanted diagonal fringes but the speckle noise produced by the dust pattern does not improve significantly relative to the laser illumination $K = 0.1$ system. Figures 17a–c show that increasing the source size (and hence the range of angular illumination) reduces

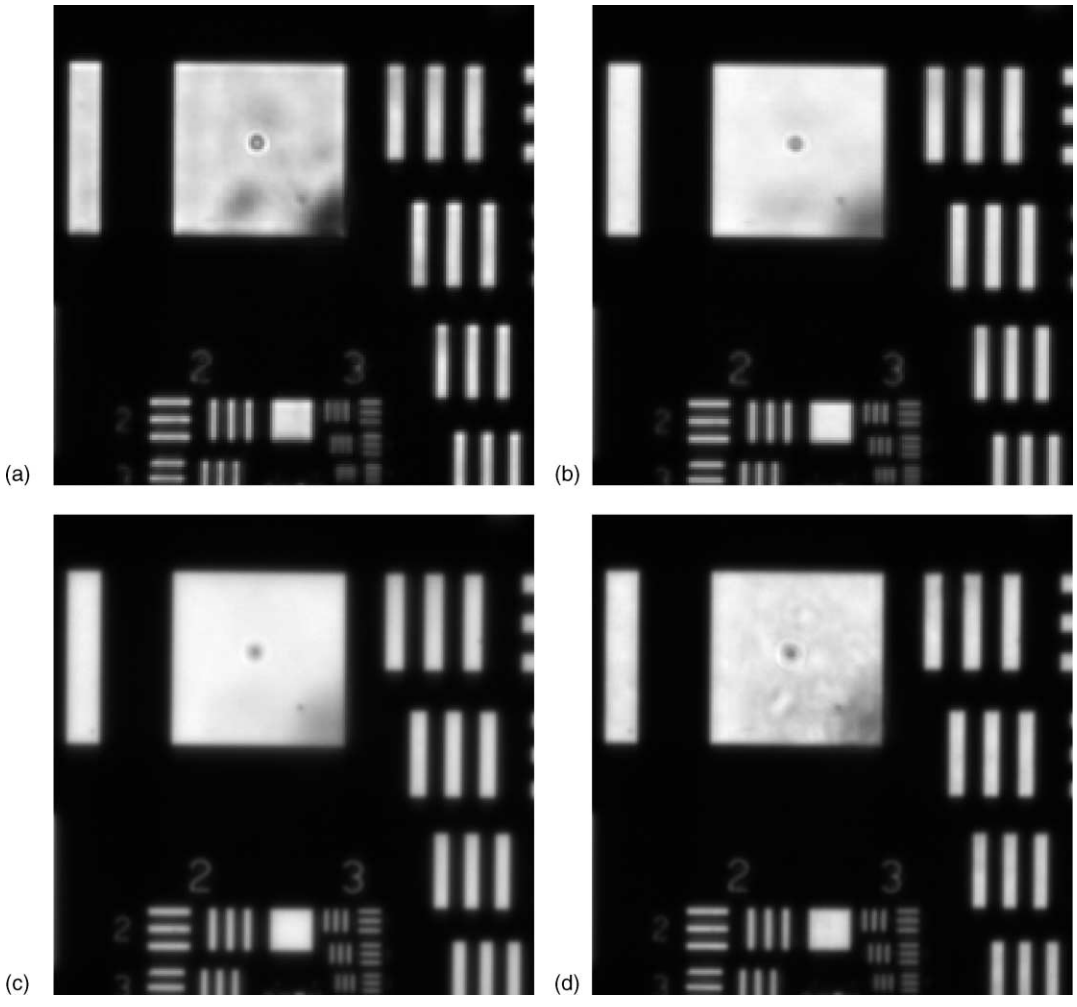

Figure 17 Low temporal coherence imaging through a dust-covered surface with various source sizes and shapes: (a) disk source with $K = 0.3$; (b) disk source with $K = 0.7$; (c) disk source with $K = 2.0$; and (d) a thin annular source with an outer diameter corresponding to $K = 0.5$ and inner diameter corresponding to $K = 0.45$.

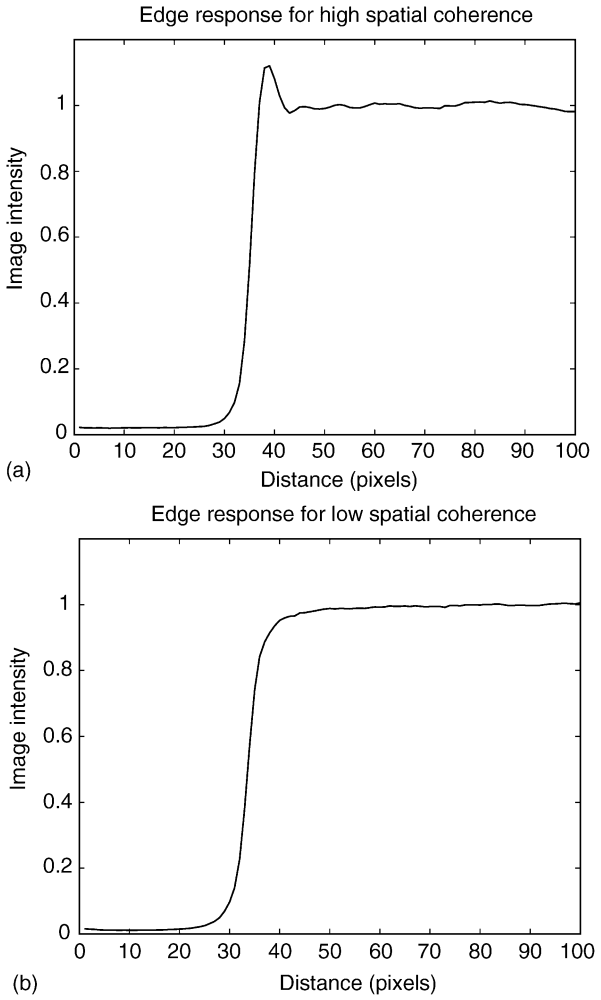

Figure 18 Slices of edge intensity images of high contrast edges taken by a laboratory system with low temporal coherence and (a) high spatial coherence (disk source with $K = 0.1$) and (b) effectively incoherent (disk source with $K = 2$).

the spatial coherence and virtually eliminates the unwanted speckle pattern. Finally, Figure 17d shows that an annular source can also provide some noise immunity. The amount of noise immunity is related to the total area of the source rather than the outer diameter of annular source. Seen from the spatial frequency model, each source point produces a noise-corrupted coherent image. Since the effect of the noise is different for each coherent image, the image plane noise averages out as the images add incoherently. This perspective suggests that an extended source provides redundancy in the transfer of object information to the image plane.

Edge Response

Spatial coherence has a strong impact on the images of edges. The sharp spatial frequency cutoff of spatially coherent imaging systems creates oscillations at the images of an edge. Figure 18 shows slices of experimentally gathered edge imagery as a function of the ratio of source diameter to pupil diameter. Higher coherence systems produce sharper edges, but tend to have overshoots. The sharper edges contribute to the sense that high-coherence systems produce higher-resolution images. One advantage to an incoherent imaging system is that the exact location of the edge corresponds to the 50% intensity location. The exact location of an edge in a partially coherent imaging system is not as easily determined. The presence or lack of edge ringing can be used to assess whether a given imaging system can be modeled as spatially incoherent or partially coherent.

Depth of Field

Coherent imaging systems exhibit an apparent increase in depth-of-field compared to spatially incoherent systems. Figure 19 shows spatially incoherent imagery for four different focus positions. Figure 20 shows imagery with the same amount of defocus produced with highly spatially coherent light. Finally, Figure 21 gives an example of how defocused imagery depends on the illumination coherence. The images of a spoke target were all gathered with a fixed amount of defocus and the source size was varied to control the illumination coherence. The images of Figure 21 differ greatly, even though the CPSF was the same for all the cases.

Digital Post-detection Processing and Partial Coherence

The model of Figure 2 suggests that post-detection image processing can be considered as part of the image formation system. Such a general view can result in imaging that might be otherwise unobtainable by classical means. In fact, microscopists routinely use complicated deblurring methods to reconstruct out-of-focus imagery and build up three-dimensional images from multiple image slices.

The coherence of the illumination should be considered when undertaking such image restoration. Rigorous restoration of partially coherent imagery is computationally intensive and requires precise knowledge of the coherence. In practice, a linear-in-intensity model for the image formation is almost always used in developing image restoration algorithms. Even nonlinear restoration algorithms have built-in linear assumptions about the image formation models which imply spatially incoherent illumination.

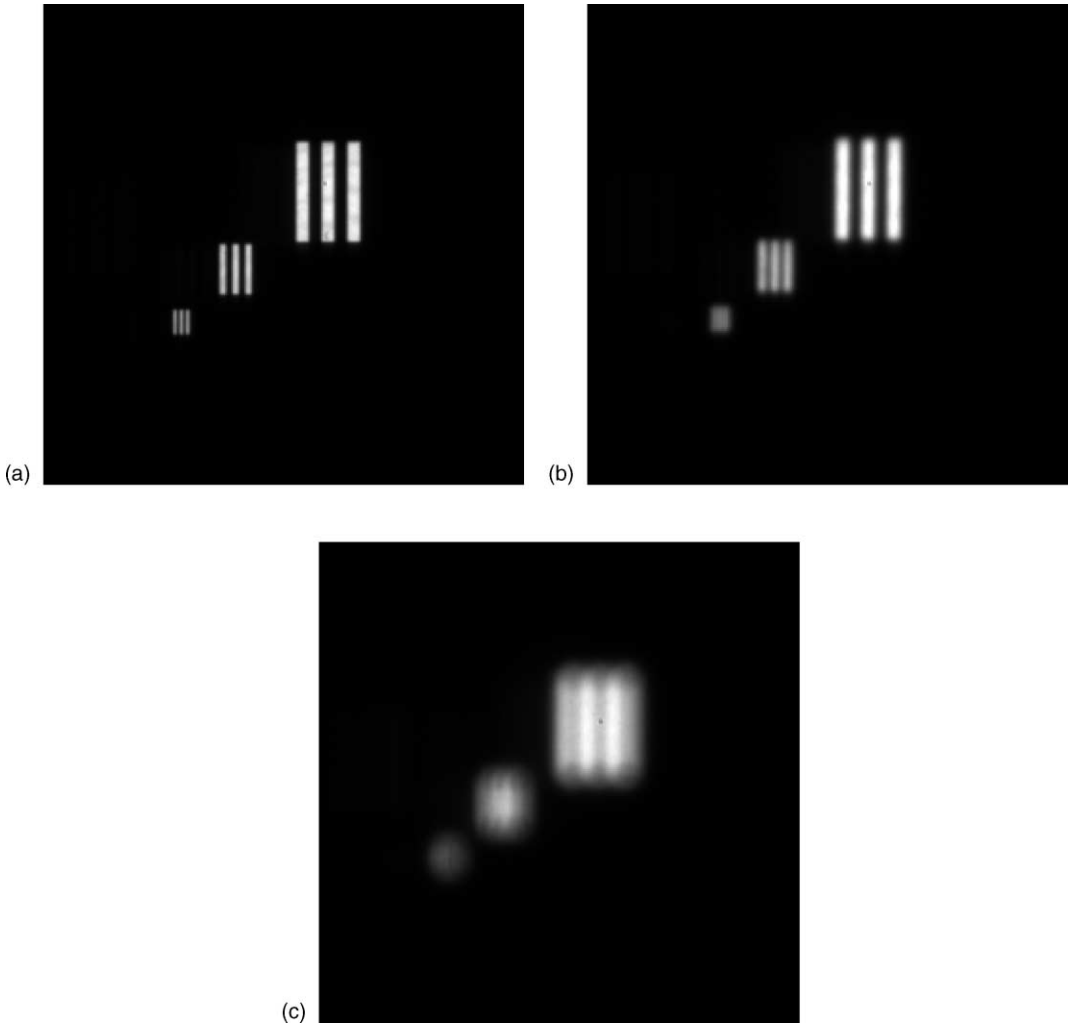

Figure 19 Spatially incoherent imaging for (a) best focus, (b) moderate misfocus, and (c) high misfocus.

The images of Figures 22a and b are digitally restored versions of the images of Figure 19b and Figure 20b. The point spread function was directly measured and used to create a linear restoration filter that presumed spatially incoherent illumination. The restored image in Figure 22a is faithful since the assumption of spatially incoherent light was reasonable. The restored image of Figure 22b suffers from a loss in fidelity since the actual illumination coherence was relatively high. The image is visually pleasing and correctly conveys the presence of three bar targets. However, the width of the bars is not faithful to the original target which had spacings equal to the widths of the bars.

As discussed earlier, the ideal image is not always the optimal image for a given task. In general, restoration of partially coherent imaging with an implicit spatially incoherent imaging model will produce visually pleasing images that are not necessarily faithful to the object plane intensity. While they are not faithful, they often preserve and even enhance edge information and the overall image may appear sharper than the incoherent image. When end task performance is improved, the image may be considered to be more optimal than the ideal image. It is important to keep in mind that some of the spatial information may be misleading and a more complete understanding of the coherence may be needed for precise image plane measurements. This warning is relevant in microscopy where the user is often encouraged to increase image contrast by reducing illumination spatial coherence. Annular sources can produce highly complicated spatial coherence functions that will strongly impact the restoration of such images.

Summary and Discussion

The coherence of the illumination at the object plane is important in understanding image formation.

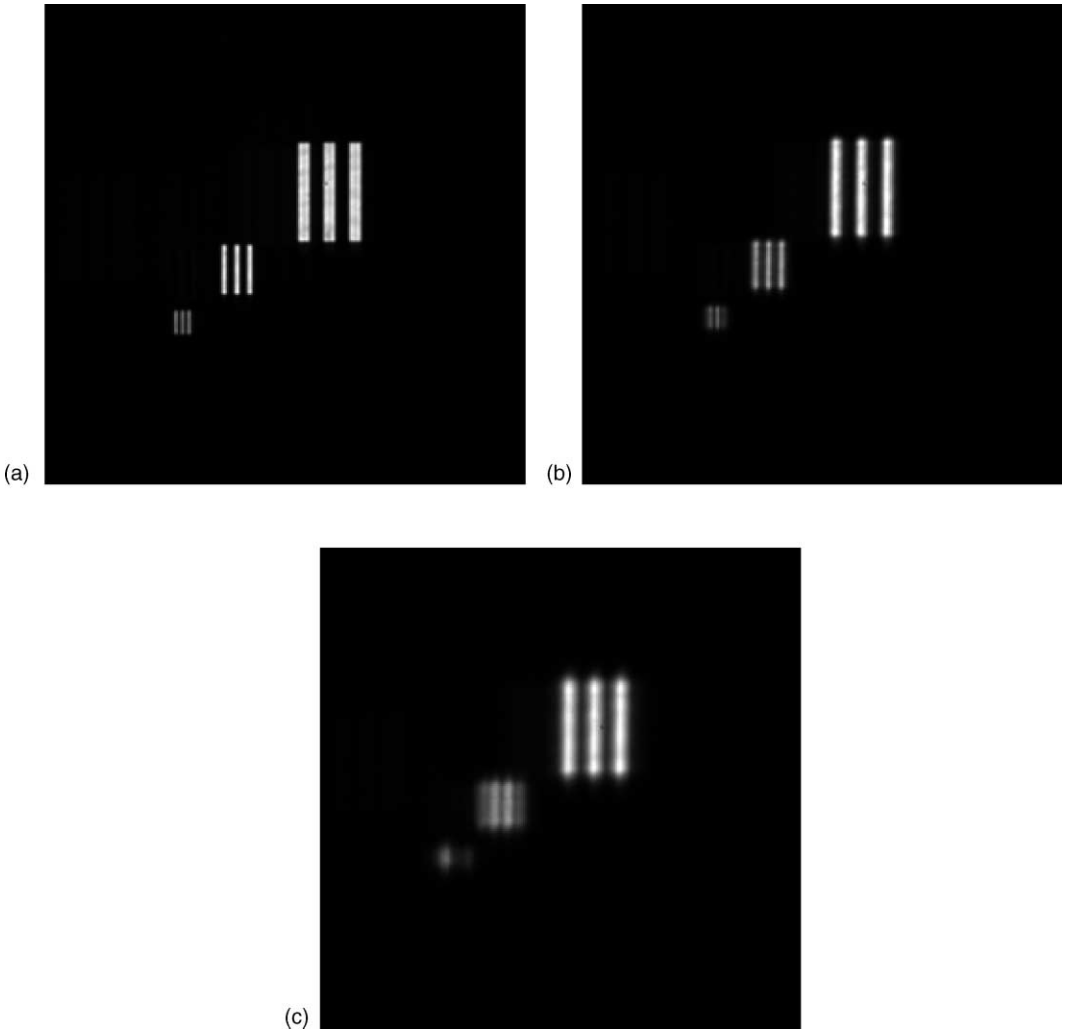

Figure 20 High spatial coherence disk source ($K = 0.2$) imaging for (a) best focus, (b) moderate misfocus, and (c) high misfocus.

Highly coherent imaging systems produce high-contrast images with high depth of field and provide the opportunity for sophisticated manipulation of the image with frequency plane filtering. Darkfield imaging and phase contrast imaging are examples of frequency plane filtering. Unfortunately, coherent systems are sensitive to optical noise and are generally avoided in practical system design. Relaxing the temporal coherence of the illumination can provide some improvement, but reducing the spatial coherence is more powerful in combating noise artifacts. Research microscopes, machine vision systems, and optical lithography systems are the most prominent examples of partially coherent imaging systems. These systems typically employ adjustable spatially incoherent extended sources in the shapes of disks or annuli. The exact shape and size of the primary source, shapes the angular extent of the illumination at the object plane and determines the spatial coherence at the object plane. Spatial coherence effects can be significant, even for broadband light. Control over the object plane spatial coherence allows the designer to find a tradeoff between the various strengths and weaknesses of coherent and incoherent imaging systems.

As more imaging systems employ post-detection processing, there is an opportunity to design fundamentally different systems that effectively split the image formation process into a physical portion and a post-detection portion. The simple example of image deblurring cited in this article shows that object plane coherence can affect the nature of the digitally restored image. The final image can be best understood when the illumination coherence effects are well understood. The spatially incoherent case results in the most straightforward model for image interpretation, but is not always the best choice since the coherence can often be manipulated to increase the contrast and hence the amount of useful information in the raw image. A completely general approach to

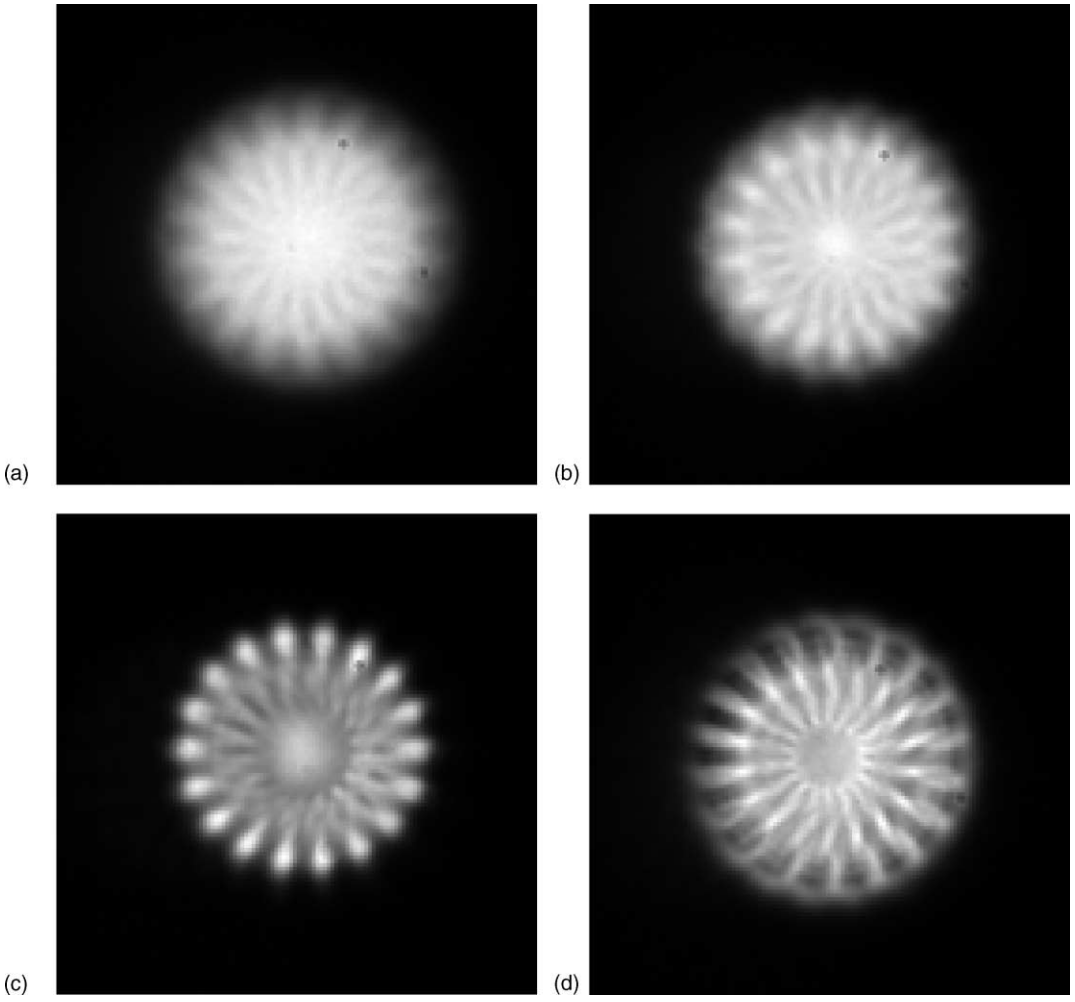

Figure 21 Imaging with a fixed amount of misfocus and varying object spatial coherence produced by: (a) highly incoherent disk source illumination ($K = 2$); (b) moderate coherence disk source ($K = 0.5$); (c) high coherence disk source ($K = 0.2$); and (d) annular source with outer diameter corresponding to $K = 0.5$ and inner diameter corresponding to $K = 0.45$.

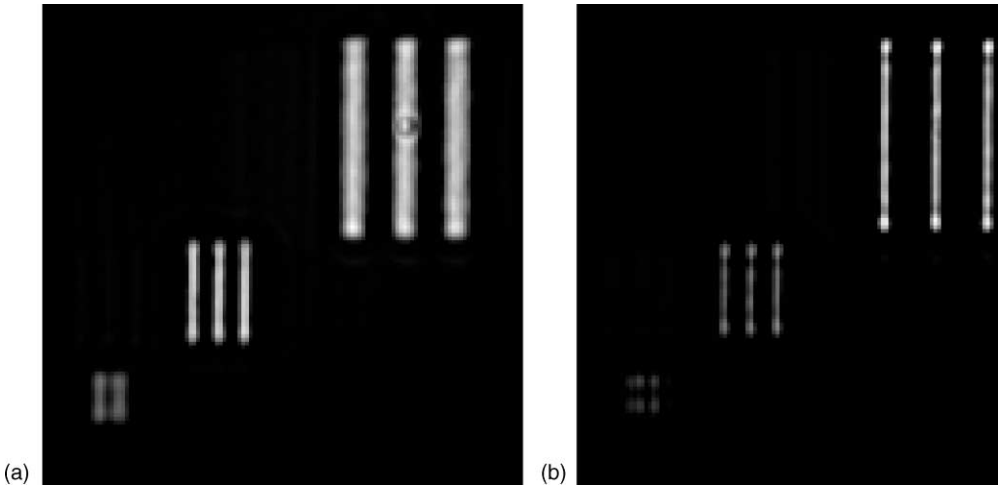

Figure 22 Digital restoration of blurred imagery with an inherent assumption of linear-in-intensity imaging for (a) highly spatially incoherent imaging ($K = 2$) and (b) high spatial coherence ($K = 0.2$).

imaging would treat the coherence of the source, the imaging optics, and the post-detection restoration all as free variables that can be manipulated to produce the optimal imaging system for a given task.

Speckle and Coherence

Introduction

Opticists are aware that the amount of coherence plays a significant role in imaging systems: laser speckles are known to add significant noise to the image, as well as parasitic interferences from dusty lenses. Optical systems are often called coherent, if a laser is used (right), and incoherent if other sources come into play (wrong). Many users of optical systems are unaware that it is not the high temporal coherence but the spatial coherence that commonly afflicts the image quality, and that this parasitic spatial coherence is ubiquitous, even though not obvious. Coherent artifacts can occur without the use of lasers, although speckle noise is more prominent with lasers. Even opticists sometimes underestimate the damage that residual coherent noise can cause, and as laser oriented sensor funding programs are 'en vogue', nonexperts are disappointed if some metrology device does not include a laser.

This encyclopedia addresses the many uses of lasers. In this article, we will discuss the costs of coherence. The commonly pretended incoherent approach of everyday optics may lead to significant quantitative measuring errors of illumination or reflectivity, 3d shape, distance or size. Spatial coherence is the dominant source of noise. We will give some rules of thumb to estimate these errors and a few tricks to reduce coherent noise. These rules will help to minimize coherent noise, however, it turns out that as spatial coherence is ubiquitous, there are only limited options available to clear it. One of the options to build good sensors that measure shape, reflectivity, etc. is avoiding the use of lasers!

To become familiar with some basics of the theory of coherence we refer the reader the Further Reading section at the end of this article.

Coherence can be boon or disaster for the opticist, as is explained in other articles of this encyclopedia about interferometry, diffraction, and holography. A specific topic is information acquisition from coherently scattered light. An enlightening example is where speckles in white light interferometry at rough surfaces and in speckle interferometry are exploited. We will briefly discuss white light interferometry at rough surfaces in the section on speckles as carriers of information below.

Practical Coherence Theory

A major issue of this chapter will be corrupting properties of coherence in the daily life of an optical metrologist. We will demonstrate that 'speckle' noise is ever present, and essentially unavoidable, in the images of (diffusively reflecting) objects. Its influence on the quality of optical measurements leads to a lower limit of the physical measuring uncertainty.

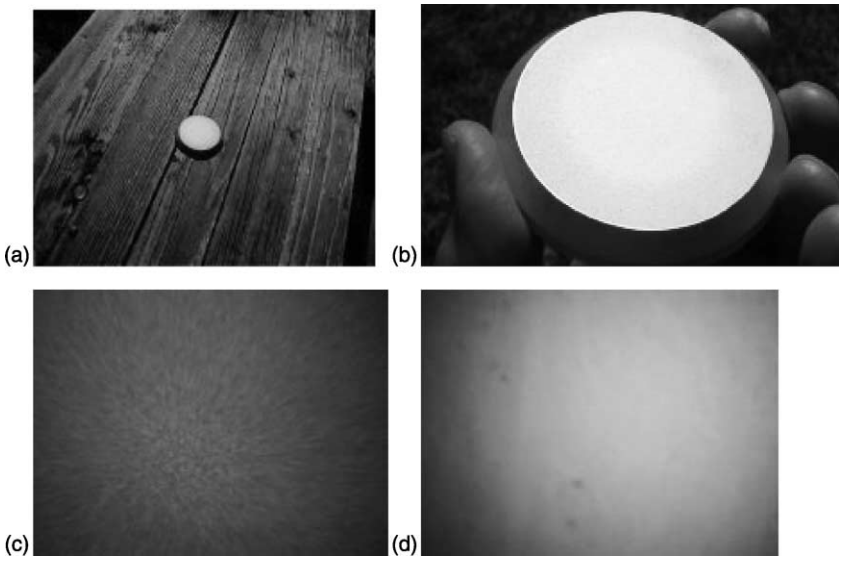

Figure 1 Ground glass in sunlight: (a) the image of a ground glass, illuminated by the sun, observed with small aperture (from large distance), displays no visible speckles; (b) a medium observation aperture (smaller distance) displays weak visible speckles; (c) observation with very high aperture displays strong contrast speckles; and (d) the image of the ground glass on a cloudy day does not display speckles, due to the very big aperture of illumination. Reproduced with permission from Häusler G (1999) Optical sensors and algorithms for reverse engineering. In: Donah S (ed.) Proceedings of the 3rd Topical Meeting on Optoelectronic Distance/Displacement Measurements and Applications. IEEE-LEOS.

This 'coherent noise' limit is, not surprisingly, identical to Heisenberg's limit. We will start by summarizing the important results, and will give some simple explanations later.

Some Basic Observations

(i) The major source of noise in optical measurements is spatial coherence, the temporal coherence status, generally, does not play a significant role.
(ii) An optically rough surface displays subjective speckles with contrast $C = 1$, if the observation aperture $\sin u_o$ is larger than the illumination aperture $\sin u_q$.
(iii) The speckle contrast is $C \sim \sin u_q / \sin u_o$, if the observation aperture is smaller than the illumination aperture.

Figure 1 illustrates the situation by a simple experiment.

The results of Figure 1 can be explained simply by summarizing some 80 pages of coherence theory in a nutshell, by useful simplifications and approximations (Figure 2).

If the source is at an infinite distance, the coherence function no longer depends on the two variables but just on the slit distance $d = |x_1 - x_2|$. In this case, the coherence function $\Gamma(d)$ can be easily calculated as the Fourier transform of the spatial intensity

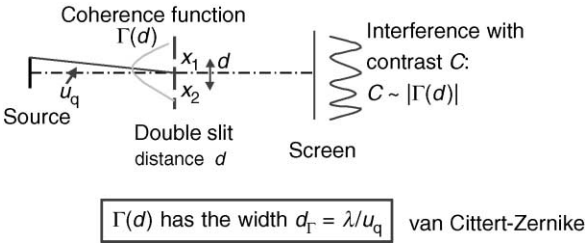

Figure 2 Basic experiment for spatial coherence. An extended source, such as the sun or some incandescent lamp illuminates a double slit, from a large distance. On a screen behind the double slit we can observe 'double slit interference', if the waves coming from x_1 and x_2 display coherence. The contrast of the interference fringes is given by the magnitude of the coherence function Γ (neglecting some normalization factor). Γ is a function of the two slit locations x_1 and x_2.

distribution of the source (van Cittert-Zernike theorem). Let us assume a one dimensional source with an angular size of $2u_q$, where u_q is commonly called the aperture of the illumination. In this case, the coherence function will be:

$$\Gamma(d) \sim \sin c(2u_q d/\lambda) \qquad [1]$$

The width of the coherence function which gives the size of the coherently illuminated area (coherence area) can be approximated from eqn [1]:

$$d_\Gamma = \lambda/u_q \qquad [2]$$

Equation [1] includes some approximations: for circular sources such as the sun, we get an additional

factor 1.22 for the width of the coherence function – the 'sinc-function' has to be replaced by the Bessel function $J_1(r)/(r)$. There is another approximation: we should replace the aperture angle u_q by $\sin u_q$, for larger angles. We choose the wavelength of the maximum sensitivity of the eye, at $\lambda = 0.55\ \mu m$, which is the wavelength of the maximum emission of the sun also.

In conclusion, if two points at the object are closer than d_Γ these points will be illuminated with a high degree of coherence. The light waves, scattered from these object-locations can display interference contrast. Specifically, they may cancel each other out, causing a low signal-to-noise ratio of only 1:1. This does not happen if the points have a distance larger than d_Γ.

From Figure 3 we learn that the width of the spatial coherence function from sunlight illumination at the earth's surface is ~110 μm. (Stars more distant than the sun appear smaller, and hence have a wider coherence function, at the earth's surface. Michelson was able to measure the angular size of some close stars, by measuring the width of this coherence function, which was about $d_\Gamma \sim 10$ m.)

Figure 4 again displays an easy to perform experiment. We can see speckles at sunlight illumination. We can observe speckles as well in shops because they often use small halogen spot illumination.

So far we have only discussed the first stage (from the source to the object). We still have to discuss the way from the object to the retina (or CCD-chip of a video camera). This is illustrated by Figure 5.

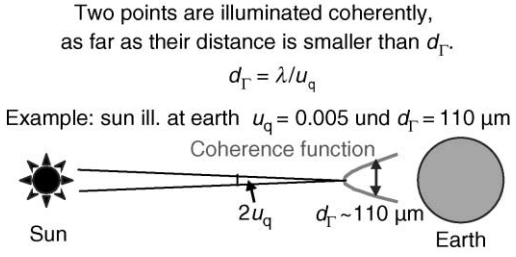

Figure 3 Coherence from sunlight illumination. With the van Cittert–Zernike theorem and an approximate illumination aperture of the sun $u_q^{sun} \sim 0.005$ (0.25°), we get a width of the coherence function at the Earth's surface of about $d_\Gamma \sim 110\ \mu m$.

Figure 4 Finger nail in sunlight, with speckles.

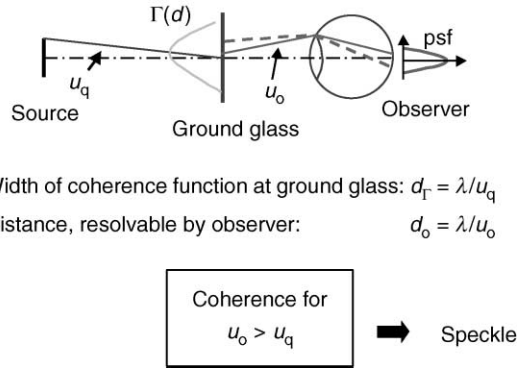

Figure 5 Coherence in a nutshell: spatial coherence and observer.

As an object, we choose some diffusely reflecting or transmitting surface (such as a ground glass). The coherence function at the ground glass has again a width of d_Γ. What happens if we image this ground glass onto our retina? Let us assume our eye to be diffraction limited (which, in fact, it is at sunlight conditions, where the eye pupil has only a diameter $\Phi_{pupil} = 2.5$ mm diameter or less). Then a point x_1 at the ground glass will cause a diffraction spot at the retina, with a size of:

$$d'_{diffr} = \lambda/u'_o = 8\ \mu m \qquad [3]$$

The image sided aperture of observation u'_0 of the eye is calculated from Φ_{pupil} and from its focal length $f_{eye} = 18$ mm as $u'_o = \Phi_{pupil}/2f_{eye} = 0.07$. If we project the diffraction spot at the retina back onto the object, we get its size d from:

$$d_{diffr} = \lambda/u_o = \lambda/(\Phi_{pupil}/2z_o) \qquad [4]$$

with z_o = observation distance of the object from the eye. We call $u_o = \Phi_{pupil}/2z_o$ the object sided observation aperture. Let us calculate the laterally resolvable distance d_{diffr} at the object, with a distance $z_o = 250$ mm, which is called the 'comfortable viewing distance':

$$d_{diffr}(z_o = 250\ mm) = 110\ \mu m \qquad [5]$$

After these preparations we come to the crucial issue: how does the image at the retina appear if we cannot resolve distances at an object smaller than d_Γ, and how does it appear if the resolution of the eye is sufficient to resolve distances smaller than d_Γ?

Let us start with the first assumption: $d_{diffr} \gg d_\Gamma$. Now the images of points at the object, over an area of the diffraction spot are more or less incoherently averaged at the retina, so we will see little interference contrast or 'speckles'. From eqn [4] we see that at

this incoherent averaging starts for distances larger than 250 mm, which is the comfortable viewing distance. Adults cannot see objects from much closer distances. We generally do not see speckles, not just at the limit of maximum accommodation. For larger distances, if we take $z_o = 2500$ mm, the resolvable distance at the object will be 1.1 mm, which is 10 times larger than the diameter of the coherence area. Averaging over such a large area will drop the interference contrast by a factor of 10. Note that such a small interference contrast might not be visible, but it is not at zero!

Coming to the second assumption we can laterally resolve distances smaller than d_Γ. In order to understand this, we first have to learn what is an 'optically rough' object surface. Figure 6 illustrates the problem.

A surface commonly is called 'rough' if the local height variations are larger than λ. However, a surface appears only rough, if the height variation within the distance that can be resolved by the observer, is larger than λ (reflected light will travel the distance twice, hence a roughness of $\lambda/2$ will be sufficient). Then the scattered different phasors, or 'Huygens elementary waves':

$$u_s \sim \exp[i2kz(x, y)] \qquad [6]$$

scattered from the object at x, y may have big phase differences so that destructive interferences (and speckle) can occur in the area of the diffraction image. So the attribute 'rough' depends on the object as well as on the observation aperture. With a high observation aperture (microscope), the diffraction image is small and within that area the phase differences might be small as well. So a ground glass may then look locally like a mirror, while with a small observation aperture it appears 'rough'.

With the 'rough' observation mode assumption, we can summarize what we have assumed: with resolving distances smaller than the coherence width d_Γ we will see high interference contrast; in fact we see a speckle contrast of $C = 1$, if the roughness of the object is smaller than the coherence length of the source. This is the case for most metal surfaces, for ground glasses, or for worked plastic surfaces. The assumption is not true for 'translucent' surfaces, such as skin, paper, or wood. This will be discussed below.

The observation that coherent imaging is achieved, if we can resolve distances smaller than the coherence width d_Γ, is identical to the simple rule that fully coherent imaging occurs if the observation aperture u_o is larger than the illumination aperture u_q.

As mentioned, we will incoherently average in the image plane, over some object area, determined by the size of the diffraction spot. According to the rules of speckle-averaging, the speckle contrast C decreases with the inverse square root of the number N of incoherently averaged speckle patterns. This number N is equal to the ratio of the area A_{diff} of the diffraction spot divided by the coherence area $A_\Gamma = d_\Gamma^2$. So we obtain for the speckle contrast C:

$$C = 1 \quad \text{for } u_q < u_o \qquad [7a]$$

$$C = 1/\sqrt{(N)} = u_o/u_q, \quad \text{for } u_q >= u_o \qquad [7b]$$

We summarize the results in Figure 7.

Equation [7b] has an interesting consequence: we never get rid of speckle noise, even for large illumination apertures and small observation apertures. In many practical instruments, such as a slide projector, the illumination 'aperture stop' cannot be greater than the imaging lens. Fortunately, the observer's eye commonly has a pupil smaller than that of the projector, and/or looks from a distance at the projection screen. Laser projection devices however cause strong and disturbing speckle effects for the user and significant effort is invested to cope with this effect.

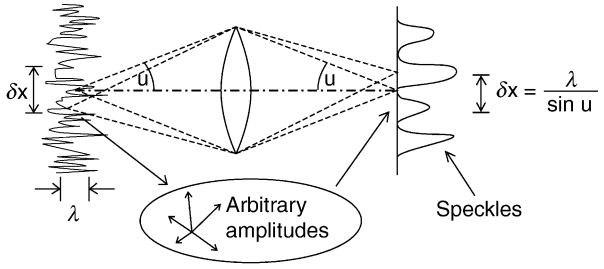

Figure 6 What is a rough surface?

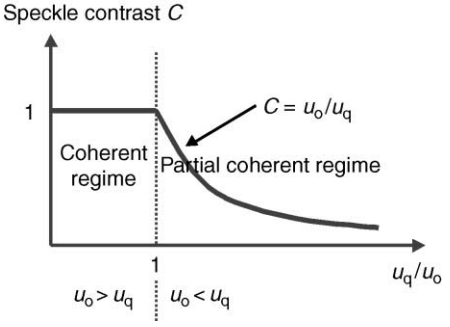

Figure 7 Coherence in a nutshell: what are the conditions for incoherent and coherent imaging?

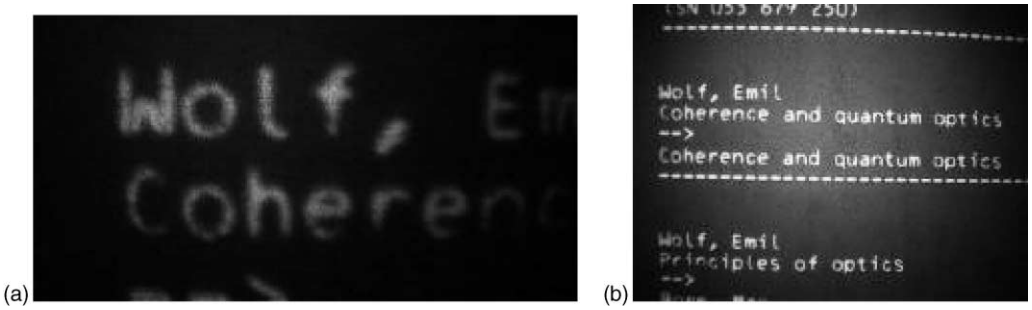

Figure 8 Microfiche projection. For high observation aperture (a) strong speckles occur, and for small observation aperture (b), the speckle contrast is low.

In Figure 8, an image is depicted from a microfiche reading projector. Figure 8a displays the close-up look (high observation aperture) and Figure 8b depicts a more distant view (small observation aperture). The amount of noise is much less in the second case, as it should be according to the rules of eqn [7].

Let us finish this section with some speculation. How would a fly see the sunny world, with a human type of eye? With high observation aperture and at short distance, the world is full of speckle noise. Fortunately, nature invented the facet-eye, for insects, as depicted in Figure 9.

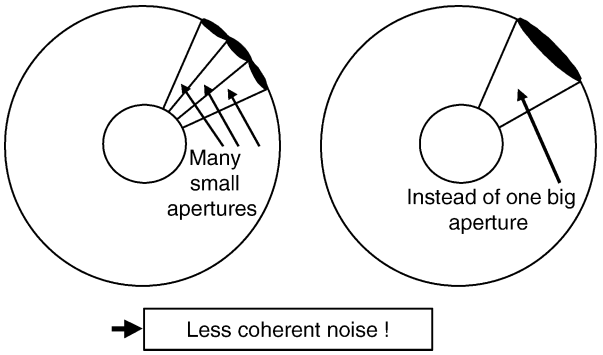

Figure 9 Facet eye and 'human' eye. The facet eye consists of many low aperture lenses, in contrast to the human eye.

Speckle Limits of Metrology

The consequences of the effects discussed above are often underestimated. We should be suspicious, if some effect in nature that disturbs us – like our coherent noise – is ubiquitous, that there might be some deep underlying principle that does not allow us to know everything about the object under observation. Indeed, it turns out that Heisenberg's uncertainty principle is strongly connected with coherent noise (Figure 10).

We can see this from the following experiment: a laser spot is projected onto a ground glass, and imaged with high magnification by a video camera, with an aperture sin u_o. The ground glass is macroscopically planar. When the ground glass is laterally shifted, we find that the observed spot is 'dancing' at the video target. Its observed position is not constant, although its projected position is. It turns out that the standard deviation of the observed position is equal to the uncertainty calculated from the aperture by Heisenberg's principle.

We can calculate the limit for the distance measuring uncertainty, from speckle theory, as well from Heisenberg's principle (within some factor of order 1):

$$\delta z \cdot \delta p_z \gg h/4\pi \qquad [8]$$

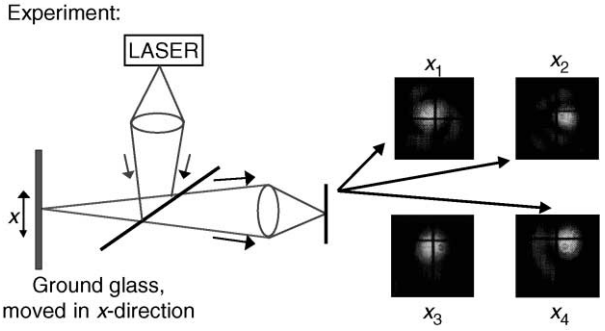

Figure 10 Coherence makes it impossible to localize objects with very high accuracy. Laser spots projected onto a ground glass cannot be imaged without some uncertainty of the lateral position. The four pictures of the spot images, taken with different lateral positions of the ground glass, display the cross bar (true position) and the apparent position of the spot images. The position uncertainty is equal to the uncertainty calculated from Heisenberg's uncertainty principle.

where δp_z is the uncertainty of the photon impulse h/λ in the z-direction (along the optical axis of the measuring system) and h is Planck's constant. For a small measurement uncertainty of the distance, we should allow a big uncertainty δp_z. This can be achieved by a large aperture of the observation system, giving the photons a wide range of possible directions to the lens. We can also allow different

wavelengths, and come to white light interferometry, see section on speckles as carriers of information below. The result is – not surprising – the same as Rayleigh scattering found for the depth of field:

$$\delta z = \lambda / \sin^2 u_o \qquad [9]$$

Coherent noise is the source of the fundamental limit of the distance measuring uncertainty δz of triangulation based sensors.

$$\delta z = C \cdot \lambda / (\sin u_o \sin \theta) \qquad [10]$$

where C is the speckle contrast, λ is the wavelength, $\sin u_o$ is the aperture of observation, and θ is the angle of triangulation (between the direction of the projection and the direction of observation). For a commercially available laser triangulation sensor, (see Figure 11), with $\sin u_o \sim 0.01, C = 1$ and $\theta = 30°$, the measuring uncertainty δz will be larger than 100 μm. We may add, that for $\sin u_o = \sin \theta$, which is valid for auto-focus sensors (such as the confocal scanning microscope), eqn [10] degenerates to the well known Rayleigh depth of field (eqn [9]).

The above results are remarkable in that we cannot know the accurate position of the projected spot or about the position of an intrinsic reflectivity feature; we also cannot know the accurate local reflectivity of a coherently illuminated object. A further consequence is that we do not know the accurate shape of an object in 3D-space. We can calculate this 'physical measuring uncertainty' from the considerations above.

These consequences hold for optically rough surfaces, and for measuring principles that exploit the local intensity of some image, such as with all triangulation type of sensors. The consequences of these considerations are depressing: triangulation with a strong laser is not better than triangulation with only one single photon. The deep reason is, that all coherent photons stem from the same quantum mechanical phase cell and are indistinguishable.

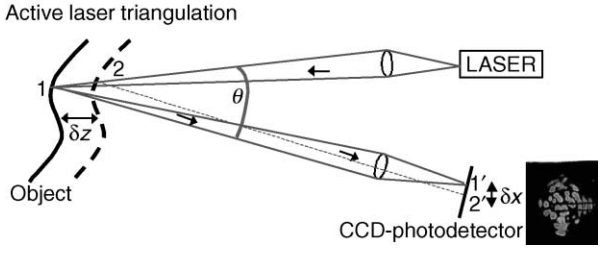

Figure 11 Principle of laser triangulation. The distance of the projected spot is calculated from the location of the speckled spot image and from the angle of triangulation. The speckle noise introduces an ultimate limit of the achievable measuring uncertainty. Reproduced with permission from *Physikalische Plätter* (May 1997): 419.

Hence, many photons do not supply more information than one single photon.

Why Are We Not Aware of Coherence

Generally, coherent noise is not well visible, even in sophisticated technical systems the visibility might be low. There are two main reasons; first, the observation aperture might be much smaller than the aperture of illumination. This is often true, for large distance observation, even with small apertures of illumination. The second reason holds for technical systems, if the observation is implemented via pixelized video targets. If the pixel size is much larger than a single speckle, which is commonly so, then, by averaging over many speckles, the noise is greatly reduced. However, we have to take into account that we pay for this by loss of lateral resolution $1/\delta x$. We can formulate another uncertainty relation:

$$\delta x > \lambda / (C \cdot \sin u_o) \qquad [11]$$

which says that if we want to reduce the speckle contrast C (noise), by lateral averaging, we can do this but lose lateral resolution $1/\delta x$.

Can We Overcome Coherence Limits?

Since the daily interaction of light with matter is coherent scattering, we can overcome the limit of eqn [10] only by looking for measuring principles that are not based on the exploitation of local reflectivity, i.e., on 'conventional imaging'. Concerning optical 3D-measurements, the principle of triangulation uses the position of some image detail, for the calculation of the shape of objects, and has to cope with coherent noise.

Are there different mechanisms of photon–matter interaction, with noncoherent scattering? Fluorescence and thermal excitation are incoherent mechanisms. It can be shown (see Figure 12) that triangulation utilizing fluorescent light, displays much less noise than given by eqn [10]. This is exploited in fluorescent confocal microscopy.

Thermally excited matter emits perfectly incoherent radiation as well. We use this incoherence to measure the material wear in laser processing (see Figure 13), with, again, much better accuracy than given by eqns [9,10].

The sensor is based on triangulation. Nevertheless, by its virtually zero coherent noise, it allows a measuring uncertainty which is limited only by camera noise and other technical imperfections. The uncertainty of the depth measurement through the narrow aperture of the laser nozzle is only a few

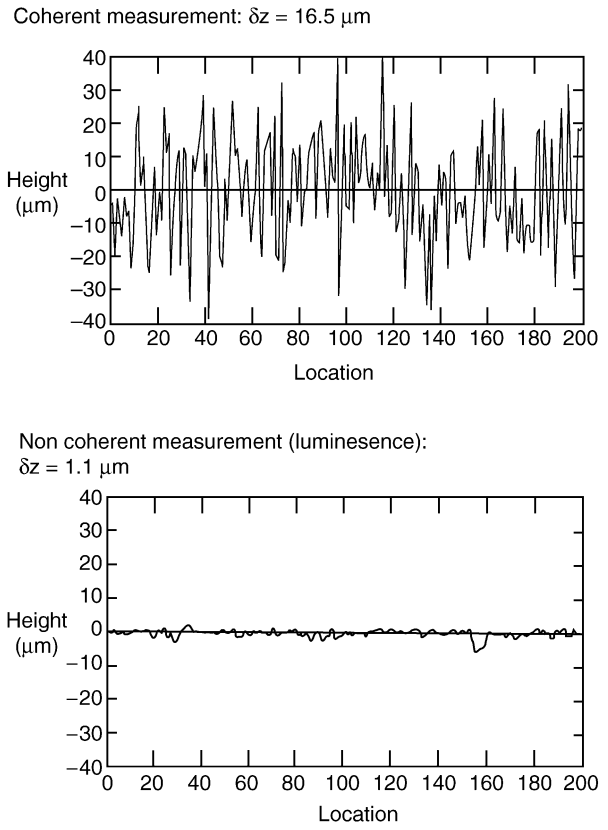

Figure 12 Reduction of speckle noise by triangulation with fluorescent light. A flat metal surface is measured by laser triangulation. Top: surface measured by laser triangulation with full speckle contrast. Bottom: the surface is covered with a very thin fluorescent layer, and illuminated by the same laser, however, the triangulation is done after suppressing the scattered laser light, and utilizing the (incoherent!) fluorescent light. This experiment proves that it is the coherent noise that causes the measuring uncertainty.

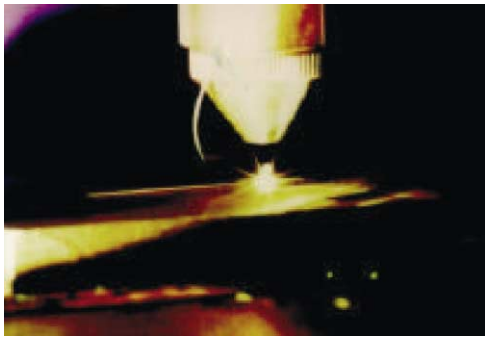

Figure 13 A 100 W laser generates a plasma that emits perfectly incoherent radiation at the object surface. The emitted light can be used to measure on-line the distance of the object surface. A triangulation sensor, exploiting the incoherent plasma emission, controls surface ablation with an accuracy of only a few microns. Reproduced with permission from F & M, *Feinwerktechnik Mikrotechnik Masstechnik* (1995) Issue 9.

microns, beating the limitation of eqn [10] by a factor of about 5, even in the presence of a turbulent plasma spot with a temperature of 3000 K.

Broadband Illumination

Speckle noise can hardly be avoided by broadband illumination. The speckle contrast C is related to the surface roughness σ_z and the coherence length l_c by eqn [12]:

$$C^2 \sim l_c/2\sigma_z \quad \text{for} \quad \sigma_z \gg l_c \qquad [12]$$

So, only for very rough surfaces, and white light illumination, C can be reduced. However, the majority of technical objects is smooth, with a roughness of a few micrometers, hence speckles can be observed even with white light illumination ($l_c \sim 3\ \mu m$). This situation is different for 'translucent' objects such as skin, paper, or some plastic material.

Speckles as a Carrier of Information

So far we discussed the problems of speckles when measuring rough surfaces. We can take advantage of speckles, if we do not stick to triangulation as the basic mechanism of distance measurement. We may utilize the fact that although the phase within each speckle has a random value, this phase is constant over some area. This observation can be used to build an interferometer that works even at rough surfaces. So, with proper choice of the illumination aperture and observation aperture, and with a surface roughness less than the coherence length, we can measure distances by the localization of the temporal coherence function. This function can easily be measured by moving the object under test along the optical axis and measuring the interference intensity (correlogram) at each pixel of the camera. The signal generating mechanism of this 'white light interferometer' distance measurement is not triangulation but 'time of flight'. Here we do not suffer from the limitations of eqn [10]. The limits of white light rough surface interferometry are discussed in the Further Reading section at the end of this article.

The 'coherence radar' and the correlograms of different speckles are depicted in Figures 14 and 15.

The physical mechanism of the signal formation in white light interferometry at rough surfaces is different from that of white light interferometry at smooth surfaces. That is why the method is sometimes referred as 'coherence radar'. We will briefly summarize some advantageous, and – probably unexpected – features of the coherence radar.

We call the real shape of the object, or the surface profile, $z(x, y)$, where z is the local distance at the position (x, y). We give the measured data an index 'm^2':

(i) The physical measuring uncertainty of the measured data is independent from the observation aperture. This is quite a remarkable property, as it enables us to take accurate measurements at the bottom of deep boreholes.

(ii) The standard deviation σ_z of the object can be calculated from the measured data z_m: $\sigma_z = <|z_m|>$. According to German standards, σ_z corresponds to the roughness measure R_q. This measure R_q was calculated from measurements at different roughness gauges, with different observation apertures. Two measurements are depicted in Figure 16.

The experiments shown in Figure 16 display the correct roughness measure, even if the higher frequencies of the object spectrum $Z(\nu, \mu)$ (Figure 17), are not optically resolved. The solution of this paradox might be explained as follows.

From the coherently illuminated object each point scatters a spherical wave. The waves scattered from different object points have, in general, a different phase. At the image plane, we see the laterally

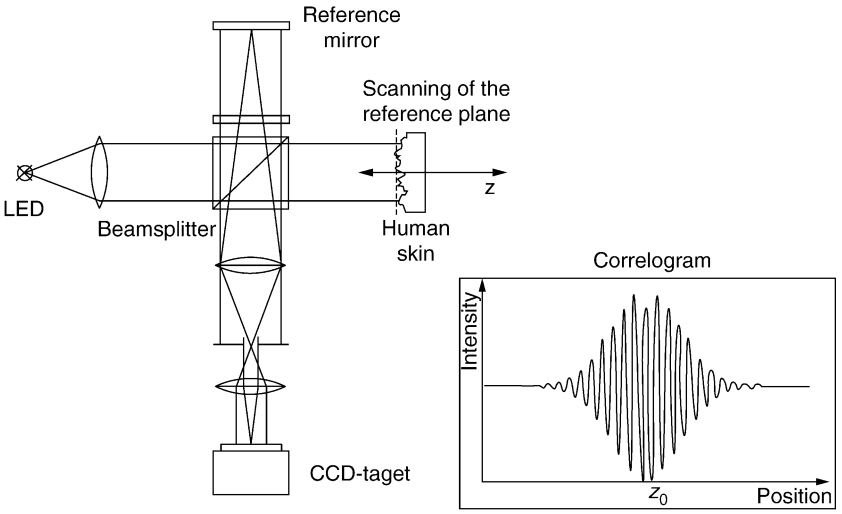

Figure 14 'Coherence radar', white light interferometry at rough surfaces. The surface under test is illuminated with high spatial coherence and low temporal coherence. We acquire the temporal coherence function (correlogram) within each speckle, by scanning the object under test in depth.

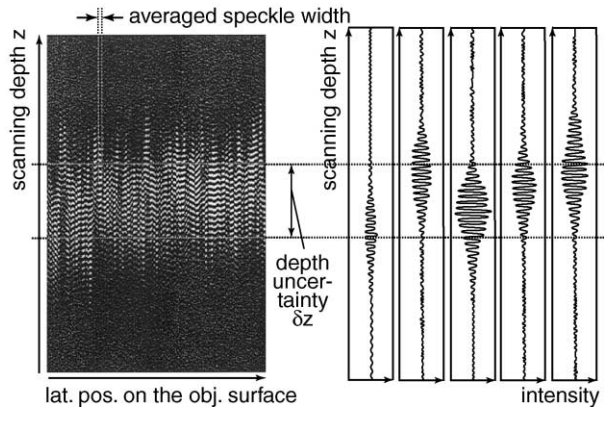

Figure 15 White light speckles in the $x-z$ plane. The left side displays the acquired correlograms, for a couple of speckles, the right side shows the graphs of some of the correlograms. We see that the correlograms are not located at a constant distance, but display some 'distance uncertainty'. This uncertainty does not originate from the instrument, but from the roughness of the object.

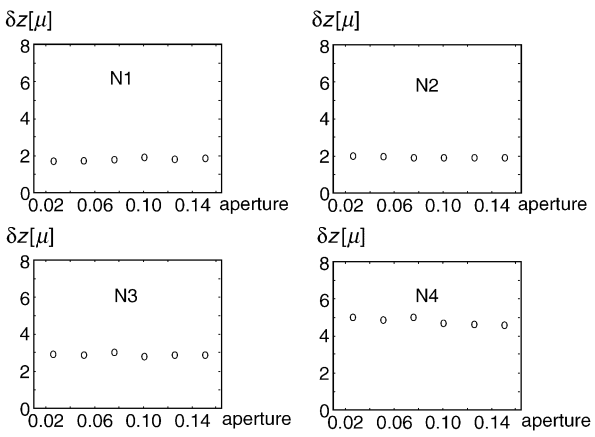

Figure 16 Optical measurement of the roughness beyond the Abbe resolution limit. The roughness is measured for 4 roughness standards N1–N4, with different observation apertures. The roughness is measured correctly, although the microtopology is not resolved by the observing optics.

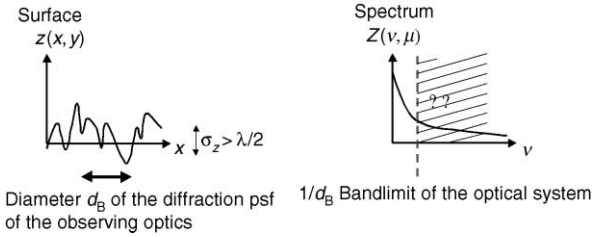

Figure 17 Signal generation beyond the Abbe limit. The microtopology of the object $z(x, y)$ is not resolved, due to the large diffraction image with diameter d_B. Yet we get information from beyond the bandlimit $1/d_B$ of the observing optics.

averaged complex amplitude $<u>$, according to eqn [6]. The averaging is due to the diffraction limited resolution.

Equation [6] reveals that the (spatially) averaged field amplitude $<u>$ is a nonmonotonic, nonlinear function of the surface profile $z(x, y)$, if the surface is rough (i.e., $z \gg \lambda$). We do not average over the profile z but over the complex amplitude. As a consequence of this nonlinearity, the limited observation aperture does not only collect the spatial frequencies ν, μ of the spatial Fourier spectrum $Z(\nu, \mu)$ within the bandlimit $1/d_B$, but also acquires information beyond this bandlimit. The reason is the 'down conversion' of higher spatial frequencies by nonlinear mixing. Simulations and experiments confirm the consequences.

Thus we can evaluate the surface roughness, even without laterally resolving the microtopology. However, there is a principal uncertainty on the measured data. We do not see the true surface but a surface with a 'noise' equivalent to the roughness of the real surface.

Nonlinear nonmonotonic nonlinearities in a sequence of operations may cause 'chaotic' behavior, in other words, small parameter changes such as vibrations, humidity on the surface, etc. may cause large differences of the outcome. In fact, we observe a significant variation of the measured data $z_m(x, y)$ within a sequence of repeated measurements. Our conjecture is that the complex signal formation may be involved in this irregular behavior. The hypothesis may be supported by the observation that much better repeatability can be achieved at specular surfaces, where eqn [6] degenerates to a linear averaging over the surface profile:

$$<u> \sim 1 + ik <z(x, y)>, \quad \text{for } z \ll \lambda \qquad [13]$$

Summary

Spatial coherence is ubiquitous and unavoidable. Spatial coherence disturbs most optical measurements, where optically rough surfaces exist. Then, coherence gives the ultimate limit of the achievable measuring uncertainty. There are simple rules to estimate the measuring uncertainty, by calculating the width of the coherence function and the resolution of the observation system. Spatial coherence and Heisenberg's uncertainty principle lead to the same results of measuring uncertainty.

On the other hand – the formation of signals from coherent light that is scattered at rough surfaces is quite complex and a strongly nonlinear process, which sometimes might encode information which is not otherwise available. One example appears to be the measurement of the roughness with white light interferometry – which is possible, even if the microtopology of the surface is not optically resolved.

Introduction

Since the inception of quantum mechanics almost a century ago, a prime activity has been the observation of quantum phenomena in virtually all areas of chemistry and physics. However, the natural evolution of science leads to the desire to go beyond passive observation to active manipulation of quantum mechanical processes. Achieving control over quantum phenomena could be viewed as engineering at the atomic scale guided by the principles of quantum mechanics, for the alteration of system properties or dynamic behavior. From this perspective, the construction of quantum mechanically operating solid-state devices through selective material growth would fall into this category. The focus of this article is principally on the manipulation of quantum phenomena through tailored laser pulses. The suggestion of using coherent radiation for the active alteration of microworld processes may be traced to the early 1960s, almost immediately after the discovery of lasers. Since then, the subject has grown enormously to encompass the manipulation of (1) chemical reactions, (2) quantum electron transport in semiconductors, (3) excitons in solids, (4) quantum information systems, (5) atom lasers, and (6) high harmonic generation, amongst other topics. Perhaps the most significant use of these techniques may be their provision of refined tools to ultimately better understand the basic physical interactions operative at the atomic scale.

Regardless of the particular application of laser control over quantum phenomena, there is one basic operating principle involved: active manipulation of constructive and destructive quantum wave interferences. This process is depicted in Figure 1, showing the evolution of a quantum system from the initial state $|\psi_i\rangle$ to the desired final state $|\psi_f\rangle$ along three of possibly many interfering pathways. In general, there may be many possible final accessible states $|\psi_f\rangle$, and often the goal is to achieve a high amplitude in one of these states and low amplitude in all the others. The target state might actually be a superposition of states, and an analogous picture to

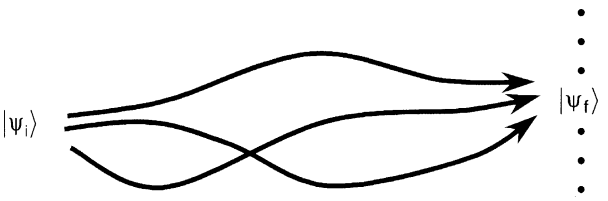

Figure 1 The evolution of a quantum system under laser control from the initial state $|\psi_i\rangle$ to the final state $|\psi_f\rangle$. The latter state is chosen to have desirable physical properties, and three of possibly many pathways between the states are depicted. Successful control of the process $|\psi_i\rangle \rightarrow |\psi_f\rangle$ by a tailored laser pulse generally requires creating constructive quantum wave interferences in the state $|\psi_f\rangle$ from many pathways, and destructive interferences in all other accessible final states $|\psi_{f'}\rangle \neq |\psi_f\rangle$.

that in Figure 1 would also apply to steering about the density matrix. The process depicted in Figure 1 may be thought of as a microscale analog of the classic double-slit experiment for light waves. As the goal is often high-finesse focusing into a particular target quantum state, success may call for the manipulation of many quantum pathways (i.e., the notion of a 'many-slit' experiment). Most applications are concerned with achieving a desirable outcome for the expectation value $\langle\psi_f|O|\psi_f\rangle$ associated with some observable Hermitian operator O.

The practical realization of the task above becomes a control problem when the system is expressed through its Hamiltonian $H = H_0 + V_c$, where H_0 is the free Hamiltonian describing the dynamics without explicit control; it is assumed that the free evolutionary dynamics under H_0 will not satisfactorily achieve the physical objective. Thus, a laboratory-accessible control term V_c is introduced in the Hamiltonian to achieve the desired manipulation. Even just considering radiative interactions, the form of V_c could be quite diverse depending on the nature of the system (e.g., nuclear spins, electrons, atoms, molecules, etc.) and the intensity of the radiation field. Many problems may be treated through an electric dipole interaction $V_c = -\boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)$ where $\boldsymbol{\mu}$ is a system dipole moment and $\boldsymbol{\varepsilon}(t)$ is the laser electric field. Where appropriate, this article will consider the interaction in this form, but other suitable radiative control interactions may be equally well treated. Thus, the laser field $\boldsymbol{\varepsilon}(t)$ as a function of time (or frequency) is at our disposal for attempted manipulation of quantum systems.

Before considering any practical issues associated with the identification of shaped laser control fields, a fundamental question concerns whether it is, in principle, possible to steer about any particular quantum system from an arbitrary initial state $|\psi_i\rangle$ to an arbitrary final state $|\psi_f\rangle$. Questions of this sort are addressed by a controllability analysis of Schrödinger's equation

$$i\hbar\frac{\partial|\psi(t)\rangle}{\partial t} = [H_0 - \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)]|\psi(t)\rangle, \quad |\psi(0)\rangle = |\psi_i\rangle \qquad [1]$$

Controllability concerns whether, in principle, some field $\boldsymbol{\varepsilon}(t)$ exists, such that the quantum system described by $H_0 = H_0 - \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)$ permits arbitrary degrees of control. For finite-dimensional quantum systems (i.e., those described by evolution amongst a discrete set of quantum states), the formal tools for such a controllability analysis exist both for evaluating the controllability of the wave function, as well as the more general time evolution operator $U(t)$, which satisfies

$$i\hbar\frac{\partial U}{\partial t} = [H_0 - \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)]U, \quad U(0) = 1 \qquad [2]$$

Analyses of this type can be quite insightful, but they require detailed knowledge about H_0 and $\boldsymbol{\mu}$. Cases involving quantum information science applications are perhaps the most demanding with regard to achieving total control. Most other physical applications would likely accept much more modest levels of control and still be categorized as excellent achievements.

Theoretical tools and concepts have a number of roles in considering the control of quantum systems, including (1) an exploration of physical/chemical phenomena under active control, (2) the design of viable control fields, (3) the development of algorithms to actively guide laboratory control experiments towards achieving their dynamical objectives, and (4) the introduction of special algorithms to reveal the physical mechanisms operative in the control of quantum phenomena. Activities (1)–(3) have thus far been the primary focus of theoretical studies in this area, and it is anticipated that item (4) will grow in importance in the future.

A few comments on the history of laser control over quantum systems are relevant, as they speak to the special nature of the currently employed successful closed-loop quantum control experiments. Starting in the 1960s and spanning roughly 20 years, it was thought that the design of lasers to manipulate molecular motion could be achieved by the application of simple physical logic and intuition. In particular, the thinking at the time focused on using cw laser fields resonant with one or more local modes of the molecule, as state or energy localization was believed to be the key to successful control. Since quantum dynamics phenomena typically occur on ultrafast time-scales, possibly involving spatially dispersed wave packets, expecting to achieve high quality control with a light source operating at one or two resonant frequencies is generally wishful thinking. Quantum dynamics phenomena occur in a multifrequency domain, and controls with a few frequencies will not suffice. Over approximately the last decade, it became clear that successful control often calls for manipulating multiple interfering quantum pathways (cf., Figure 1). In turn, this recognition led to the need for broad-bandwidth laser sources (i.e., tailored laser pulses). Fortunately, the necessary laser pulse-shaping technologies have become available, and these sources continue to expand into new frequency ranges with enhanced bandwidth capabilities. Many chemical and physical

applications of control over quantum phenomena involve performing a significant amount of work (i.e., quantum mechanical action), and sufficient laser field intensity is required. A commonly quoted adage is 'no field, no yield', and at the other extreme, there was much speculation that operating nonlinearly at high field intensities would lead to a loss of control because the quantum system would effectively act as an amplifier of even weak laser field noise. Fortunately, the latter outcome has not occurred, as is evident from a number of successful high field laser control experiments.

Quantum control may be expressed as an inverse problem with a prescribed chemical or physical objective, and the task being the discovery of a suitable control field $\boldsymbol{\varepsilon}(t)$ to meet the objective. Normally, Schrödinger's equation [1] is viewed as linear, and this perspective is valid if the Hamiltonian is known a priori, leaving the equation to be solved for the wave function. However, in the case of quantum control, neither the wave function nor the control field is known a priori, and the two enter bilinearly on the right-hand side of eqn [1]. Thus, quantum control is mathematically a nonlinear inverse problem. As such, one can anticipate possibly diverse behavior in the process of seeking successful controls, as well as in the ensuing quantum dynamical control behavior. The control must take into account the evolving system dynamics, thereby resulting in the control field being a function(al) of the current state of the system $\boldsymbol{\varepsilon}(\psi)$ in the case of quantum control design, or dependent on the system observations $\boldsymbol{\varepsilon}(\langle O\rangle)$ in the case of laboratory closed-loop field discovery efforts where $\langle O\rangle = \langle\psi|O|\psi\rangle$. Furthermore, the control field at the current time t will depend in some implicit fashion on the future state of the evolving system at the final target time T. It is evident that control field design and laboratory discovery present highly nontrivial tasks.

Although the emphasis in this review is on the theoretical aspects of quantum control theory, the subject exists for its laboratory realizations, and those realizations, in turn, intimately depend on the capabilities of theoretical and algorithmic techniques for their successful implementations. Accordingly, theoretical laser control field design techniques will be discussed, along with algorithmic aspects of current laboratory practice. This material respectively will focus on optimal control theory (OCT) and optimal control experiments (OCEs), as seeking optimality provides the best means to achieve any posed objective. Finally, the last part of the article will present some general conclusions on the state of the quantum control field.

Quantum Optimal Control Theory for Designing Laser Fields

When considering control in any domain of application, a reasonable approach is to computationally design the control for subsequent implementation in the laboratory. Quantum mechanical laser field design has taken on a number of realizations. At one limit is the application of simple intuition for design purposes, and in some special cases (e.g., the weak field perturbation theory regime), this approach may be applicable. Physical insights will always play a central role in laser field design, but to be especially useful, they need to be channeled into the proper mathematical framework. Many of the interesting applications operate in the strong-field nonperturbative regime. In this domain, serious questions arise regarding whether sufficient information is available about the Hamiltonian to execute reliable designs. Regardless of whether the Hamiltonian is known accurately or is an acknowledged model, the theoretical study of quantum control can provide physical insight into the phenomena involved, as well as possibly yielding trial laser pulses for further refinement in the laboratory.

Achieving control over quantum mechanical phenomena often involves a balance of competing dynamical processes. For example, in the case of aiming to create a particular excitation in a molecule or material, there will always be the concomitant need to minimize other unwanted excitations. Often, there are also limitations on the form, intensity, or other characteristics of the laser controls that must be adhered to. Another goal is for the control outcome to be as robust as possible to the laser field fluctuations and Hamiltonian uncertainties. Overriding all of these issues is merely the desire to achieve the best possible physical result for the posed quantum mechanical objective. In summary, all of these desired extrema conditions translate over to posing the design of control laser fields as an optimization problem. Thus, optimal control theory forms a basic foundation for quantum control field design.

Control field design starts by specification of the Hamiltonian components H_0 and $\boldsymbol{\mu}$ in eqn [1], with the goal of finding the best control electric field $\boldsymbol{\varepsilon}(t)$ to balance the competing objectives. Schrödinger's equation must be solved as part of this process, but this effort is not merely a forward propagation task, as the control field is not known a priori. As an optimal design is the goal, a cost functional $J = J(\text{objectives, penalties, } \boldsymbol{\varepsilon}(t))$ is prescribed, which contains the information on the physical objectives, competing penalties, and any costs or constraints associated with the structure of the laser field. The functional J could

contain many terms if the competing physical goals are highly complex. As a specific simple illustration, consider the common goal of steering the system to achieve an expectation value $\langle\psi(T)|O|\psi(T)\rangle$ as close as possible to the target value O_{target} associated with the observable operator O at time T. An additional cost is imposed to minimize the laser fluence. These criteria may be embodied in a cost functional of the form

$$J = \left(\langle\psi(T)|O|\psi(T)\rangle - O_{\text{target}}\right)^2 + \omega\int_0^T \varepsilon^2(t)\,\mathrm{d}t - 2\Im\int_0^T \mathrm{d}t\left\langle\lambda(t)|\mathrm{i}\hbar\frac{\partial}{\partial t} - H_0 + \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)|\psi(t)\right\rangle \quad [3]$$

Here, the parameter $\omega \geq 0$ is a weight to balance the significance of the fluence term relative to achieving the target expectation value, and $|\lambda(t)\rangle$ serves as a Lagrange multiplier, assuring that Schrödinger's equation is satisfied during the variational minimization of J with respect to the control field. Carrying out the latter minimization will lead to eqn [1], along with the additional relations

$$\mathrm{i}\hbar\frac{\partial}{\partial t}|\lambda(t)\rangle = [H_0 - \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(t)]|\lambda(t)\rangle, \quad |\lambda(T)\rangle = 2\sigma O|\lambda(T)\rangle \quad [4]$$

$$\boldsymbol{\varepsilon}(t) = \frac{1}{\omega}\Im\langle\lambda(t)|\boldsymbol{\mu}|\psi(t)\rangle \quad [5]$$

$$\sigma = \langle\psi(T)|O|\psi(T)\rangle - O_{\text{target}} \quad [6]$$

Equations [1] and [4]–[6] embody the OCT design equations that must be solved to yield the optimal field $\boldsymbol{\varepsilon}(t)$ given in eqn [5]. These design equations have an unusual mathematical structure within quantum mechanics. First, insertion of the field expression in eqn [5] into eqns [1] and [4] produces two cubically nonlinear coupled Schrödinger-like equations. These equations are in the same family as the standard nonlinear Schrödinger equation, and as such, one may expect that unusual dynamical behavior could arise. Although eqn [4] for $|\lambda(t)\rangle$ is identical in form to the Schrödinger equation [1], only $|\psi(t)\rangle$ is the true wavefunction, with $|\lambda(t)\rangle$ serving to guide the controlled quantum evolution towards the physical objective. Importantly, eqn [1] is an initial value problem, while eqn [4] is a final value problem. Thus, the two equations together form a two-point boundary value problem in time, which is an inherent feature of temporal engineering optimal control as well. The boundary value nature of these equations typically leads to the existence of multiple solutions, where σ in eqn [6] plays the role of a discrete eigenvalue, specifying the quality of the particular achieved control field design. The fact that there are generally multiple solutions to the laser design equations can be attractive from a physical perspective, as the designs may be sorted through to identify those being most attractive for laboratory implementation.

The overall mathematical structure of eqns [1] and [4]–[6] can be melded together into a single design equation

$$\mathrm{i}\hbar\frac{\partial}{\partial t}|\psi(t)\rangle = [H_0 - \boldsymbol{\mu}\cdot\boldsymbol{\varepsilon}(\psi, \sigma, t)]|\psi(t)\rangle, \quad |\psi(0)\rangle = |\psi_{\text{i}}\rangle \quad [7]$$

The structure of this equation embodies the comments in the introduction that control field design is inherently a nonlinear process. The main source of complexity arising in eqn [7] is through the control field $\boldsymbol{\varepsilon}(\psi, \sigma, t)$ depending not only on the wave function at the present time t, but also on the future value of the wavefunction at the target time T contained in σ. This structure again reflects the two-point boundary value nature of the control equations.

Given the typical multiplicity of solutions to eqns [1] and [4]–[6], or equivalently, eqn [7], it is attractive to consider approximations to these equations (except perhaps for the inviolate Schrödinger equation [1], and much work continues to be done along these lines. One case involves what is referred to as tracking control, whereby a path is specified for $\langle\psi(t)|O|\psi(t)\rangle$ evolving from $t = 0$ out to $t = T$. Tracking control eliminates σ to produce a field of the form $\boldsymbol{\varepsilon}(\psi,t)$, thereby permitting the design equations to be explicitly integrated as a forward-marching problem toward the target; the tracking equations are still nonlinear with respect to the evolving state. Many variations on these concepts can be envisioned, and other approximations may also be introduced to deal with special circumstances. One technique appropriate for at least few-level systems is stimulated Raman adiabatic passage (STIRAP), which seeks robust adiabatic passage from an initial state to a particular final state, typically with nearly total destructive interference occurring in the intermediate states. This design technique can have special attractive robustness characteristics with respect to field errors. STIRAP, tracking, and various perturbation theory-based control design techniques can be expressed as special cases of OCT, with suitable cost functionals and constraints. Further approximation methods will surely be developed, with the rigorous OCT concepts forming the general foundation for control field design.

As the OCT equations are inherently nonlinear, their solution typically requires numerical iteration,

and a variety of procedures may be utilized for this purpose. Almost all of the methods employ local search techniques (e.g., gradient methods), and some also show monotonic convergence with respect to each new iteration step. Local techniques typically evolve to the nearest solution in the space of possible control fields. Such optimizations can be numerically efficient, although the quality of the attained result can depend on the initial trial for the control field and the details of the algorithm involved. In contrast, global search techniques, such as simulated annealing or genetic algorithms, can search more broadly for the best solution in the control field space. These more expansive searches are attractive, but at the price of typically requiring more intensive computations. Effort has also gone into seeking global or semiglobal input $\rightarrow$ output maps relating the electric field $\boldsymbol{\varepsilon}(t)$ structure to the observable $O[\boldsymbol{\varepsilon}(t)]$. Such maps may be learned, hopefully, from a modest number of computations with a selected set of fields, and then utilized as high-speed interpolators over the control field space to permit the efficient use of global search algorithms to attain the best control solution possible. At the foundation of all OCT design procedures is the need to solve the Schrödinger equation. Thus, computational technology to improve this basic task is of fundamental importance for designing laser fields.

Many computations have been carried out with OCT to attain control field designs for manipulating a host of phenomena, including rotational, vibrational, electronic, and reactive dynamics of molecules, as well as electron motion in semiconductors. Every system has its own rich details, which in turn, are compounded by the fact that multiple control designs will typically exist in many applications producing comparable physical outcomes. Collectively, these control design studies confirm the manipulation of constructive and destructive quantum wave interferences as the general mechanism for achieving successful control over quantum phenomena. This conclusion may be expressed as the following principle:

> **Control field–system cooperativity principle:** Successful quantum control requires that the field must have the proper structure to take full advantage of all of the dynamical opportunities offered by the system, to best satisfy the physical objective.

This simple statement of system–field cooperativity embodies the richness, as well as the complexity, of seeking control over quantum phenomena, and also speaks to why simple intuition alone has not proved to be a generally viable design technique. Quantum systems can often exhibit highly complex dynamical behavior, including broad dispersion of the wave packet over spatial domains or multitudes of quantum states. Handling such complexity can require fields with subtle structure to interact with the quantum system in a global fashion to manage all of the motions involved. Thus, we may expect that successful control pulses will often have broad bandwidth, including amplitude and phase modulation. Until relatively recently, laser sources with these characteristics were not available, but the technology is now in hand and rapidly evolving (see the discussion later).

The cooperativity principle above is of fundamental importance in the control of all quantum phenomena, and a simple illustration of this principle is shown in Figure 2 for the control of wave packet motion on an excited state of the NO molecule. The target for the control is a narrow wave packet located over the well of the excited B state. The optimal control field consists of two coordinated pulses, at early and late times, with both features having internal structure. The figure indicates that the ensuing excited state wave packet has two components, one of which actually passes through the target region during the initial evolution, only to return again and meet the second component at just the right place and time, to achieve the target objective as best as possible. Similar cooperativity interpretations can be found in virtually all implementations with OCT.

The main reason for performing quantum field design is to ultimately implement the designs in the laboratory. The design procedures must face laboratory realities, which include the fact that most Hamiltonians are not known to high accuracy (especially for polyatomic molecules and complex solid-state structures), and secondly, a variety of laboratory field imperfections may unwittingly be present. Notwithstanding these comments, OCT has been fundamental to the development of quantum control, including laying out the logic for how to perform the analogous optimal control experiments. Design implementations and further OCT development will continue to play a basic role in the quantum control field. At present, perhaps the most important contribution of OCT has been to (1) highlight the basic control cooperativity principle above, and (2) provide the basis for developing algorithms to successfully guide optimal control experiments, as discussed below.

Algorithms for Implementing Optimal Control Experiments

The ultimate purpose of considering control theory within quantum mechanics is to take the matter into

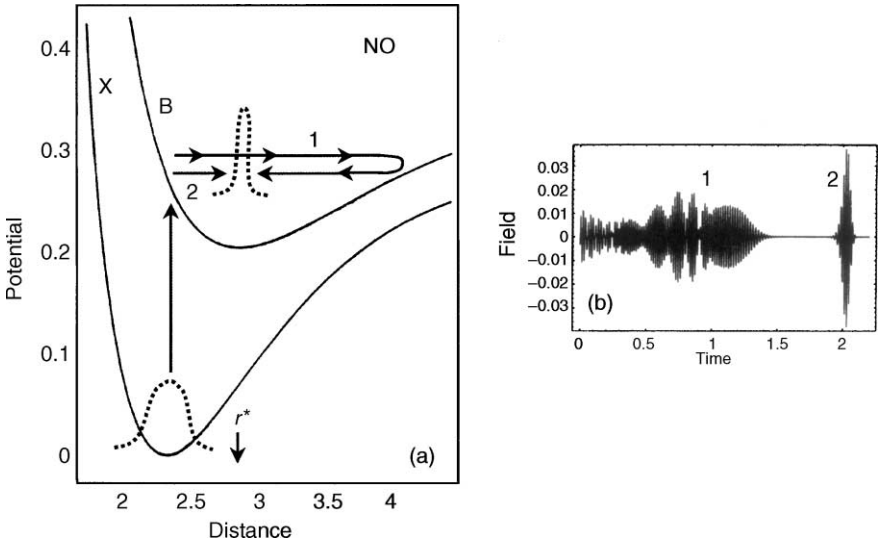

Figure 2 Control of wave packet evolution on the electronically excited B state of NO, with the goal of creating a narrow final packet over the excited state well. (a) indicates that the ground-state packet is brought up in two pieces using the coordinated dual pulse in (b). The piece of the packet from the first pulse actually passes through the target region, then bounces off the right side of the potential, to finally meet the second piece of the packet at just the right time over the target location r^* for successful control. This behavior is an illustration of the control field–system cooperativity principle stated in the text.

the laboratory for implementation and exploitation of its capabilities. Ideally, theoretical control field designs may be attained using the techniques discussed above, followed by the achievement of successful control upon execution of the designs in the laboratory. This appealing approach is burdened with three difficulties: (1) Hamiltonians are often imprecisely known, (2) accurately solving the design equations can be a significant task, and (3) realization of any given design will likely be imperfect due to laboratory noise or other unaccounted-for systematic errors. Perhaps the most serious of these difficulties is point (1), especially considering that the best quality control will be achieved by maximally drawing on subtle constructive and destructive quantum wave interference effects. Exploiting such subtleties will generally require high-quality control designs that, in turn, depend on having reliable Hamiltonians. Although various designs have been carried out seeking robustness with respect to Hamiltonian uncertainties, the issue in point (1) should remain of significance in the foreseeable future, especially for the most complex (and often, the most interesting!) chemical/physical applications. Mitigating this serious problem is the ability to create shaped laser pulse controls and apply them to a quantum system, followed by a probe of their effects at an unprecedented rate of thousands or more independent trials per minute. This unique capability led to the suggestion of partially, if not totally, sidestepping the design process by performing closed-loop experiments to let the quantum system teach the laser how to achieve its control in the laboratory. Figure 3 schematically shows this closed loop process, drawing on the following logic:

1. **The molecular view.** Although there may be theoretical uncertainty about the system Hamiltonian, the actual chemical/physical system under study 'knows' its own Hamiltonian precisely! This knowledge would also include any unusual exigencies, perhaps associated with structural or other defects in the particular sample. Furthermore, upon exposure to a control field, the system 'solves' its own Schrödinger equation impeccably accurately and as fast as possible in real time. Considering these points, the aim is to replace the offline arduous digital computer control field design effort with the actual quantum system under study acting as a precise analog computer, solving the true equations of motion.
2. **Control laser technology.** Pulse shaping under full computer control may be carried out using even hundreds of discrete elements in the frequency domain controlling the phase and amplitude structure of the pulse. This technology is readily available and expanding in terms of pulse center frequency flexibility and bandwidth capabilities.

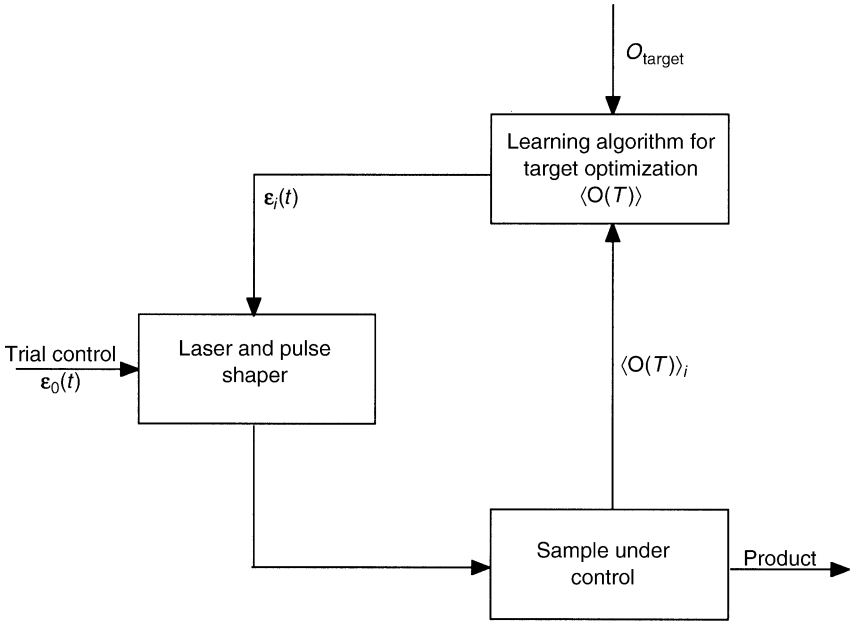

Figure 3 A schematic of the closed-loop concept for allowing the quantum system to teach the laser how to achieve its control. The actual quantum system under control is in a loop with a laser and pulse shaper all slaved together with a pattern recognition algorithm to guide the excursions around the loop. The success of this concept relies on the ability to perform very large numbers of control experiments in a short period of time. In principle, no knowledge of the system Hamiltonian is required to steer the system to the desired final objective, although a good trial design $\varepsilon_0(t)$ may accelerate the process. The ith cycle around the loop attempts to find a better control field $\varepsilon_i(t)$ such that the system response $\langle O(T) \rangle_i$ for the observable operator O comes closer to the desired value O_{target}.

3. **Quantum mechanical objectives**. Many chemical/physical objectives may be simply expressed as the desire to steer a quantum mechanical flux out one clearly defined channel versus another.
4. **Detection of the control action**. Detection of the control outcome can often be carried out by a second laser pulse or any other suitable high duty cycle detection means, such as laser-induced mass spectrometry. The typical circumstance in point (3) implies that little, if any, time-consuming offline data analysis will be necessary beyond that of simple signal averaging.
5. **Fast learning algorithms**. All of the four points above may be slaved together using pattern recognition learning algorithms to identify those control fields which are producing better results, and bias the next sequence of experiments in their favor for further improvement. Although many algorithms may be employed for this purpose, the global search capabilities of genetic algorithms are quite attractive, as they may take full advantage of the high throughput nature of the experiments.

In linking together all of these components into a closed-loop OCE, it is important that no single operational step significantly lags behind any other, for efficiency reasons. Fortunately, this economy is coincident with all the tasks and technologies involved. For achieving control alone, there is no requirement that the actual laser pulse structure be identified on each cycle of the loop. Rather, the laser control 'knob' settings are adequate information for the learning algorithm, as the only criterion is to suitably adjust the knobs to achieve an acceptable value for the chemical/physical objective. The learning algorithm in point (5) operates with a cost functional J, analogous to that used for computational design of fields, but now the cost functional can only depend on those quantities directly observable in the laboratory (i.e., minimally, the current achieved target expectation value). In cases where a physical understanding is sought about the control mechanism, the laser field structure must also be measured. This additional information is typically also not a burden to attain, as it often is only required for the single best control field at the end of the closed-loop learning experiments.

The OCE process in Figure 3 and steps (1)–(5) above constitute the laboratory process for achieving optimal quantum control, and exactly the same reasons put forth for OCT motivate the desire for attaining optimal performance: principally, seeking

the best control result that can possibly be obtained. Seeking optimal performance also ensures some degree of inherent robustness to field noise, as fleeting observations would not likely survive the signal averaging carried out in the laboratory. Additionally, robustness as a specific criterion may also be included in the laboratory cost functional in item (5). When a detailed physical interpretation of the controlled dynamics is desired, it is essential to remove any extraneous control field features that have little impact on the system manipulations. Without the latter clean-up carried out during the experiments, the final field may be contaminated by structures that have little physical impact. Although quantum dynamics typically occurs on femtosecond or picosecond time-scales, the loop excursions in Figure 3 need not be carried out on the latter time-scales. Rather, the loop may be traversed as rapidly as convenient, consistent with the capabilities of the apparatus. A new system sample is introduced on each cycle of the loop. This process is referred learning control, to distinguish it from real-time feedback control.

The closed-loop quantum learning control algorithm can be self-starting, requiring no prior control field designs, under favorable circumstances. Virtually all of the current experiments were carried out in this fashion. It remains to be seen if this procedure of 'going in blind' will be generally applicable in highly complex situations where the initial state is far from the target state. Learning control can only proceed if at least a minimal signal is observed in the target state. Presently, this requirement has been met by drawing on the overwhelmingly large number of exploratory experiments that can be carried out, even in a brief few minutes, under full computer control. However, in some situations, the performance of intermediate observations along the way to the target goal may be necessary in order to at least partially guide the quantum dynamics towards the ultimate objective. Beneficial use could also be made from prior theoretical laser control designs $\boldsymbol{\varepsilon}_0(t)$ capable of at least yielding a minimal target signal.

The OCE closed-loop procedure was based on the growing number of successful theoretical OCT design calculations, even with all of their foibles, especially including less than perfect Hamiltonians. The OCT and OCE processes are analogous, with their primary distinction involving precisely what appears in their corresponding cost functionals. Theoretical guidance can aid in identifying the appropriate cost functionals and learning algorithms for OCE, especially for addressing the needs associated with attaining a physical understanding about the mechanisms governing controlled quantum dynamics phenomena.

A central issue is the rate that learning control occurs upon excursions around the loop in Figure 3. A number of factors control this rate of learning, including the nature of the physical system, the choice of objective, the presence of field uncertainties and measurement errors, the number of control variables, and the capabilities of the learning algorithm employed. Achieving control is a matter of discrimination, and some of these factors, whether inherent to the system or introduced by choice, may work against attaining good-quality discrimination. At this juncture, little is known quantitatively about the limitations associated with any of these factors.

The latter issues have not prevented the successful performance of a broad variety of quantum control experiments, and at present the ability to carry out massive numbers of closed-loop excursions has overcome any evident difficulties. The number of examples of successful closed-loop quantum control is rapidly growing, with illustrations involving the manipulation of laser dye fluorescence, chemical reactivity, high harmonic generation, semiconductor optical switching, fiber optic pulse transmission, and dynamical discrimination of similar chemical species, amongst others. Perhaps the most interesting cases are those carried out at high field intensities, where prior speculation suggested that such experiments would fail due to even modest laser field noise being amplified by the quantum dynamics. Fortunately, this outcome did not occur, and theoretical studies have indicated that surprising degrees of robustness to field noise may accompany the manipulation of quantum dynamics phenomena. Although the presence of field noise may diminish the beneficial influence of constructive and destructive interferences, evidence shows that field noise does not appear to kill the actual control process, at least in terms of obtaining reasonable values for the control objectives. One illustration of control in the high-field regime is shown in Figure 4, demonstrating the learning process for the dissociative rearrangement of acetophenone to form toluene. Interestingly, this case involves breaking two bonds, with the formation of a third, indicating that complex dynamics can be managed with suitably tailored laser pulses.

Operating in the strong-field regime, especially for chemical manipulations, also has the important benefit of producing a generic laser tool to control a broad variety of systems by overcoming the long-standing problem of having sufficient bandwidth. For example, the result in Figure 4 uses a Ti:sapphire laser in the near-infrared regime. Starting with a bandwidth-limited pulse of intensity near

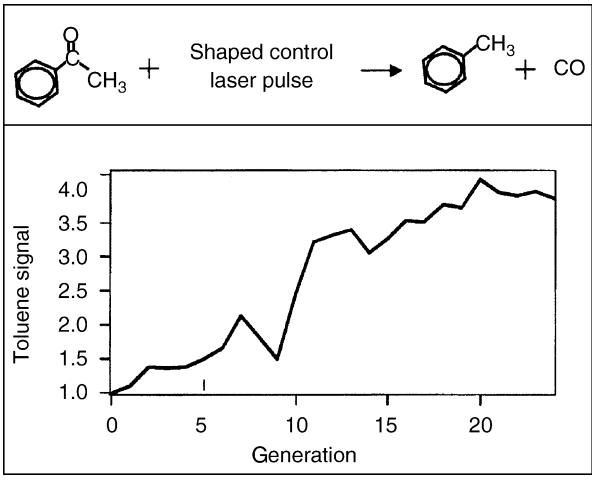

Figure 4 An illustration of dissociative rearrangement achieved by closed-loop learning control in **Figure 3**. The optimally deduced laser pulse broke two bonds in the parent acetophenone molecule and formed a new one to yield the toluene product. The laboratory learning curve is shown for the toluene product signal as a function of the generations in the genetic algorithm guiding the experiments. The fluctuations in the learning curve for optimizing the toluene yield corresponds to the algorithm searching for the optimal yield as the experiments proceed.

$\sim 10^{14}$ W cm^{-2}, in this regime, the dynamic power broadening can easily be on the order of ~ 1 eV or more, thereby effectively converting the otherwise discrete spectrum of the molecule into an effective continuum for ready multiphoton matching by the control laser pulse. Operating under these physical conditions is very attractive, as the apparatus is generic, permitting a single shaped-pulse laser source (e.g., a Ti:sapphire system with phase and amplitude modulation) to be utilized with virtually any chemical system where manipulations are desired. Although every desired physical/chemical goal may not be satisfactorily met (i.e., the goals must be physically attainable!), the means are now available to explore large numbers of systems. Operating under closed loop in the strong-field tailored-pulse regime eliminates the prior serious limitation of first finding a physical system to meet the laser capabilities; now, the structure of the laser pulse can be shaped to meet the molecule's characteristics. Strong field operations may be attractive for these reasons, but other broadband laser sources, possibly working at weaker field intensities, might be essential in some applications (e.g., controlling electron dynamics in semiconductors, where material damage is to be avoided). It is anticipated that additional broadband laser sources will become available for these purposes.

The coming years should be a period of rapid expansion, including a thorough exploration of closed-loop quantum control capabilities. As with the use of any laboratory tool, certain applications may be more amenable than others to attaining successful control. The particular physical/chemical questions need to be well posed, and controls need to have sufficient flexibility to meet the objectives. The experiments ahead should be able to reveal the degree to which drawing on optimality in OCE, combined with the performance of massive numbers of experiments can lead to broad-scale successful control of quantum phenomena. One issue of concern is the richness associated with the large numbers of phase and amplitude control knobs that may be adjusted in the laboratory. Some experiments have already operated with hundreds of knobs, while others have restricted their number in a variety of ways, to simplify the search process. Additional technological and algorithmic advances may be required to manage the high-dimensional control space searches. Fortunately, for typical applications, the search does not reduce to seeking a needle in a haystack, as generally there are multiple control solutions, possibly all of very good quality.

As a final comment on OCE, it is useful to appreciate the subtle distinction of the procedure from closed-loop feedback experiments. This distinction is illustrated in **Figure 5**, pointing to three types of closed-loop quantum control laboratory experiments. The OCE procedure in **Figure 5a** produces a generic laser tool capable of controlling a broad variety of systems with an emphasis in the figure placed on the point that each cycle around the loop starts with a new sample for control. The replacement of the sample on each cycle eliminates a number of difficulties, principally including concerns about sample damage, avoidance of operating the loop at the ultrafast speed of the quantum mechanical processes, and elimination of the effect that 'to observe is to disturb' in quantum mechanics. Thus, learning control provides a generic practical procedure, regardless of the nature of the quantum system. **Figure 5b** has the same structure as that of **Figure 5a**, except the loop is now closed around the same single quantum system, which is followed throughout its evolution. All of the issues mentioned above that are circumvented by operating through laboratory learning control in **Figure 5a** must now be directly faced in the setup of **Figure 5b**. The procedure in **Figure 5b** will likely only be applicable in special circumstances, at least for the reason that many quantum systems operate on time-scales far too fast for opto-electronics and computers to keep up with. However, there are certain quantum mechanical processes that are sufficiently slow to meet the criteria. Furthermore, a period of free evolutionary

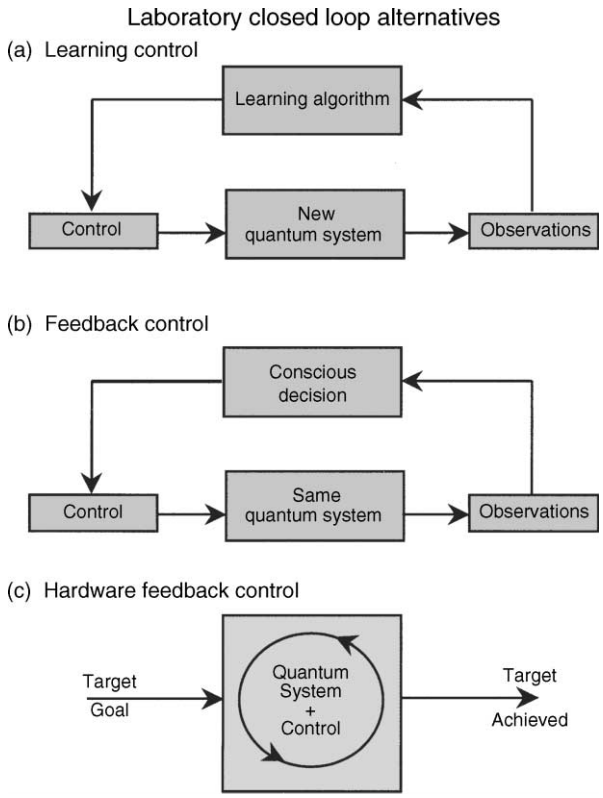

Figure 5 Three possible closed-loop formulations for attaining laser control over quantum phenomena. (a) is a learning control process where a new system is introduced on each excursion around the loop. (b) utilizes feedback control with the loop being traversed with the same sample, generally calling for an accurate model of the system to adjust the controls on each loop excursion. (c) is, at present, a dream machine where the laser and the sample under control are one unit operating without external algorithmic guidance. The closed-loop learning control procedure in (a) appears to form the most practical means to achieve laser control over quantum phenomena, especially for complex systems.

quantum dynamics may be permitted to occur between one control pulse and the next, to make the time issue manageable. While the learning control process in Figures 3 and 5a can be performed model-free, the feedback algorithm in Figure 5b generally must operate with a sufficiently reliable system Hamiltonian to carry out fast design corrections to the control field, based on the previous control outcome. These are very severe demands, but they may be met under certain circumstances. One reason for considering closed-loop feedback control in Figure 5b is to explore the basic physical issue of quantum mechanical limitations inherent in the statement 'to observe is to disturb'. It is suggestive that control over many types of quantum phenomena may fall into the semiclassical regime, lying somewhere between classical engineering behavior and the hard limitations of quantum mechanics. Experiments of the type in Figure 5b will be most interesting for exploring this matter. Finally, Figure 5c introduces a *gedanken* experiment in the sense that the closed-loop process is literally built into the hardware. That is, the laser control and quantum system act as a single functioning unit operating in a stable fashion, so as to automatically steer the system to the desired target. This process may involve engineering the quantum mechanical system prior to control in cases where that freedom exists, as well as engineering the laser components involved. The meaning of such a device in Figure 5c can be understood by considering an analogy with airplane flight, where the aircraft is constructed to have an inherent degree of aerodynamic stability and will essentially fly (glide) on its own accord when pushed forward. It is an open question whether closing the loop in the hardware can be attained for quantum control, and an exploration of this concept may require additional laser technologies.

Conclusions

This article presented an overview of theoretical concepts and algorithmic considerations associated with the control of quantum phenomena. Theory has played a central role in this area by revealing the fundamental principles underlying quantum control, as well as by providing algorithms for designing controls and guiding experiments to discover successful controls in the laboratory. The challenge of controlling quantum phenomena, in one sense, is an old subject, going back at least 40 years. However, roughly the first 30 of these years would best be described as a period of frustration, due to a lack of full understanding of the principles involved and the nature of the lasers needed to achieve success. Thus, from another perspective, the subject is quite young, with perhaps the most notable development being the introduction of closed-loop laboratory learning procedures. At the time of writing this article, these procedures are just beginning to be explored for their full capabilities. To appreciate the young nature of this subject, it is useful to note that the analogous engineering control disciplines presently occupy many thousands of engineers worldwide, both theoreticians and practitioners, and have done so for many years. Yet, engineering control is far from considered a mature subject. Armed now with the basic concepts and proper laboratory tools, one may anticipate a thorough exploration of control over quantum phenomena, including its many possible applications.

Introduction

The experimental control of quantum phenomena in atoms, molecules, and condensed phase materials has been a long-standing challenge in the physical sciences. For example, the idea that a laser beam could be used to selectively cleave a chemical bond has been pursued since the demonstration of the laser in the early 1960s. However, it was not until very recent times that one could realize selective bond cleavage. One key to the rapid acceleration of such experiments is the capability of manipulating the relative phases between two or more paths leading to the same final state. This is done in practice by controlling the phase of two (or two thousand!) laser frequencies coupling the initial state to some desired final state. The present interest in phase-related control stems in part from research focusing on quantum information sciences, controlling chemical reactivity, and developing new optical technologies, such as in biophotonics for imaging cellular materials. Ultimately, one would like to identify coherent control applications having impact similar to linear regime applications like compact disk reading (and writing), integrated circuit fabrication, and photodynamic therapy. Note that in each of these the phase of the electromagnetic field is not an important parameter and only the brightness of the laser at a particular frequency is used. While phase is of negligible importance in any one photon process, for excitations involving two or more photons, phase not only becomes a useful characteristic, it can modulate the yield of a desired process between zero and one hundred percent.

The use of optical phase to manipulate atomic and molecular systems rose to the forefront of laser science in the 1980s. Prior to this there was considerable effort directed toward using the intensity and high spectral resolution features of the laser for various applications. For example, the high spectral resolution character was employed in purifying nuclear isotopes. Highly intense beams were also used in the unsuccessful attempt to pump enough energy into a single vibrational resonance to selectively dissociate a molecule. The current revolution in coherent control has been driven in part by the realization that controlling energy deposition into a single degree of freedom (such as selectively breaking a bond in a polyatomic molecule) can not be accomplished by simply driving a resonance with an ever more intense laser source. In the case of laser-induced photo dissociation, such excitation ultimately results in statistical dissociation throughout the molecule due to vibrational mode coupling. In complex systems, controlling energy deposition into a desired quantum state requires a more sophisticated approach and one scheme involves coherent control.

The two distinct regimes for excitation in coherent control, the time and frequency domain experiments, are formally equivalent. While the experimental approach and level of success for each domain is vastly different, both rely on precisely specifying the phase relations for a series of excitation frequencies. The basic idea behind phase control is simple. One emulates the interference effects that can be easily visualized in a water tank experiment with a wave propagating through two slits. In the coherent control experiment, two or more indistinguishable pathways must be excited that connect one quantum state to another. In either water waves, or coherent control, the probability for observing constructive or destructive interference at a target state depends on the phase difference between the paths connecting the two locations in the water tank, or the initial and final states in the quantum system. In the case of coherent control, the final state may have some technological

value, for instance, a desirable chemical reaction product or an intermediate in the implementation of quantum computation.

Frequency domain methods concentrate on interfering two excitation routes in a system by controlling the phase difference between two distinct frequencies coupling an initial state to a final state. Perhaps the first mention of the concept of phase control in the optical regime can be traced to investigations in Russia in the early 1960s, where the interference between a one- and three-photon path was theoretically proposed as a means to modulate a two-photon absorption. This two-path interference idea lay dormant until the reality of controlling the relative phase of two distinct frequencies was achieved in 1990 using gas phase pressure modulation for frequency domain experiments. The idea was theoretically extended to the control of nuclear motion in 1988. The first experimental example of two-color phase control over nuclear motion was demonstrated in 1991. It is interesting that the first demonstrations of coherent control did not, however, originate in the frequency domain approach, but came from time domain investigations in the mid-1980s. This was work that grew directly out of the chemical dynamics community and will be described below.

While frequency domain methods were developed exclusively for the observation of quantum interference, the experimental implementation of time-domain methods was first developed for observing nuclear motion in real time. In the time domain, a superposition of multiple states is prepared in a system using a short duration ($\sim$50 fs) laser pulse. The superposition state will subsequently evolve according to the phase relationships of the prepared states and the Hamiltonian of the system. At some later time the evolution must be probed using a second, short-time-duration laser pulse. The time-domain methods for coherent control were first proposed in 1985 and were based on wavepacket propagation methods developed in the 1970s. The first experiments were reported in the mid-1980s.

To determine whether the time or frequency domain implementation is more applicable for a particular control context, one should compare the relevant energy level spacing of the quantum system to the bandwidth of the excitation laser. For instance, control of atomic systems is more suited to frequency domain methods because the characteristic energy level spacing in an atom (several electron volts) is large compared to the bandwidth of femtosecond laser pulses (millielectron volts). In this case, preparation of a superposition of two or more states is impractical with a single laser pulse at the present time, dictating that the control scheme must employ the initial state and a single excited eigenstate. In practice, quasi-CW nanosecond duration laser pulses are employed for such experiments because current ultrafast (fs duration) laser sources cannot typically prepare a superposition of electronic states. One instructive exception involves the excitation of Rydberg states in atoms. Here the electronic energy level spacing can be small enough that the bandwidth of a femtosecond excitation laser may span several electronic states and thus can create a superposition state. One should also note that the next generation of laser sources in the attosecond regime may permit the preparation of a wavepacket from low-lying electronic states in an atom. In the case of molecules, avoiding a superposition state is nearly impossible. Such experiments employ pico- to femtosecond duration laser pulses, having a bandwidth sufficient to excite many vibrational levels, either in the ground or excited electronic state manifold of a molecule. To complete the time-dependent measurement, the propagation of the wavepacket to the final state of interest must be observed (probed) using a second ultrafast laser pulse that can produce fluorescence, ionization, or stimulated emission in a time-resolved manner. The multiple paths that link the initial and final state via the pump and the probe pulses are the key to the equivalence of the time and frequency domain methods.

There is another useful way to classify experiments that have been performed recently in coherent control, that is into either open-loop or closed-loop techniques. Open-loop signifies that a calculation may be performed to specify the required pulse shape for control before the experiment is attempted. All of the frequency-based, and most of the time-based experiments fall into this category. Closed-loop, on the other hand, signifies that the results from experimental measurements must be used to assist in determining the correct parameters for the next experiment, this pioneering approach was suggested in 1992. It is interesting that in the context of control experiments performed to date, closed-loop experiments represent the only route to determining the optimal laser pulse shape for controlling even moderately complex systems. In this approach, no input from theoretical models is required for coherent control of complex systems. This is unlike typical control engineering environments, where closed-loop signifies the use of experiments to refine parameters used in a theoretical model.

There is one additional distinction that is of value for understanding the state of coherent control at the present time. Experiments may be classified into systems having Hamiltonians that allow calculation of frequencies required for the desired interference

patterns (thus enabling open-loop experiments) and those having ill-defined Hamiltonians (requiring closed-loop experiments). The open-loop experiments have demonstrated the utility of various control schemes, but are not amenable to systems having even moderate complexity. The closed-loop experiments are capable of controlling systems of moderate complexity but are not amenable to precalculation of the required control fields. Systems requiring closed-loop methods include propagation of short pulses in an optical fiber, control of high harmonic generation for soft X-ray generation, control of chemical reactions and control of biological systems. In the experimental regime, the value of learning control for dealing with complex systems has been well documented.

The remainder of this article represents an overview of the experimental implementation of coherent control. The earliest phase control experiments involved time-dependent probing of molecular wavepackets, and were followed by two-path interference in an atomic system. The most recent, and general, implementation of control involves tailoring a time-dependent electromagnetic field for a desired objective using closed-loop techniques. Since the use of tailored laser pulses appears to be rather general, a more complete description of the experiment is provided.

Time-Dependent Methods

The first experiments demonstrating the possibility of coherent control were performed to detect nuclear motion in molecules in real time. These investigations were the experimental realization of the pump-dump or pulse-timing control methods as originally described in 1985. The experimental applications have expanded to numerous systems including diatomic and triatomic molecules, small clusters, and even biological molecules. For such experiments, a vibrational coherence is prepared by exciting a superposition of states. These measurements implicitly used phase control both in the generation of the ultrashort pulses and in the coherent probing of the superposition state by varying the time delay between the pump and probe pulses, in effect modulating the outcome of a quantum transition. Since the earliest optical experiment in the mid-1980s, there have been many hundreds of such experiments reported in the literature. The motivation for the very first experiments was not explicitly phase control, but rather the observation of nuclear motion of molecules in real time. In such later measurements, oscillations in the superposition states were observable for many cycles, up to many tens of picoseconds in favorable cases, i.e., diatomic molecules in the gas phase. The loss of signal in the coherent oscillations is ultimately due to passage of the superposition state in to surrounding bath states. This may be due to collision with another molecule, dissociation of the system or redistribution of the excitation energy into other modes of the system not originally excited in the superposition. It is notable that coherence can be maintained in solution phase systems for tens of picoseconds and for the case of resonances having weak coupling to other modes, coherence can even be modulated in large biological systems on the picosecond time scale.

Decoherence represents loss of phase information about a system. In this context, phase information represents our detailed knowledge of the electronic and nuclear coordinates of the system. In the case of vibrational coherence, decoherence may be represented by intramolecular vibrational energy transfer to other modes of the molecule. This can be thought of as the propensity of vibrational modes of a molecule to couple together in a manner that randomizes deposited energy throughout the molecule. Decoherence in a condensed phase system includes transfer of energy to the solvent modes surrounding the system of interest. For an electronically excited molecule or atom, decoherence can involve spontaneous emission of radiation (fluorescence), or dissociation in the case of molecules. Certain excited states may have high probability for fluorescence and would represent a significant decoherence pathway and an obstacle for coherent control. These states may be called 'lossy' and are often used in optical pumping schemes as well as for stimulated emission pumping. An interesting question arises as to whether one can employ such states in a pathway leading to a desired final state, or must such lossy states be avoided at all costs in coherent control. This question has been answered to some degree by the method of rapid adiabatic passage. In this experiment, an initial state is coupled to a final state by way of a lossy state. The coupling is a coherent process and the preparation involves dressed states that are eigenstates of the system. In this coherent superposition the lossy state is employed, but no population is allowed to build up and thus decoherence is circumvented.

Two-Path Interference Methods

Interference methods form perhaps the most intuitive example of coherent control. The first experimental demonstration was reported in 1990 and involved the modulation of ionization probability in Hg by interfering a one-photon and three-photon excitation

pathway to an excited electronic state (followed by two-photon ionization). The long delay between the introduction of the two-path interference concept in 1960 and the demonstration in 1990 was the difficulty in controlling the relative phase of the one- and three-photon paths. The solution involved generating the third harmonic of the fundamental in a nonlinear crystal, and copropagating the two beams through a low-density gas. Changing the pressure of the gas changes the optical phase retardance at different rates for different frequencies, thus allowing relative phase control between two colors. The ionization yield of Hg was clearly modulated as a function of pressure. Such schemes have been extended to diatomic molecular systems and the concept of determining molecular phase has been investigated. While changing the phase of more than two frequencies has not been demonstrated using pressure tuning (because of experimental difficulties), a more flexible method has been developed to alter relative phase of up to 1000 frequency bands, as will be described next.

Closed-Loop Control Methods

Perhaps the most exciting new aspect of control in recent years concerns the prospect for performing closed-loop experiments. In this approach a more complex level of control in matter is achieved in comparison to the two-path interference and pump-probe control methods. In the closed-loop method, an arbitrarily complex time-dependent electromagnetic field is prepared that may have multiple subpulses and up to thousands of interfering frequency bands. The realization of closed-loop control over complex processes relies on the confluence of three technologies: (i) production of large bandwidth ultrafast laser pulses; (ii) spatial modulation methods for manipulating the relative phases and amplitudes of component frequencies of the ultrafast laser pulse; and (iii) closed-loop learning control methods for sorting through the vast number of pulse shapes available as potential control fields. In the closed-loop method, the result of a laser molecule interaction is used to tailor an optimized pulse.

In almost all of the experimental systems used for closed-loop control today, Kerr lens mode-locking in the Ti:sapphire crystal is used to phase lock the wide bandwidth of available frequencies (750–950 nm) to create the ultrafast pulse. In this phenomenon, the intensity variation in the short laser pulse creates a transient lens in the Ti:sapphire lasing medium that discriminates between free lasing and mode-locked pulses. As a result, all of the population inversion available in the lasing medium may be coerced into enhancing the ultrashort traveling wave in the cavity in this way. The wide bandwidth available may then be amplified and tailored into a shaped electromagnetic field. Spatial light modulation is one such method for modulating the relative phases and amplitudes of the component frequencies in the ultrafast laser pulse to tailor the shaped laser pulse. Pulse shaping first involves dispersing the phase-locked frequencies on an optical grating, the dispersed radiation is then collimated using a cylindrical lens and the individual frequencies are focused to a line forming the Fourier plane. At the Fourier plane, the time-dependent laser pulse is transformed into a series of phase-locked continuous wave (CW) laser frequencies, and thus Fourier transformed from time to frequency space. The relative phases and amplitudes may be modulated in the Fourier plane using an array of liquid crystal pixels. After altering the spectral phase and amplitude profile, the frequencies are recombined on a second grating to form the shaped laser pulse. With one degree of phase control and 10 pixels there are an astronomic number (360^{10}) of pulse shapes that may be generated in this manner. (At the present time, pulse shapers have up to 2000 independent elements.) Evolutionary algorithms are employed to manage the available phase space. Realizing that the pulse shape is nothing more than the summation of a series of sine waves, each having an associated phase and amplitude, we find that a certain pulse shape can be represented by a genome consisting of an array of these frequency-dependent phases and amplitudes. This immediately suggests that the methods of evolutionary search strategies may be useful for determining the optimal pulse shape for a desired photoexcitation process.

The method of closed-loop optimal control for experiments was first proposed in 1992 and the first experiments were reported in 1997 regarding optimization of the efficiency of a laser dye molecule in solution. Since that time a number of experiments have been performed in both the weak and strong field regime. In the weak field regime, the intensity of the laser does not alter the field free structure of the excited states of the system under investigation. In the strong field, the field free states of the system are altered by the electric field of the laser. Whether one is in the weak or strong field regime depends on parameters including the characteristic level spacing of the states of the system to be controlled and the intensity of the laser coupling into those states. Examples of weak field closed-loop control include optimization of laser dye efficiency, compression of an ultrashort laser pulse, dissociation of alkali clusters, optimization of coherent anti-Stokes

Raman excitation, and optical pulse propagation in fibers. In the strong field, the laser field is used to manipulate the excited states of the molecule as well as induce population transfer among these states. In this sense, the laser is both creating and exciting resonances, in effect allowing universal excitation with a limited frequency bandwidth of 750–850 nm. For chemical applications, it is worth noting that most molecules do not absorb in this wavelength region in the weak field. Strong field control has been used for controlling bond dissociation, chemical rearrangement, photonic reagents, X-ray generation, molecular centrifuges and the manipulation of mass spectral fragmentation intensities. In the latter case, a new sensing technology has emerged wherein each individual pulse shape represents an independent sensor for a molecule. Given the fact that thousands of pulse shapes can be tested per minute, this represents a new paradigm for molecular analysis.

At the time of this writing, the closed-loop method for adaptively tailoring control fields, has far outstripped our theoretical understanding of the process (particularly in the strong field regime). Adaptive control is presently an active field of investigation, encompassing the fields of physics, engineering, optics, and chemistry. In the coming years, there will be as much work done on the mechanism of control as in the application of the methods. Due to small energy level spacings and complexity of the systems, we anticipate the majority of applications to be in the chemical sciences.

Introduction

Interference phenomena are well-known in classical optics. In the early 19th century, Thomas Young showed conclusively that light has wave properties, with the first interference experiment ever performed. He passed quasi-monochromatic light from a single source through a pair of double slits using the configuration of Figure 1a and observed an interference pattern consisting of a series of bright and dark fringes on a distant screen. The intensity distribution can be explained only if it is assumed that light has wave or phase properties. In modern terminology, if E_1 and E_2 are the complex electric fields of the two light beams arriving at the screen, by the superposition principle of field addition the intensity at a particular point on the screen can be written as

$$I \propto |E_1 + E_2|^2 = |E_1|^2 + |E_2|^2 + |E_1||E_2| \cos(\phi_1 - \phi_2) \qquad [1]$$

where $\phi_1 - \phi_2$ is the phase difference of the beams arriving at the screen. While this simple experiment was used originally to demonstrate the wave properties of light, it has subsequently been used for many other purposes, such as measuring the wavelength of light. However, for our purposes, here the Young's double slit apparatus can also be viewed as a device that redistributes light, or

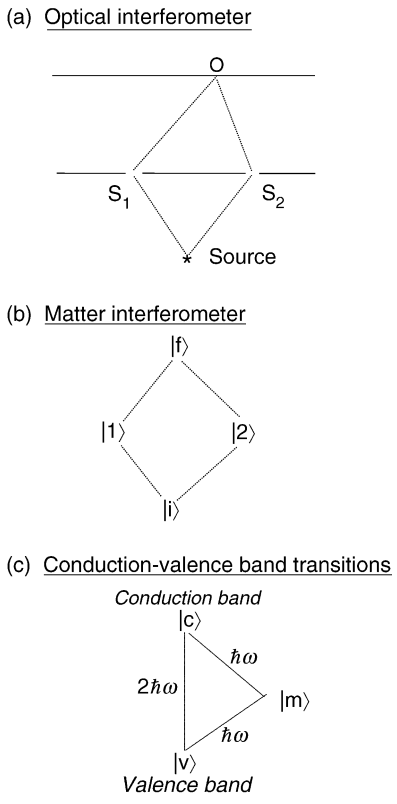

Figure 1 (a) Interference effects in the Young's double slit experiment; (b) illustration of the general concept of coherence control via multiple quantum mechanical pathways; (c) interference of single- and two-photon transitions connecting the same valence and conduction band states in a semiconductor.

controls its intensity at a particular location. For example, let's consider one of the slits to be a source, with the other slit taken to be a gate, with both capable of letting through the same amount of light. If the gate is closed, the distant screen is nearly uniformly illuminated. But if the gate is open, at a particular point on the distant screen there might be zero intensity or as much as four times the intensity emerging from one slit because of interference effects, with all the light merely being spatially redistributed. In this sense the double slit system can be viewed as a device to redistribute the incident light intensity. The key to all this is the superposition principle and the properties of optical phase.

The superposition principle and interference effects also lie at the heart of quantum mechanics. For example, let's now consider a system under the influence of a perturbation with an associated Hamiltonian that has phase properties. In general the system can evolve from one quantum state $|i\rangle$ to another $|f\rangle$ via multiple pathways involving intermediate states $|m\rangle$. Because of the phased perturbation, interference between those pathways can influence the system's final state. If a_m is the (complex) amplitude associated with a transition from the initial to the final state, via intermediate virtual state $|m\rangle$, then for all possible intermediate states the overall transition probability, W, can be written as

$$W = \left| \sum_m a_m \right|^2 \qquad [2]$$

In the case of only two pathways, as illustrated in Figure 1b, W becomes

$$\begin{aligned} W &= |a_1 + a_2|^2 \\ &= |a_1|^2 + |a_2|^2 + |a_1||a_2| \cos(\phi_1 - \phi_2) \end{aligned} \qquad [3]$$

where ϕ_1 and ϕ_2 are now the phases of the two transition amplitudes. While this expression strongly resembles that of eqn [1], here ϕ_1 and ϕ_2 are influenced by the phase properties of the perturbation Hamiltonian that governs the transition process; these phase factors arise, for example, if light fields constitute the perturbation. But overall it is clear that the change in the state of the system is affected by both the amplitude and phase properties of the perturbation. Analogous with the classical interferometer, equality of the transition amplitudes leads to maximum contrast in the transition rate. Although it has been known since the early days of quantum mechanics that the phase of a perturbation can influence the evolution of a system, generally phase has only been discussed in a passive role. Only in recent years has phase been used as a control parameter for a system, on the same level as the strength of the perturbation itself.

Coherence Control

Coherence control, or quantum control as it is sometimes called, refers to the active process through which one can use phase-dependent perturbations originating with, for example, coherent light waves, to control one or more properties of a quantum system, such as state population, momentum, or spin. This more general perspective of interference leads to a picture of interference of matter waves, rather than simply light waves, and one can now speak of an effective 'matter interferometer'. Laser beams, in particular, are in a unique position to play a role in such processes, since they offer a macroscopic 'phase handle' with which to create such effects. This was recognized by the community of atomic and molecular scientists who emphasized the active manifestations of quantum interference effects, and proposed that branching ratios in photochemical reactions

might be controlled through laser-induced interference processes. The use of phase as a control parameter also represents a novel horizon of applications for the laser since most previous applications had involved only amplitude (intensity).

Of course, just as the 'visibility' of the screen pattern for a classical Young's double slit interferometer is governed by the coherence properties of the two slit source, the evolution of a quantum system reflects the coherence properties of the perturbations, and the degree to which one can exercise phase control via external perturbations is also influenced by the interaction of the system of interest with a reservoir – essentially any other degrees of freedom in the system – which can cause decoherence and reduce the effectiveness of the 'matter interferometer'. Since the influence of a reservoir will generally increase with the complexity of a system, one might think that coherence control can only be effectively achieved in simple atomic and molecular systems. Indeed, some of the earliest suggestions for coherence control of a system involved using interference between single and three photon absorption processes, connecting the same initial and final states with photons of frequency 3ω and ω, respectively, and controlling the population of excited states in atomic or diatomic systems. However, it has been difficult to extend this 'two color' paradigm to more complex molecular systems. Since the reservoir leads to decoherence of the system overall, shorter and shorter pulses must be used to overcome decoherence effects. However, short pulses possess a large bandwidth with the result that, for complex systems, selectivity of the final state can be lost. One must therefore consider using interference between multiple pathways in order to control the system, as dictated by the details of the unperturbed Hamiltonian of the system.

For a polyatomic molecule or a solid, the complete Hamiltonian is virtually impossible to determine exactly and it is therefore equally difficult to prescribe the optimal spectral (amplitude and phase) content of the pulses that should be used for control purposes. An alternative approach has therefore emerged, in which one foregoes knowledge of the eigenstates of the Hamiltonian and details of the different possible interfering transition paths in order to achieve control of the end state of a system. This branch of coherence control has come to be known as optimal control. In optimal control one employs an optical source for which one can (ideally) have complete control over the spectral and phase properties. One then uses a feedback process in which experiments are carried out, the effectiveness of achieving a certain result is determined, and the pulse characteristics are then altered to obtain a new result. A key component is the use of an algorithm to select the new pulse properties as part of the feedback system. In this approach the molecule teaches the external control system what it 'requires' for a certain result to be optimally achieved. While the 'best' pulse properties may not directly reveal details of the multiple interference process required to achieve the optimal result, this technique can nonetheless be used to gain some insight into the properties of the unperturbed Hamiltonian and, regardless of such understanding, achieve a desirable result. It has been used to control chemical reaction rates involving several polyatomic molecules, with considerable enhancement in achieving a certain product relative to what can be done using simple thermodynamics.

Coherence Control in Semiconductors

Since coherence control of chemical reactions involving large molecules has represented a significant challenge, it was generally felt that ultrafast decoherence processes would also make control in solids, in general, and semiconductors, in particular, difficult. Early efforts therefore focused on atomic-like situations in which the electrons are bound and associated with discrete states and long coherence times. In semiconductors, the obvious choice is the excitonic system, defect states, or discrete states offered by quantum wells. Population control of excitons and directional ionization of electrons from quantum wells has been clearly demonstrated, similar to related population control of and directional ionization from atoms. Other manifestations of coherence control of semiconductors include control of electron–phonon interactions and intersub-band transitions in quantum wells.

Among the different types of coherence control in semiconductors is the remarkable result that it is possible to coherently control the properties of free electrons associated with continuum states. Although optimal control might be used for some of these processes, we have achieved clear illustrations of control phenomena based on the use of harmonically related beams and interference of single- and two-photon absorption processes connecting the continuum valence and conduction band states as generically illustrated in Figure 1c. Details of the various processes observed can be found elsewhere. Of course, the momentum relaxation time of electrons or holes in continuum states is typically of the order of 100 fs at room temperature, but this time is sufficiently long that it can permit phase-controlled processes. Indeed, with respect to conventional carrier transport, this 'long time' lapse is responsible

for the typically high electrical mobilities in crystalline semiconductors such as Si and GaAs. In essence, a crystalline semiconductor with translational symmetry has crystal momentum as a good quantum number, and selection rules for scattering prevent the momentum relaxation time from being prohibitively small. Since electrons or holes in any continuum state can participate in such control processes, one need not be concerned about pulsewidth or bandwidth, unless the pulses were to be so short that carriers of both positive and negative effective mass were generated within one band.

Coherent Control of Electrical Current Using Two Color Beams

We now illustrate the basic principles that describe how the interference process involving valence and conduction band states can be used to control properties of a bulk semiconductor. We do so in the case of using one or two beams to generate and control carrier population, electrical current, and spin current. In pointing out the underlying ideas behind coherence control of semiconductors, we will skip or suppress many of the mathematical details which are required for a full understanding but which might obscure the essential physics. In particular we consider how phase-related optical beams with frequencies ω and 2ω interact with a direct gap semiconductor such that $\hbar\omega < E_g < 2\hbar\omega$ where E_g is the electronic bandgap. For simplicity we consider exciting electrons from a single valence band via single-photon absorption at 2ω and two-photon absorption at ω. As is well known, within an independent particle approximation, the states of electrons and holes in semiconductors can be labeled by their vector crystal momentum $\mathbf{k}$; the energy of states near the conduction or valence bandedges varies quadratically with $|\mathbf{k}|$. For one-photon absorption the transition amplitude can be derived using a perturbation Hamiltonian of the form $H = e/mc\ \mathbf{A}^{2\omega} \cdot \mathbf{p}$ where $\mathbf{A}^{2\omega}$ is the vector potential associated with the light field and $\mathbf{p}$ is the momentum operator. The transition amplitude is therefore of the form

$$\mathrm{a}^{2\omega} \propto E^{2\omega} e^{i\phi_{2\omega}} p_{cv} \qquad [4]$$

where p_{cv} is the interband matrix element of $\mathbf{p}$ along the field ($E^{2\omega}$) direction; for illustration purposes the field is taken to be linearly polarized. The overall transition rate between two particular states of the same $\mathbf{k}$ can be expressed as $W_1 \propto \mathrm{a}^{2\omega}(\mathrm{a}^{2\omega})^* \propto I^{2\omega}|p_{cv}|^2$ where $I^{2\omega}$ is the intensity of the beam. This rate is independent of the phase of the light beam as well as the sign of $\mathbf{k}$. Hence the absorption of light via single-photon transitions generally populates states of equal and opposite momentum with equal probability or, equivalently, establishes a standing electron wave with zero crystal momentum. This is not surprising since photons possess very little momentum and, in the approximation of a uniform electric field, do not give any momentum to an excited electron. The particular states that are excited depends on the light polarization and crystal orientation. However, the main point is that while single-photon absorption can lead to anisotropic filling of electron states, the distribution in momentum space is not polar (dependent on sign of $\mathbf{k}$). Similar considerations apply to the excited holes, but to avoid repetition we will focus on the electrons only.

For two-photon absorption involving the ω photons and connecting states similar to those connected with single-photon absorption, one must employ the 2nd order perturbation theory using the Hamiltonian $H = e/mc\mathbf{A}^{\omega} \cdot \mathbf{p}$. For two-photon absorption there is a transition from the valence band to an (energy nonallowed) intermediate state followed by a transition from the intermediate state to the final state. To determine the total transition rate one must sum over all possible intermediate states. For semiconductors, by far the dominant intermediate state is the final state itself, so that the associated transition amplitude has the form

$$\mathrm{a}^{\omega} \propto (E^{\omega} e^{i\phi_{\omega}} p_{cv})(E^{2\omega} e^{i\phi_{\omega}} p_{cc}) \propto (E^{\omega})^2 e^{2i\phi_{\omega}} p_{cv} \hbar k \qquad [5]$$

where the matrix element p_{cc} is simply the momentum of the conduction band state ($\hbar k$) along the direction of the field. Note that unlike an atomic system, p_{cc} is nonzero, since Bloch states in a crystalline solid do not possess inversion symmetry. If two-photon absorption acts alone, the overall transition rate between two particular $\mathbf{k}$ states would be $W_2 \propto (I^{\omega})^2 |p_{cv}|^2 k^2$. As with single-photon absorption, because this transition rate is independent of the sign of k, two-photon absorption leads to production of electrons with no net momentum.

When both single- and two-photon transitions are present simultaneously, the transition amplitude is the sum of the transition amplitudes expressed in eqn [3]. The overall transition rate is then found using eqn [1] and yields $W = W_1 + W_2 + Int$ where the interference term Int is given by

$$Int \propto E^{2\omega} E^{\omega} E^{\omega} \sin(\phi_{2\omega} - 2\phi_{\omega}) k \qquad [6]$$

Note, however, that the interference effect depends on the sign of k and hence can be constructive for one part of the conduction band but destructive for other parts of that band, depending on the value of the

relative phase, $\Delta\phi = \phi_{2\omega} - 2\phi_{\omega}$. In principle one can largely eliminate transitions with $+\mathbf{k}$ and enhance those with $-\mathbf{k}$. This effectively generates a net momentum for electrons or holes and hence, at least temporarily, leads to an electrical current in the absence of any external bias. The net momentum of the carriers, which is absent in the individual processes, must come from the lattice. Because the carriers are created with net momentum during the pulses one has a form of current injection that can be written as

$$dJ/dt \propto E^{2\omega}E^{\omega}E^{\omega}\sin(\Delta\phi) \qquad [7]$$

where J is the current density. This type of current injection is allowed in both centrosymmetric and noncentrosymmetric materials. The physics and concepts behind the quantum interference leading to this form of current injection are analogous with the Young's double slit experiment. Note as well that if this 'interferometer' is balanced (single- and two-photon transition rates are similar), then it is possible to control the overall transition rate with great contrast. Roughly speaking, one balances the two arms of the 'effective interferometer' involved in the interference process, one 'arm' corresponding to the one-photon process and the other to the two-photon process. As an example, let's consider the excitation of GaAs, which has a room-temperature bandgap of 1.42 eV (equivalent to 870 nm). For excitation of GaAs using 1550 and 775 nm light under balanced conditions, the electron cloud is injected with a speed close to 500 km s^{-1}. Under 'balanced' conditions, nearly all the electrons are moving in the same direction. Assuming that the irradiance of the 1550 nm beam is 100 MW cm^{-2}, while that of the second harmonic beam is only 15 kW cm^{-2} (satisfying the 'balance' condition), with Gaussian pulse widths of 100 fs, one obtains a surprisingly large peak current of about 1 kA cm^{-2} for a carrier density of only 10^{14} cm^{-3} if scattering effects are ignored. When scattering is taken into account, the value of the peak current is reduced and the transient current decays on a time-scale of the momentum relaxation time. Figure 2a shows an experimental setup which can be used to demonstrate coherence control of electrical current using the above parameters. Figure 2a shows the region between a pair of electrodes on GaAs being illuminated by a train of harmonically related pulses. Figure 2b illustrates how the steady-state experimental voltage across the capacitor changes as the phase parameter $\Delta\phi$ is varied. Transient electrical currents, generated though incident femtosecond optical pulses, have also been detected through the emission of the associated Terahertz radiation.

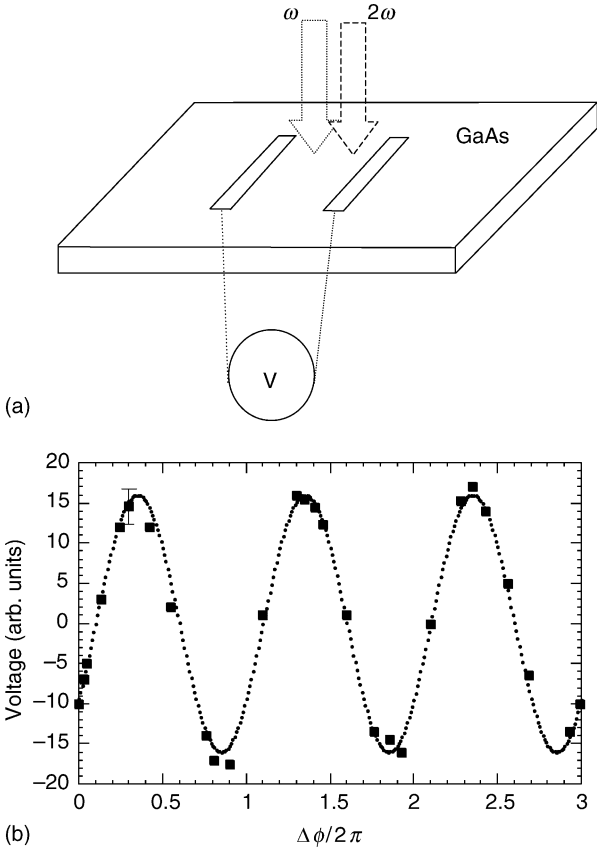

Figure 2 (a) Experimental setup to measure steady-state voltage (V) across a pair of electrodes on GaAs with the intervening region illuminated by phased radiation at ω and 2ω; (b) induced voltage across a pair of electrodes on a GaAs semiconductor as a function of the phase parameter associated with two harmonically related incident beams.

The current injection via coherence control and conventional cases (i.e., under a DC bias) differs with respect to their evolution. The current injected via coherent control has an onset determined by the rise time of the optical pulses. In the case of normal current production, existing carriers are accelerated by an electric field, and the momentum distribution is never far from isotropic. For a carrier density of 10^{14} cm^{-3} a DC field $\sim$80 kV cm^{-1} is required to produce a current density of 1 kA cm^{-2}. In GaAs, with an electron mobility of 8000 cm^2 V^{-1} s^{-1} this current would occur about 1/2 ps after the field is 'instantaneously' turned on. This illustrates that the coherently controlled phenomenon efficiently and quickly produces a larger current than can be achieved with the redirecting of statistically distributed electrons.

A more detailed analysis must take into account the actual light polarization, crystal symmetry, crystal face, and orientation relative to the optical polarization. For given optical intensities of the two beams,

the maximum electrical current injection in the case of GaAs occurs for linearly polarized beams both oriented along the (111) or equivalent direction. However, large currents can also be observed with the light beams polarized along other high symmetry directions.

Coherent Control of Carrier Density, Spin Population, and Spin Current Using Two Color Beams

The processes described above do not exhaust the coherent control effects that can be observed in bulk semiconductors using harmonic beams. Indeed, for noncentrosymmetric materials, certain light polarizations and crystal orientations allow one to coherently control the total carrier generation rate with or without generating an electrical current. In the case of the cubic material GaAs, provided the ω beam has electric field components along two of the three principal crystal axes, with the 2ω beam having a component along the third direction, one can coherently control the total carrier density. However, the overall degree of control here is determined by how 'noncentrosymmetric' the material is.

The spin degrees of freedom of a semiconductor can also be controlled using two color beams. Due to the spin–orbit interaction, the upper valence bands of a typical semiconductor have certain spin characteristics. To date, optical manipulation of electron spin has been largely based on the fact that partially spin-polarized carriers can be injected in a semiconductor via one-photon absorption of circularly polarized light from these upper valence bands. In such carrier injection – where in fact two-photon absorption could be used as well – spins with no net velocity are injected, and then are typically dragged by a bias voltage to produce a spin-polarized current. However, given the protocols discussed above it should not come as a surprise that the two color coherence scheme, when used with certain light polarizations, can coherently control the spin polarization, making it dependent on $\Delta\phi$. Furthermore, for certain polarization combinations it is also possible to generate a spin current with or without an electrical current. Given the excitement surrounding the field of spintronics, where the goal is the use of the spin degree of freedom for data storage and processing, the control of quantities involving the intrinsic angular momentum of the electron is of particular interest.

Various polarization and crystal geometries can be examined for generating spin currents with or without electrical current. For example, with reference to Figure 3a, for both beams propagating in the **z** (*normal*) direction of a crystal and possessing the same circular polarization, an electrical current can be injected in the (*xy*) plane, at an angle from the crystallographic **x** direction dependent on the relative phase parameter, $\Delta\phi$; this current is spin-polarized in the **z** direction. As well, the injected carriers have a $\pm$**z** component of their velocity, as many with one component as with the other; but those going in one direction are preferentially spin-polarized in one direction in the (*xy*) plane, while those in the other direction are preferentially spin-polarized in the opposite direction. This is an example of a spin current in the absence of an electrical current.

Such a pure spin current that is perhaps more striking is observable with the two beams cross linearly polarized, for example with the fundamental beam in the **x** direction and the second harmonic beam in the **y** direction as shown in Figure 3b. Then there is no net spin injection; the average spin in any

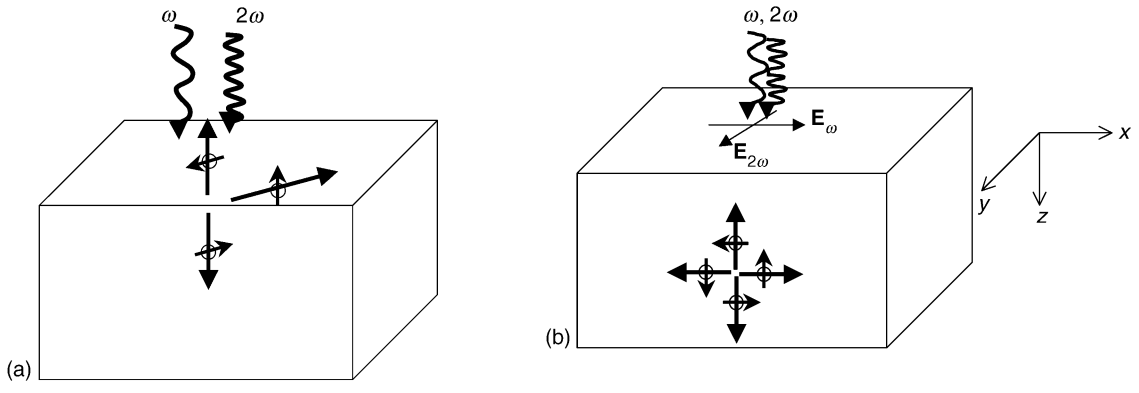

Figure 3 (a) Excitation of a semiconductor by co-circularly polarized ω and 2ω pulses. Arrows indicate that a spin polarized electrical current is generated in the $x-y$ plane in a direction dependent on $\Delta\phi$ while a pure spin current is generated in the beam propagation (z) direction. (b) Excitation of a semiconductor by orthogonally, linearly polarized ω and 2ω pulses. Arrows indicate that a spin polarized electrical current is generated in the direction of the fundamental beam polarization as well as along the beam propagation (z) direction.

direction is zero. And for a vanishing phase parameter $\Delta\phi$ there is no net electrical current injection. Yet, for example, the electrons injected with a $+\mathbf{x}$ velocity component will have one spin polarization with respect to the $\mathbf{z}$ direction, while those injected with a $-\mathbf{x}$ component to their velocity will have the opposite spin polarization with respect to the $\mathbf{z}$ direction.

The examples given above are the spin current analog of the two-color electrical current injection discussed above. There should also be the possibility of injecting a spin current with a single beam into crystals lacking center-of-inversion symmetry.

The simple analysis presented above relies on simple quantum mechanical ideas and calculations using essentially nothing more than Fermi's Golden Rule. Yet the process involves a mixing of two frequencies, and can therefore be thought of as a nonlinear optical effect. Indeed, one of the key ideas to emerge from the theoretical study of such phenomena is that an interpretation of coherence control effects alternate to that provided by the simple quantum interference picture that is provided by the usual susceptibilities of nonlinear optics. These susceptibilities are, of course, based on quantum mechanics, but the macroscopic viewpoint allows for the identification and classification of the effects in terms of 2nd order nonlinear optical effects, 3rd order optical effects, etc. Indeed, one can generalize many of the processes we have discussed above to a hierarchy of frequency mixing effects or high-order nonlinear processes involving multiple beams with frequency $n\omega, m\omega, p\omega\ldots$ with n, m, p being integers. Many of theses schemes require high intensity of one or more of the beams, but can occur in a simple semiconductor.

Coherent Control of Electrical Current Using Single Color Beams

It is also possible to generate coherence control effects using beams at a single frequency (ω), if one focuses on the two orthogonal components (e.g., x and y) polarization states and uses a noncentrosymmetric semiconductor of reduced symmetry such as a strained cubic semiconductor or a wurtzite material such as CdS or CdSe. In this case, interference between absorption pathways associated with the orthogonal components can lead to electrical current injection given by

$$dJ/dt \propto E^{\omega}E^{\omega}\sin(\phi_{\omega}^{x} - \phi_{\omega}^{y}) \qquad [8]$$

Since in this process current injection is linear in the beam's intensity, the high intensities necessary for two-photon absorption are not necessary. Nonetheless, the efficacy of this process is limited by the fact that it relies on the breaking of center-of-inversion symmetry of the underlying crystal. It is also clear that the maximum current occurs for circularly polarized light and that right and left circularly polarized light lead to a difference in sign of the current injection. Finally, for this particular single beam scheme, when circularly polarized light is used the electrical current is partially spin polarized.

Conclusions

Through the phase of optical pulses it is possible to control electrical and spin currents, as well as carrier density, in bulk semiconductors on a time-scale that is limited only by the rise time of the optical pulse and the intrinsic response of the semiconductor. A few optically based processes that allow one to achieve these types of control have been illustrated here. Although at one level one can understand these processes in terms of quantum mechanical interference effects, at a macroscopic level one can understand these control phenomena as manifestations of nonlinear optical phenomena. For fundamental as well as applied reasons, our discussion has focused on coherence control effects using the continuum states in bulk semiconductors, although related effects can also occur in quantum dot, quantum well, and superlattice semiconductors. Applications of these control effects will undoubtedly exploit the all-optical nature of the process, including the speed at which the effects can be turned on or off. The turn-off effects, although not discussed extensively here, are related to transport phenomena as well as momentum scattering and related dephasing processes.

Introduction

Conventional optical communication systems are based on the intensity modulation (IM) of an optical carrier by an electrical data signal and direct detection (DD) of the received light. The simplest scheme employs on/off keying (OOK), whereby turning on or off, an optical source transmits a binary 1 or 0. The signal light is transmitted down an optical fiber and at the receiver is detected by a photodetector, as shown in Figure 1. The resulting photocurrent is then processed to determine if a 1 or 0 was received. In the ideal case, where a monochromatic light source is used and where no receiver noise (detector dark current and thermal noise) is present, the probability of error is determined by the quantum nature (shot noise) of the received light. In this case, the number of photons/bit required (sensitivity) at the receiver, to achieve a bit-error-rate (BER) of 10^{-9}, is 10. This is called the quantum-limit. In practical receivers without an optical preamplifier, operating in the 1.3 μm and 1.55 μm optical fiber communication windows, the actual sensitivity is typically 10–30 dB less than the theoretical sensitivity. This is due to receiver noise, in particular thermal noise. This means that the actual sensitivity is between 100 to 10 000 photons/bit. The capacity of IM/DD fiber links can be increased using wavelength division multiplexing (WDM). At the receiver the desired channel is selected using a narrowband optical filter. Some advanced commercial IM/DD systems utilize dense WDM with 50 GHz spacing and single-channel bit rates as high as 40 Gb/s. Indeed, IM/DD systems with terabit (10^{12} bit/s) capacity are now possible.

Compared to IM/DD systems, coherent optical communication systems have greater sensitivity and selectivity. In the context of coherent lightwave systems, the term coherent refers to any technique employing nonlinear mixing between two optical waves on a photodetector, as shown in Figure 2. Typically, one of these is an information-bearing signal and the other is a locally generated wave (local oscillator). The result of this heterodyne process is a modulation of the photodetector photocurrent at a frequency equal to the difference between the signal and local oscillator frequencies. This intermediate frequency (IF) electronic signal contains the information in the form of amplitude, frequency, or phase that was present in the original optical signal. The IF signal is filtered and demodulated to retrieve the transmitted information. An automatic frequency control circuit is required to keep the local-oscillator frequency stable.

It is possible for the information signal to contain a number of subcarriers (typically at microwave frequencies), each of which can be modulated by a separate data channel. It is a simple matter to select the desired channel at the receiver by employing electronic heterodyning and low pass filtering, as shown in Figure 3. In IM/DD systems, channel selection can only be carried out using narrowband optical filters.

Coherent optical communications utilize techniques that were first investigated in radio communications. Most of the basic research work on coherent optical communications was carried out in the 1980s and early 1990s, and was primarily motivated by the need for longer fiber links using no repeaters. Improving receiver sensitivity using coherent techniques made it possible to increase fiber link spans. In the mid-1990s, reliable optical fiber amplifiers became available. This made it possible to construct fiber links using optical amplifiers spaced at appropriate intervals to compensate for fiber and other transmission losses.

The sensitivity of an IM/DD receiver can be greatly improved by the use of an optical preamplifier. Indeed the improvement is so marked that coherent techniques are not a viable alternative to IM/DD in the vast majority of commercial optical communication systems due to their complexity and higher cost. Moreover, because semiconductor lasers with very precise wavelengths and narrowband optical filters can be fabricated, the selectivity advantage of coherent optical communications has become less important. This has meant that the research work currently being carried out on coherent optical communications is very limited, and in particular, very few field trials have been carried out since the early 1990s.

We will review the basic principles underlying coherent optical communications, modulation schemes, detection schemes, and coherent receiver sensitivity. The effects of phase noise and polarization on coherent receiver performance will be outlined. A brief summary of pertinent experimental results will also be presented.

The power spectrum of the detected signal is shown: (a) after IF filtering; (b) after multiplication by the IF oscillator; (c) after multiplication with the subcarrier oscillator (in this case channel 1's carrier frequency); and (d) after low pass filtering prior to demodulation and data detection. LPF: lowpass filter.

Basic Principles

In coherent detection, a low-level optical signal field E_s is combined with a much larger power optical signal field E_{LO} from a local oscillator laser. E_s and E_{LO} can be written as

$$E_s(t) = \sqrt{2P_s}\cos[2\pi f_s t + \phi_s(t)] \quad [1]$$

$$E_{LO}(t) = \sqrt{2P_{LO}}\cos[2\pi f_{LO} t + \phi_{LO}(t)] \quad [2]$$

where P_s, f_s, and ϕ_s are the signal power, optical frequency, and phase (including phase noise), respectively. P_{LO}, f_{LO}, and ϕ_{LO} are the equivalent quantities for the local oscillator. For ideal coherent detection, the polarization states of the signal and local oscillator must be equal. If this is the case, the photocurrent is given by

$$i_d(t) = R[E_s(t) + E_{LO}(t)]^2 \quad [3]$$

where R is the detector responsivity. Because the detector cannot respond to optical frequencies, we have

$$i_d(t) = R\left\{P_s + P_{LO} + 2\sqrt{P_s P_{LO}} \times \cos[2\pi f_{IF} t + \phi_s(t) - \phi_{LO}(t)]\right\} \quad [4]$$

The IF signal is centered at frequency $f_{IF} = f_s - f_{LO}$. In homodyne detection $f_s = f_{LO}$ and the homodyne signal is centered at baseband. In heterodyne detection $f_s \neq f_{LO}$ and the signal generated by the photodetector is centered around f_{IF} (typically three to six times the bit rate). The IF photocurrent is proportional to $\sqrt{P_s}$, rather than P_s as is the case in

direct detection, and is effectively amplified by a factor proportional to $\sqrt{P_{LO}}$. If P_{LO} is large enough, the signal power can be raised above the receiver noise, thereby leading to a greater sensitivity than possible with conventional IM/DD receivers using p–i–n or avalanche photodiodes. Theoretically it is possible to reach shot noise limited receiver sensitivity although this is not possible in practice. Homodyne optical receivers usually require less bandwidth and are more sensitive than heterodyne receivers but require that the local oscillator is phase locked to the information signal. This requires an optical phase locked loop (OPLL), which is very difficult to design.

Modulation Schemes

The three principal modulation schemes used in coherent optical communications; amplitude shift keying (ASK), frequency shift keying (FSK) and phase shift keying (PSK), are shown in Figure 4. ASK modulation is essentially the same as the OOK scheme used in IM/DD systems. The optical signal is given by

$$E_s(t) = 2a(t)\sqrt{2P_s}\cos[2\pi f_s t + \phi_s(t)] \qquad [5]$$

where $a(t) = 0$ or 1 for transmission of a 0 or 1, respectively. P_s is the average signal power, assuming that it is equally likely that a 0 or 1 is transmitted. ASK modulation can be achieved by modulating the output of a semiconductor laser using an external modulator. The most common type is based on $LiNbO_3$ waveguides in a Mach–Zehnder interferometer configuration.

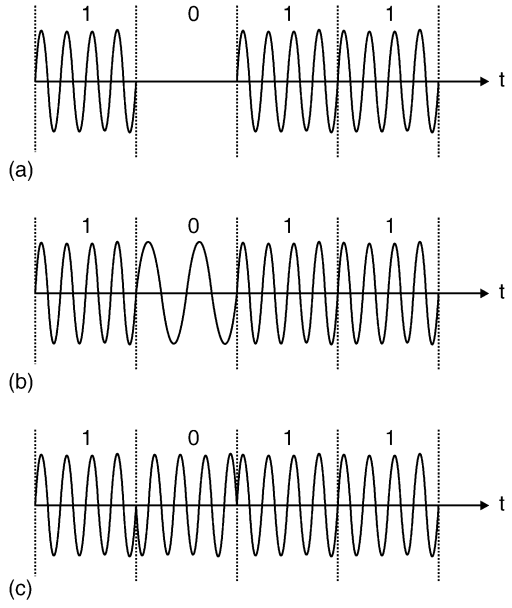

Figure 4 Modulation schemes for coherent optical communications: (a) ASK; (b) FSK; and (c) PSK.

In FSK modulation, the optical frequency of the signal lightwave is changed slightly by the digital data stream. In binary FSK, the optical signal is given by

$$E_s(t) = \sqrt{2P_s}\cos[2\pi(f_s + a(t)\Delta f)t + \phi_s(t)] \qquad [6]$$

where $a(t) = -1$ or 1 for transmission of a 0 or 1, respectively. The choice of the frequency deviation Δf depends on the available bandwidth, the bit rate B_T and the demodulation scheme used in the receiver. The modulation index m is given by

$$m = \frac{2\Delta f}{B_T} \qquad [7]$$

The minimum value of m that produces orthogonality (for independent detection of the 0s and 1s) is 0.5. If $m = 0.5$, the signal is referred to as minimum FSK (MFSK). When $m \geq 2$, the signal is referred to as wide-deviation FSK, and when $m < 2$, as narrow-deviation FSK. Wide-deviation FSK receivers are more resilient to phase noise than narrow-deviation FSK receivers. FSK modulation can be achieved using $LiNbO_3$ external modulators, acoustic optic modulators and distributed feedback semiconductor lasers. The phase of the lightwave does not change between bit transitions.

In PSK modulation, the digital data stream changes the phase of the signal lightwave. In binary PSK the optical signal is given by

$$E_s(t) = \sqrt{2P_s}\cos[2\pi f_s t + a(t)\theta + \frac{\pi}{2} + \phi_s(t)] \qquad [8]$$

where $a(t) = -1$ or 1 for transmission of a 0 or 1, respectively. The phase shift between a 0 and 1 is $\theta + \pi/2$. Most PSK schemes use $\theta = \pi/2$. PSK modulation can be achieved by using an external phase modulator or a multiple quantum well electroabsorption modulator.

Detection Schemes

There are two classes of demodulation schemes: synchronous and asynchronous. The former exploits the frequency and phase of the carrier signal to perform the detection. The latter only uses the envelope of the carrier to perform the detection. In the following we review the principal demodulation schemes.

PSK Homodyne Detection

In an ideal PSK homodyne receiver, shown in Figure 5, the signal light and local oscillator have identical

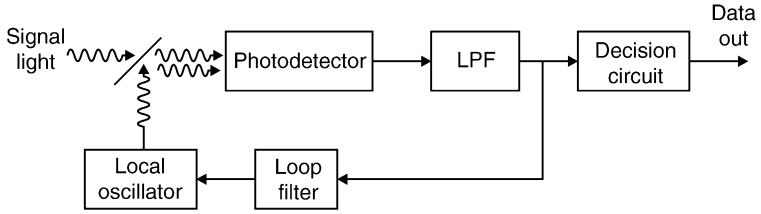

Figure 5 PSK homodyne receiver.

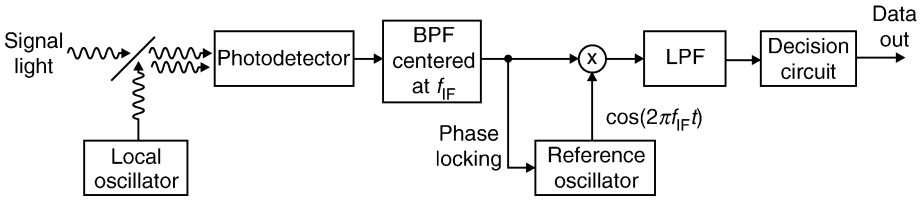

Figure 6 PSK synchronous heterodyne receiver. BPF: bandpass filter.

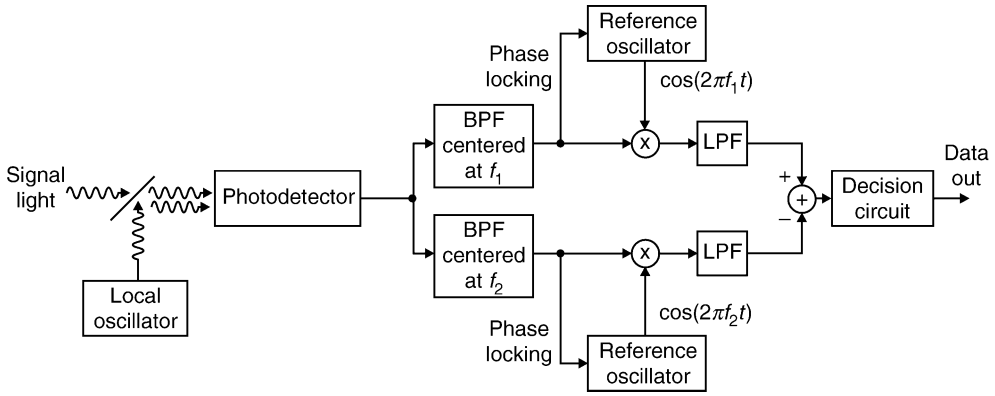

Figure 7 FSK heterodyne synchronous receiver.

optical frequency and phase. If the resulting baseband information signal is positive, then a 1 has been received. If the baseband information signal is negative, then a 0 bit has been received. This scheme has the highest theoretical sensitivity but requires an OPLL and is also highly sensitive to phase noise.

ASK Homodyne Detection

An ideal ASK homodyne receiver is identical to an ideal PSK homodyne receiver. Because the baseband information signal is either zero (0 bit) or nonzero (1 bit), the receiver sensitivity is 3 dB less than the PSK homodyne receiver.

PSK Heterodyne Synchronous Detection

Figure 6 shows an ideal PSK synchronous heterodyne receiver. The IF signal is filtered by a bandpass filter, multiplied by the phase locked reference oscillator to move the signal to baseband, low pass filtered and sent to a decision circuit that decides if the received bit is a 0 or 1. The receiver requires synchronization of the reference oscillator with the IF signal. This is not easy to achieve in practice because of the large amount of semiconductor laser phase noise.

ASK Heterodyne Synchronous Detection

This scheme is basically the same as the PSK heterodyne detection and is similarly difficult to design.

FSK Heterodyne Synchronous Detection

This scheme is shown in Figure 7 for a binary FSK signal consisting of two possible frequencies $f_1 = f_s - \Delta f$ and $f_2 = f_s + \Delta f$. There are two separate branches in which correlation with the two possible IF signals at f_1 and f_2 is performed. The two resulting signals are subtracted from each other and a decision taken on the sign of the difference. Because of the requirement for two electrical phase locked loops, the scheme is not very practical.

ASK Heterodyne Envelope Detection

In this scheme, shown in Figure 8, the IF signal is envelope detected to produce a baseband signal proportional to the original data signal. The output of the envelope detector is relatively insensitive to laser phase noise.

FSK Heterodyne Dual-Filter Detection

In this scheme, shown in Figure 9, two envelope detectors are used to demodulate the two possible IF signals at f_1 and f_2 and a decision taken based on the outputs. The scheme is tolerant to phase noise and can achieve high sensitivity. However, it needs high-bandwidth receiver electronics because a large frequency deviation is required.

FSK Heterodyne Single-Filter Detection

This scheme omits one branch of the FSK heterodyne dual-filter receiver and performs a decision in the same way as for the ASK heterodyne envelope detection. Because half the power of the detected signal is not used, the sensitivity of the scheme is 3 dB worse than the dual-filter scheme.

CPFSK Heterodyne Differential Detection

This scheme, shown in Figure 10, uses the continuous phase (CP) characteristic of an FSK signal, i.e., there is no phase discontinuity at bit transition times. After bandpass filtering, the IF photocurrent is

$$i_{\mathrm{IF}}(t) = A\cos\{2\pi[(f_{\mathrm{IF}} + a(t)\Delta f)]t\} \qquad [9]$$

where $A = R\sqrt{P_s P_{\mathrm{LO}}}$. The output from the delay-line demodulator, after low pass filtering to remove the double IF frequency term, is

$$x(t) = \frac{A^2}{2}\cos\{2\pi[f_{\mathrm{IF}} + a(t)\Delta f]\tau\} \qquad [10]$$

The function of the delay-line demodulator is to act as a frequency discriminator. We require that $x(t)$ is a maximum when $a(t) = 1$ and a minimum when $a(t) = -1$. This is the case if the following relations are satisfied:

$$2\pi(f_{\mathrm{IF}} + \Delta f)\tau = 2\pi k \qquad [11]$$

$$2\pi(f_{\mathrm{IF}} - \Delta f)\tau = (2k-1)\pi, \qquad k \text{ an integer}$$

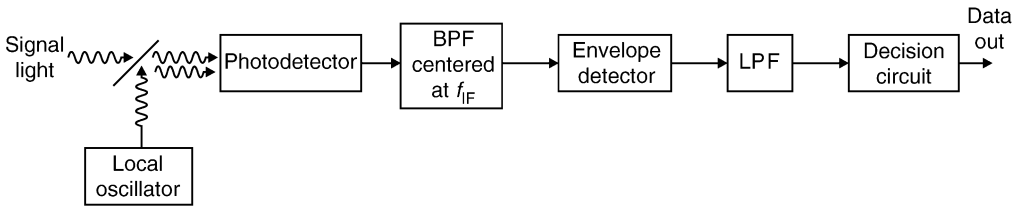

Figure 8 ASK heterodyne envelope receiver.

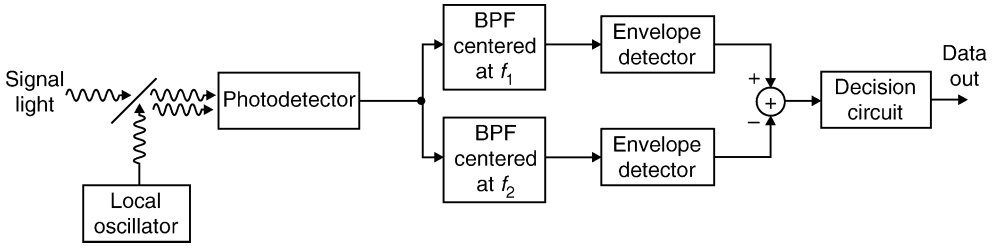

Figure 9 FSK heterodyne dual-filter receiver.

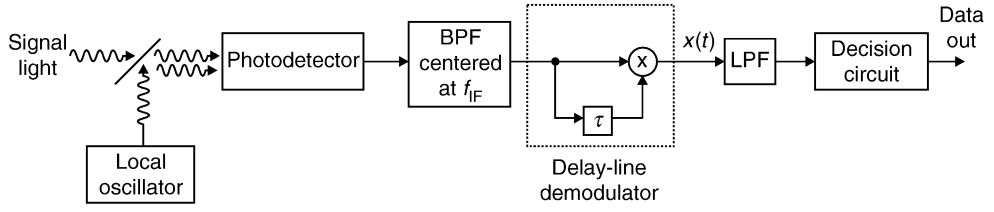

Figure 10 CPFSK heterodyne differential detection receiver.

Hence, we require that

$$\Delta f \tau = \frac{1}{4} \qquad [12]$$

$$f_{IF}\tau = \left[k - \frac{1}{4}\right], \qquad k \text{ integer}$$

In terms of the modulation index we have

$$\tau = \frac{1}{2mB_T} \qquad [13]$$

The above equation shows that it is possible to decrease the value of τ required by increasing m, thereby reducing the sensitivity of the receiver to phase noise. The minimum value of m possible is 0.5. This scheme can operate with a smaller modulation index compared to the dual-filter and single-filter schemes for a given bit rate, thereby relaxing the bandwidth requirements of the receiver electronics.

DPSK Heterodyne Differential Detection

In differential phase shift key (DPSK) modulation, a 0 is sent by changing the phase of the carrier by π with respect to the previous signal. A 1 is sent by not changing the phase. The receiver configuration is identical to the CPFSK heterodyne differential detection receiver, except that the time delay τ is equal to the inverse of the data rate. Compared to other PSK detection schemes, DPSK differential detection is relatively simple to implement and is relatively immune to phase noise.

Coherent Receiver Sensitivity

The signal-to-noise ratio γ_c of an ideal PSK homodyne receiver, in the shot-noise limit, is given by

$$\gamma_c = \frac{2RP_s}{eB_c} \qquad [14]$$

where B_c is the receiver bandwidth. The detector responsivity is given by

$$R = \frac{\eta e}{hf_s} \qquad [15]$$

where η is the detector quantum efficiency (≤ 1). The average signal power $P_s = N_s h f_s B_T$, where N_s is the average number of photons per bit. If it is assumed that $B_c = B_T$, then

$$\gamma_c = 2\eta N_s \qquad [16]$$

The actual detected number of photons per bit $N_R = \eta N_s$, so

$$\gamma_c = 2N_R \qquad [17]$$

If the noise is assumed to have a Gaussian distribution, then the bit error rate (BER) is given by

$$\text{BER} = \frac{1}{2} erfc\left(\sqrt{2N_R}\right) \qquad [18]$$

where *erfc* is the complementary error function; $erfc(x) \approx e^{-x^2}/(x\sqrt{\pi})$ for $x > 5$. The receiver sensitivity for a BER $= 10^{-9}$ is 9 photons/bit.

BER expressions and sensitivity for the demodulation schemes discussed above are listed in Table 1. The sensitivity versus N_R is plotted for some of the demodulation schemes in Figure 11. The received signal power required for a given BER is proportional to B_T. This dependency is shown in Figure 12 for some of the demodulation schemes.

Table 1 Shot-noise limited BER expressions and sensitivity for coherent demodulation schemes

Modulation scheme	*BER*	*Sensitivity (photons/bit)*
Homodyne		
PSK	$\frac{1}{2} erfc\left(\sqrt{2N_R}\right)$	9
ASK	$\frac{1}{2} erfc\left(\sqrt{N_R}\right)$	18 (peak 36)
Synchronous heterodyne		
PSK	$\frac{1}{2} erfc\left(\sqrt{N_R}\right)$	18
ASK	$\frac{1}{2} erfc\left(\sqrt{\frac{N_R}{2}}\right)$	36 (peak 72)
FSK	$\frac{1}{2} erfc\left(\sqrt{\frac{N_R}{2}}\right)$	36
Asynchronous heterodyne		
ASK (envelope)	$\frac{1}{2}\exp\left(-\frac{N_R}{2}\right)$	40 (peak 80)
FSK (dual-filter)	$\frac{1}{2}\exp\left(-\frac{N_R}{2}\right)$	40
FSK (single-filter)	$\frac{1}{2}\exp\left(-\frac{N_R}{4}\right)$	80
Differential detection		
CPFSK	$\frac{1}{2}\exp(-N_R)$	20
DPSK	$\frac{1}{2}\exp(-N_R)$	20

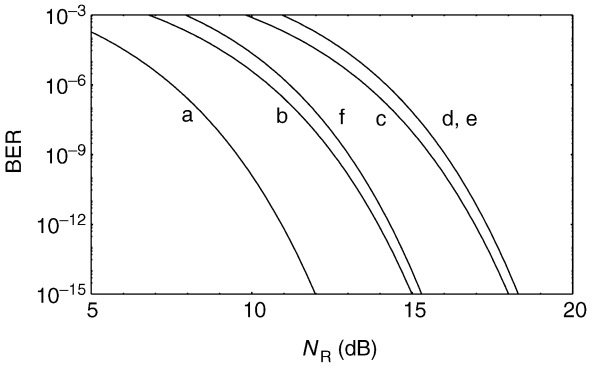

Figure 11 Shot-noise limited BER versus number of received photons/bit for various demodulation schemes: (a) PSK homodyne; (b) synchronous PSK; (c) synchronous FSK; (d) ASK envelope; (e) FSK dual-filter; and (f) CPFSK and DPSK.

Phase Noise

A major influence on the sensitivity possible with practical coherent receivers is laser phase noise, which is responsible for laser linewidth (3 dB bandwidth of the laser power spectrum). The effect of phase noise on system performance depends on the modulation and demodulation scheme used. In general, the effects of phase noise are more severe in homodyne and synchronous heterodyne schemes than in asynchronous schemes. If $\Delta\nu_{IF}$ is the beat linewidth (without modulation present) between the signal and local oscillator lasers, the normalized beat linewidth $\Delta\nu$ is defined as

$$\Delta\nu = \frac{\Delta\nu_{IF}}{B_T} \qquad [19]$$

where $\Delta\nu_{IF}$ is the IF phase noise bandwidth. Semiconductor lasers usually have a Lorentzian spectrum in which case $\Delta\nu_{IF}$ is equal to the sum of the signal and local-oscillator laser linewidths. The requirements placed on $\Delta\nu$ become less severe as the bit rate increases. Table 2 compares the $\Delta\nu$ requirement for a 1 dB power penalty at a BER of 10^{-9} for some of the principal modulation/demodulation schemes.

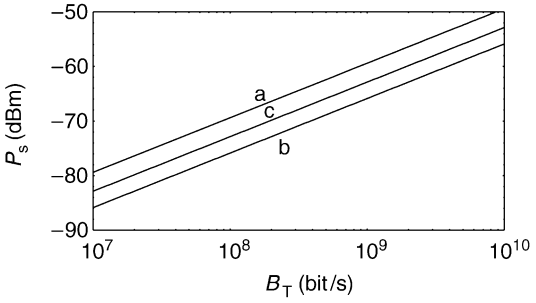

Figure 12 Required signal power versus bit rate for a BER = 10^{-9} for various shot-noise limited demodulation schemes: (a) PSK homodyne; (b) ASK envelope; and (c) CPFSK. The signal wavelength is 1550 nm and the detector is assumed to have unity quantum efficiency.

Table 2 Required normalized beat linewidth at 1 dB power penalty for a BER = 10^{-9} for various modulation/demodulation schemes

	Modulation scheme	*$\Delta\nu$ (%)*
Homodyne	PSK	6×10^{-4} (balanced loop) 0.01 (decision-driven loop)
Synchronous heterodyne	PSK	0.2–0.5
Asynchronous heterodyne	PSK	0.3–0.7
	ASK (envelope)	3
	FSK (dual-filter)	10–20
Differential detection	CPFSK	0.33 ($m = 0.5$) 0.66 ($m = 1.0$)
	DPSK	0.33

PSK Homodyne Detection – Phase Locked Loop Schemes

Practical homodyne receivers require an OPLL to lock the local-oscillator frequency and phase to that of the signal lightwave. There are a number of OPLL schemes possible for PSK homodyne detection, including the balanced PLL, Costas-type PLL and the decision-driven PLL.

The balanced PLL scheme, shown in Figure 13, requires that the PSK signal uses a phase shift of less than π between a 0 and 1, $E_s(t)$ and $E_{LO}(t)$ can be written as

$$E_s(t) = \sqrt{2P_s}\cos\left[2\pi f_0 t + a(t)\theta + \phi_{N,s}(t) + \frac{\pi}{2}\right] \qquad [20]$$

$$E_{LO}(t) = \sqrt{2P_{LO}}\cos[2\pi f_0 t + \phi_{N,LO}(t)] \qquad [21]$$

where f_0 is the common signal and local oscillator optical frequency and $\phi_{N,s}(t)$ and $\phi_{N,LO}(t)$ are the signal and local oscillator phase noise, respectively. When $\theta \neq \pi/2$, $E_s(t)$ contains an unmodulated carrier component (residual carrier) in quadrature with the information-bearing signal. $E_s(t)$ and $E_{LO}(t)$ are combined by an optical 180° hybrid. The output optical signals from the π-hybrid are given by

$$E_1(t) = \frac{1}{\sqrt{2}}[E_s(t) + E_{LO}(t)] \qquad [22]$$

$$E_2(t) = \frac{1}{\sqrt{2}}[E_s(t) - E_{LO}(t)] \qquad [23]$$

The voltage at the output of the summing circuit is given by

$$v_L(t) = 2RR_L\sqrt{P_s P_{LO}}\{a(t)\sin\theta\cos[\phi_e(t)] + \cos\theta\sin[\phi_e(t)]\} \qquad [24]$$

where the photodetectors have the same responsivity and load resistance R_L. The phase error is given by

$$\phi_e(t) = \phi_{N,s}(t) - \phi_{N,LO}(t) - \phi_c(t) \qquad [25]$$

$\phi_c(t)$ is the controlled phase determined by the control signal $v_c(t)$ at the output of the loop filter. v_L contains two terms; an information-bearing signal proportional to sin θ, which is processed by the data detection circuit, and a phase error signal proportional to cos θ used by the PLL for locking. The power penalty, due to the residual carrier transmission, is $10\log_{10}(1/\sin^2\theta)$ dB.

This scheme is not practical because the $\Delta\nu$ needed for a power penalty of <1 dB is typically less than 10^{-5}. This would require that $\Delta\nu_{IF} < 10$ kHz for

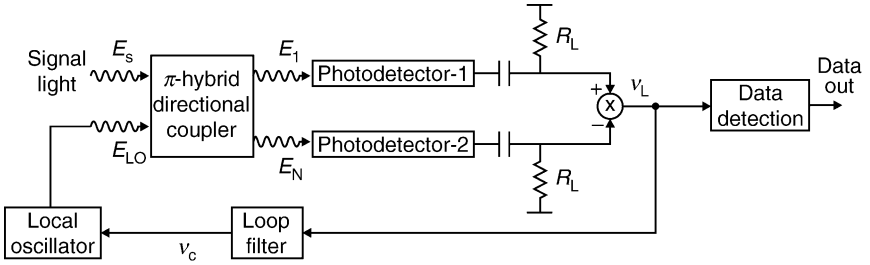

Figure 13 PSK homodyne balanced PLL receiver.

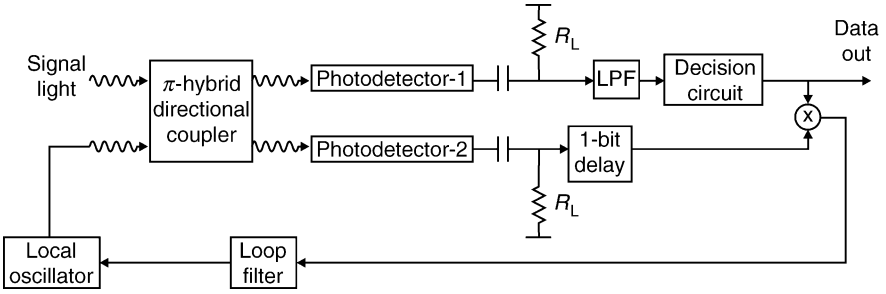

Figure 14 PSK decision-driven PLL.

a data rate of 1 Gb/s. The narrow signal and local-oscillator linewidths required are only achievable with external cavity semiconductor lasers.

The Costas-type and decision-driven PLLs also utilize π-hybrids and two photodetectors but as they have full suppression of the carrier ($\theta = \pi/2$), nonlinear processing of the detected signals is required to produce a phase error signal that can be used by the PLL for locking. In the decision-driven PLL, shown in Figure 14, the signal from one of the photodetector outputs is sent to a decision circuit and the output of the circuit is multiplied by the signal from the second photodetector. The mixer output is sent back to the local oscillator laser for phase locking. The $\Delta\nu$ required for a power penalty of <1 dB is typically less than 2×10^{-4}. This is superior to both the balanced PLL and Costas-type PLL receivers.

Heterodyne Phase Locking

In practical synchronous heterodyne receivers phase locking is performed in the electronic domain utilizing techniques from radio engineering. In the PSK case, electronic analogs of the OPLL schemes used in homodyne detection can be used. Synchronous heterodyne schemes have better immunity to phase noise than the homodyne schemes.

Asynchronous Systems

Asynchronous receivers do not require optical or electronic phase locking. This means that they are less sensitive to phase noise than synchronous receivers. They do have some sensitivity to phase noise because IF filtering leads to phase-to-amplitude noise conversion.

Differential Detection

Differential detection receivers have sensitivities to phase noise between synchronous and asynchronous receivers because, while they do not require phase locking, they use phase information in the received signal.

Phase-Diversity Receivers

Asynchronous heterodyne receivers are relatively insensitive to phase noise but require a much higher receiver bandwidth for a given bit rate. Homodyne receivers only require a receiver bandwidth equal to the detected signal bandwidth but require an OPLL, which is difficult to implement. The phase diversity receiver, shown in Figure 15, is an asynchronous homodyne scheme, which does not require the use of an OPLL and has a bandwidth approximately equal to synchronous homodyne detection. This is at the expense of increased receiver complexity and reduced sensitivity compared to synchronous homodyne detection. The phase-diversity scheme can be used with ASK, DPSK, and CPFSK modulation. ASK modulation uses an squarer circuit for the demodulator component, while DPSK and CPFSK modulation use a delay line and mixer.

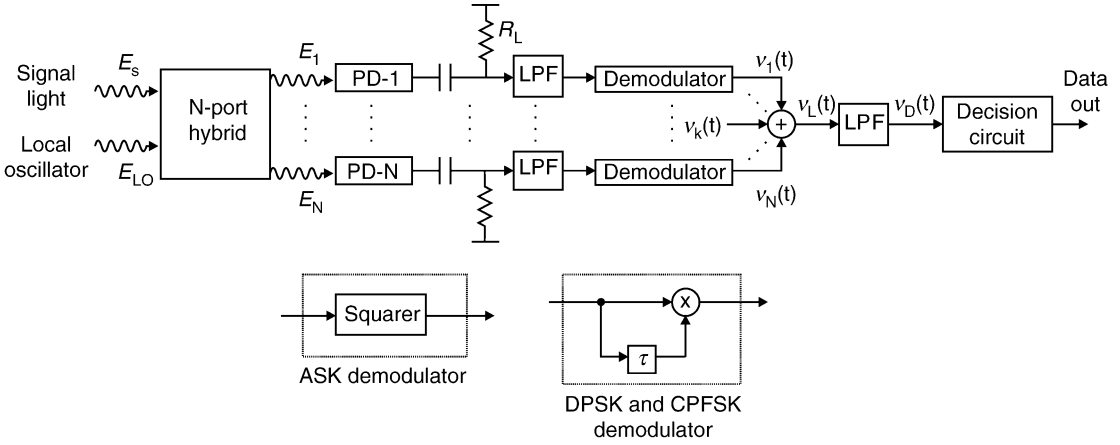

Figure 15 Multiport phase-diversity receiver. PD: photodetector.

In the case of ASK modulation, the outputs of the N-port hybrid can be written as

$$E_k(t) = \frac{1}{\sqrt{N}}\left\{a(t)\sqrt{2P_s}\cos\left[2\pi f_s t + \phi_s(t) + \frac{2\pi k}{N}\right] + \sqrt{2P_{LO}}\cos[2\pi f_{LO}t + \phi_{LO}(t)]\right\}, \quad k = 1,2,\ldots,N,\ N \geq 3 \qquad [26]$$

For $N = 2$, the phase term is $\pi/2$ for $k = 2$. The voltage input to the k-th demodulator (squarer), after the dc terms have been removed by the blocking capacitor, is given by

$$v_k(t) = a(t)\frac{RR_L}{N}2\sqrt{P_s P_{LO}}\cos\left[2\pi(f_s - f_{LO}) + \phi_s(t) - \phi_{LO}(t) + \frac{2\pi k}{N}\right] \qquad [27]$$

These voltages are then squared and added to give an output voltage

$$v_L(t) = \alpha\left(\frac{RR_L}{N}\right)^2 4P_s P_{LO}a(t)\sum_{k=1}^{N}\left\{1 + \cos\left[4\pi \times \left(f_s - f_{LO}\right)t + 2\phi_s(t) - 2\phi_{LO}(t) + \frac{4\pi k}{N}\right]\right\} \qquad [28]$$

where α is the squarer parameter. The lowpass filter at the summing circuit output effectively integrates $v_L(t)$ over a bit period. If $2(f_s - f_{LO}) \ll B_T$ and the difference between the signal and local oscillator phase noise is small within a bit period, then the input voltage to the decision circuit is

$$v_D(t) = \alpha\frac{(RR_L)^2}{N}4P_s P_{LO}a(t) \qquad [29]$$

which is proportional to the original data signal. In shot-noise limited operation, the receiver sensitivity is 3 dB worse than the ASK homodyne case. The scheme is very tolerant of laser phase noise. The $\Delta\nu$ for a power penalty of < 1 dB is of the same order as for ASK heterodyne envelope detection.

Polarization

The mixing efficiency between the signal and local-oscillator lightwaves is a maximum when their polarization states are identical. In practice the polarization state of the signal arriving at the receiver is unknown and changes slowly with time. This means that the IF photocurrent can change with time and in the worst case, when the polarization states of the signal and local-oscillator are orthogonal, the IF photocurrent will be zero. There are a number of possible solutions to this problem.

1. Polarization maintaining (PM) fiber can be used in the optical link to keep the signal polarization from changing. It is then a simple matter to adjust the local-oscillator polarization to achieve optimum mixing. However, the losses associated with PM fiber are greater than for conventional single-mode (SM) fiber. In addition most installed fiber is SM fiber.
2. An active polarization controller, such as a fiber coil using bending-induced birefringence, can be used to ensure that the local-oscillator polarization tracks the signal polarization.
3. A polarization scrambler can be used to scramble the polarization of the transmitted signal at a speed greater than the bit rate. The sensitivity degradation due to the polarization scrambling is 3 dB compared to a receiver with perfect polarization matching. However, this technique is only feasible at low bit rates.
4. The most general technique is to use a polarization-diversity receiver, as shown in Figure 16. In this scheme, the signal light and local-oscillator

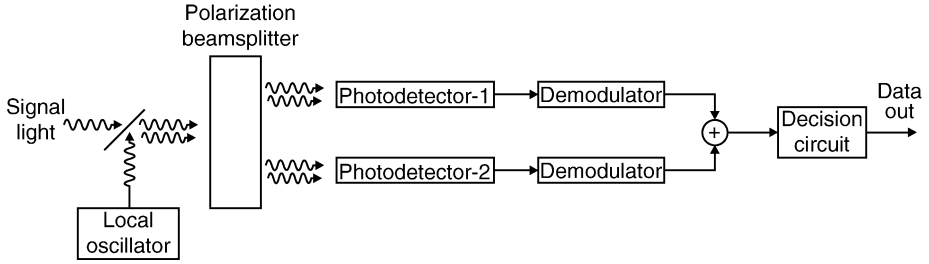

Figure 16 Polarization-diversity receiver.

Table 3 General comparisons between various modulation/demodulation schemes. The sensitivity penalty is relative to ideal homodyne PSK detection

Modulation/demodulation scheme	*Sensitivity penalty (dB)*	*Immunity to phase noise*	*IF bandwidth/bit rate*	*Complexity*
Homodyne PSK	0	Very poor	1	Requires an OPLL
Synchronous heterodyne PSK	3	Poor	3–6	Requires electronic phase locking
Asynchronous heterodyne FSK (dual-filter)	6.5	Excellent	3–6	High bandwidth IF circuits and two envelope detectors required
Differential detection CPFSK	3.5	Moderate	≈2	Relatively simple
DPSK	3.5	Moderate	≈2	Relatively simple

are split into orthogonally polarized lightwaves by a polarization beamsplitter. The orthogonal components of the signal and local-oscillator are separately demodulated and combined. The resulting decision signal is polarization independent. The demodulator used depends on the modulation format.

Comparisons Between the Principal Demodulation Schemes

General comparisons between the demodulation schemes discussed above are given in Table 3. FSK modulation is relatively simple to achieve. FSK demodulators have good receiver sensitivity and low immunity to phase noise. PSK modulation is also easy to achieve and gives good receiver sensitivity. ASK modulation has no real merit compared to FSK or PSK.

In general, homodyne schemes have the best theoretical sensitivity but require optical phase locking and are very sensitive to phase noise. Phase diversity receivers are a good alternative to homodyne receivers, in that they do not require an OPLL. Asynchronous heterodyne receivers have similar sensitivities to synchronous receivers but are much less complex. However, they require an IF bandwidth much greater than the data rate.

Differential detection schemes have good receiver sensitivity, do not require wide bandwidth IF circuits and have moderate immunity to phase noise. The advantage of CPFSK over DPSK is that the immunity to phase noise can be increased by increasing the FSK modulation index.

Polarization diversity receivers can be used with any modulation/demodulation scheme and offer the most general approach to overcoming polarization effects.

Table 4 Coherent systems experiments. The penalty is with respect to the theoretical sensitivity

Receiver	*Bit rate (Mb/s)*	*Sensitivity (dBm)*		*Penalty (dB)*
		dBm	*Photons/bit*	
ASK	400	−47.2	365	9.7
FSK (dual-filter)	680	−39.1	1600	16
CPFSK ($m = 0.5$)	1000	−37	1500	18.6
differential detection	4000	−31.3	1445	18.6
DPSK	400	−53.3	45.1	3.5
	2000	−39.0	480	13.8

System Experiments

Most coherent communication system experiments date from the 1980s and early 1990s and were based on the technology available at that time. This restricted the bit rates possible to typically <4 Gb/s. Some coherent systems experimental results obtained around this time are listed in Table 4. All of the

listed experimental trials used lasers (usually external cavity lasers) with negligible phase noise in the 1550 nm region. It can be seen that the measured sensitivities deteriorate at higher bit rates. This is attributable to the nonuniform response and bandwidth limitations of the modulator, photodetector, and demodulator. There is no doubt that the performance could be improved by the use of current optoelectronic technologies.

Conclusion

Coherent optical communication systems offer the potential for increased sensitivity and selectivity compared to conventional IM/DD systems. However, coherent optical receivers are more complex and have more stringent design parameters compared to IM/DD receivers. Moreover, advances in optoelectronic component design and fabrication along with the advent of reliable optical amplifiers has meant that coherent systems are not a viable alternative to IM/DD systems in the vast majority of optical communication systems.

Introduction

Optical spectroscopy is a method that allows one to determine atomic and molecular transition frequencies, as well as relaxation rates in atomic and molecular vapors. The transition frequencies serve as 'fingerprints' that can be used to identify and classify atoms and molecules. Optical spectroscopic methods fall into two broad categories, continuous wave (cw) or stationary spectroscopy and time-dependent or transient spectroscopy. In cw spectroscopy, the absorption or emission line shapes are measured as a function of the frequency of a probe field. On the basis of theoretical line shape formulas, it is then possible to extract the relevant transition frequencies and relaxation rates from the line shapes. In transient optical spectroscopy, pulsed optical fields are used to create atomic state populations or coherences between atomic states. Following the

excitation, the time-evolution of the atoms is monitored, from which transition frequencies and relaxation rates can be obtained.

The earliest coherent transient effects were observed with atomic nuclear spins in about 1950 by H C Torrey, who discovered transient spin nutation, and by E L Hahn who detected spin echoes and free induction decay (FID). The optical analogs of these and other nuclear magnetic resonance (NMR) effects have now been detected using either optical pulses or techniques involving Stark or laser frequency switching.

In this brief introduction to coherent optical transients, several illustrative examples of coherent transient phenomena are reviewed. The optical Bloch equations are derived and coupled to Maxwell's Equations. The Maxwell–Bloch formalism is used to analyze free precession decay, photon echoes, stimulated photon echoes, and optical Ramsey fringes. Experimental results are presented along with the relevant theoretical calculations. In addition, coherent transient phenomena involving quantized matter waves are discussed. Although the examples considered in this chapter are fairly simple, it should be appreciated that sophisticated coherent transient techniques are routinely applied as a probe of complex structures such as liquids and solids or as a probe of single atoms and molecules.

Optical Bloch Equations

Many of the important features of coherent optical transients can be illustrated by considering the interaction of a radiation field with a two-level atom. The lower state $|1\rangle$ has energy $-\hbar\omega_0/2$ and upper state $|2\rangle$ has energy $\hbar\omega_0/2$. For the moment, the atom is assumed to be fixed at $\mathbf{R} = 0$ and all relaxation processes are neglected. The incident electric field is

$$\mathbf{E}(\mathbf{R} = 0, t) = \frac{1}{2}\boldsymbol{\varepsilon}[E(t)e^{-i\omega t} + E(t)e^{i\omega t}] \qquad [1]$$

where $E(t)$ is the field amplitude, $\boldsymbol{\varepsilon}$ is the field polarization and ω is the carrier frequency. The time dependence of $E(t)$ allows one to consider pulses having arbitrary shape. A time-dependent phase for the field could have been included, allowing one to consider the effect of arbitrary frequency 'chirps,' but such effects are not included in the present discussion. It is convenient to expand the atomic state wave function in a field interaction representation as

$$|\psi(t)\rangle = c_1(t)e^{i\omega t/2}|1\rangle + c_2(t)e^{-i\omega t/2}|2\rangle \qquad [2]$$

The atom-field interaction potential is

$$V(\mathbf{R}, t) = -\mu \cdot \mathbf{E}(\mathbf{R}, t) \qquad [3]$$

where μ is a dipole moment operator. When eqn [2] is substituted into Schrödinger's equation and rapidly varying terms are neglected (rotating-wave approximation), one finds that the state amplitudes evolve according to

$$i\hbar\frac{\mathrm{d}\mathbf{c}}{\mathrm{d}t} = \tilde{\mathbf{H}}\mathbf{c}; \qquad \tilde{\mathbf{H}} = (\hbar/2)\begin{pmatrix} -\delta_0 & \Omega_0(t) \\ \Omega_0(t) & \delta_0 \end{pmatrix} \qquad [4]$$

where $\mathbf{c}$ is a vector having components (c_1, c_2)

$$\delta_0 = \omega_0 - \omega \qquad [5]$$

is an atom-field detuning

$$\Omega_0(t) = -\frac{\mu E(t)}{\hbar} = -\frac{\mu}{\hbar}\sqrt{\frac{2S(t)}{\varepsilon_0 c}} \qquad [6]$$

is a Rabi frequency, $\mu = \langle 1|\mu\cdot\varepsilon|2\rangle = \langle 2|\mu\cdot\varepsilon|1\rangle$ is a dipole moment matrix element, ε_0 is the permittivity of free space, and $\mathbf{S}(t)$ is the time-averaged Poynting vector of the field. Equation [4] can be solved numerically for arbitrary pulse envelopes.

Expectation values of physical observables are conveniently expressed in terms of density matrix elements defined by

$$\rho_{ij} = c_i c_j^* \qquad [7]$$

which obey equations of motion

$$\begin{aligned} \dot{\rho}_{11} &= -i\Omega_0(t)(\rho_{21} - \rho_{12})/2 \\ \dot{\rho}_{22} &= i\Omega_0(t)(\rho_{21} - \rho_{12})/2 \\ \dot{\rho}_{12} &= -i\Omega_0(t)(\rho_{22} - \rho_{11})/2 + i\delta_0\rho_{12} \\ \dot{\rho}_{21} &= i\Omega_0(t)(\rho_{22} - \rho_{11})/2 - i\delta_0\rho_{21} \end{aligned} \qquad [8]$$

An alternative set of equations in terms of real variables can be obtained if one defines new parameters

$$\begin{aligned} u &= \rho_{12} + \rho_{21}; & \rho_{12} &= (u + iv)/2 \\ v &= i(\rho_{21} - \rho_{12}); & \rho_{21} &= (u - iv)/2 \\ w &= \rho_{22} - \rho_{11}; & \rho_{22} &= (m + w)/2 \\ m &= \rho_{11} + \rho_{22}; & \rho_{11} &= (m - w)/2 \end{aligned} \qquad [9]$$

which obey

$$\begin{aligned} \dot{u} &= -\delta_0 v \\ \dot{v} &= \delta_0 u - \Omega_0(t)w \\ \dot{w} &= \Omega_0(t)v \\ \dot{m} &= 0 \end{aligned} \qquad [10]$$

The last of these equations reflects the fact that $\rho_{11} + \rho_{22} = 1$, while the first three can be rewritten as

$$\dot{\mathbf{U}} = \mathbf{\Omega}(t) \times \mathbf{U} \qquad [11]$$

where the *Bloch vector* $\mathbf{U}$ has components (u, v, w) and the *pseudofield vector* $\mathbf{\Omega}(t)$ has components $[\Omega_0(t), 0, \delta_0]$.

Equations [8] or [10] constitute the optical Bloch equations without decay. The vector $\mathbf{U}$ has unit magnitude and traces out a path on the Bloch sphere as it precesses about the pseudofield vector. The component w is the population difference of the two atomic states, while u and v are related to the quadrature components of the atomic polarization (see below).

Equations [8] and [10] can be generalized to include relaxation. A simplified relaxation scheme that has a wide range of applicability is one in which state 2 decays spontaneously to state 1 with rate γ_2, while the relaxation of the coherence ρ_{12} is characterized by a complex decay parameter Γ_{12}, resulting from phase-changing collisions with a background gas. When such processes are included in eqn [8], they are modified as

$$\dot{\rho}_{11} = -i\Omega_0(t)(\rho_{21} - \rho_{12})/2 + \gamma_2\rho_{22} \qquad [12a]$$

$$\dot{\rho}_{22} = i\Omega_0(t)(\rho_{21} - \rho_{12})/2 - \gamma_2\rho_{22} \qquad [12b]$$

$$\dot{\rho}_{12} = -i\Omega_0(t)(\rho_{22} - \rho_{11})/2 - \gamma\rho_{12} + i\delta\rho_{12} \qquad [12c]$$

$$\dot{\rho}_{21} = i\Omega_0(t)(\rho_{22} - \rho_{11})/2 - \gamma\rho_{21} - i\delta\rho_{21} \qquad [12d]$$

where $\gamma = \gamma_2/2 + \mathrm{Re}(\Gamma_{12})$ and the detuning $\delta = \delta_0 - \mathrm{Im}(\Gamma_{12})$ is modified to include the collisional shift. With the addition of decay, the length of the Bloch vector is no longer conserved. The quantity γ_2 is referred to as the longitudinal relaxation rate. Moreover, one usually refers to $T_1 = \gamma_2^{-1}$ as the longitudinal relaxation time and $T_2 = \gamma^{-1}$ as the transverse relaxation time. In the case of purely radiative broadening, $\gamma_2 = 2\gamma$ and $T_1 = T_2/2$.

Maxwell–Bloch Equations

As a result of atom-field interactions, it is assumed that a polarization is created in the medium of the form

$$\mathbf{P}(\mathbf{R}, t) = \frac{1}{2}\boldsymbol{\varepsilon}\left[P(Z, t)e^{i[kZ-\omega t]} + P^*(Z, t)e^{-i[kZ-\omega t]}\right] \qquad [13]$$

which gives rise to a signal electric field of the form

$$\mathbf{E}_s(\mathbf{R}, t) = \frac{1}{2}\boldsymbol{\varepsilon}\left[E_s(Z, t)e^{i[kZ-\omega t]} + E_s^*(Z, t)e^{-i[kZ-\omega t]}\right] \qquad [14]$$

The z-axis has been chosen in the direction of $\mathbf{k}$. It follows from Maxwell's equations that the quasi-steady-state field amplitude is related to the polarization by

$$\frac{\partial E_s(Z, t)}{\partial Z} = \frac{ik}{2\varepsilon_0}P(Z, t) \qquad [15]$$

To arrive at eqn [15], it is necessary to assume that transverse field variations can be neglected, that the *phase matching* condition $k = \omega/c$ is met, and that the complex field amplitudes $P(Z, t)$ and $E_s(Z, t)$ vary slowly in space compared with e^{ikZ} and slowly in time compared with $e^{i\omega t}$.

The polarization $\mathbf{P}(\mathbf{R}, t)$, defined as the average dipole moment per unit volume, is given by the expression

$$\mathbf{P}(\mathbf{R}, t) = \mathcal{N}\Big[\boldsymbol{\mu}_{21}\langle\rho_{12}(Z, t)\rangle e^{-i[kZ-\omega t]} + \boldsymbol{\mu}_{12}\langle\rho_{21}(Z, t)\rangle e^{i[kZ-\omega t]}\Big] \qquad [16]$$

where $\mathcal{N}$ is the atomic density and $\rho_{12}(Z, t)$ and $\rho_{21}(Z, t)$ are single-particle density matrix elements that depend on the atomic properties of the medium. As such, eqn [16] provides the link between Maxwell's equations and the optical Bloch equations. The $\langle\ \rangle$ brackets in eqn [16] indicate that there may be additional averages that must be carried out. For example, in a vapor, there is a distribution of atomic velocities that must be summed over, while, in a solid, there may be an inhomogeneous distribution of atomic frequencies owing to local strains in the media. By combining eqns [9], [13], [15] and [16], and using the fact that $\mu = \mu_{12}\cdot\varepsilon = \mu_{21}\cdot\varepsilon$, one arrives at

$$\frac{\partial E_s(Z, t)}{\partial Z} = \frac{ik\mathcal{N}\mu}{\varepsilon_0}\langle\rho_{21}(Z, t)\rangle = \frac{ik\mathcal{N}\mu}{2\varepsilon_0}\langle u(Z, t) - iv(Z, t)\rangle \qquad [17]$$

which, together with eqn [12], constitute the Maxwell–Bloch equations. From eqn [17], it is clearly seen that the coherence $\langle\rho_{21}(Z, t)\rangle$ drives the signal field. If $\langle\rho_{21}(Z, t)\rangle$ is independent of Z, the intensity of radiation exiting a sample of length L is proportional to

$$I(L, t) = \frac{k\mathcal{N}\mu L}{\varepsilon_0}^2|\langle\rho_{21}(t)\rangle|^2 \qquad [18]$$

Alternatively, the outgoing field can be heterodyned with a reference field to extract the field amplitude rather than the field intensity.

Coherent Transient Signals

The Maxwell–Bloch equations can be used to describe the evolution of coherent transient signals. In a typical experiment, one applies one or more 'short' radiation pulses to an atomic sample and monitors the radiation field emitted by the atoms following the pulses. A 'short' pulse, is one satisfying

$$|\delta|\tau, ku\tau, \gamma\tau, \gamma_2\tau \ll 1 \qquad [19]$$

where τ is the pulse duration. Conditions [19] allow one to neglect any effects of detuning (including Doppler shifts or other types of inhomogeneous broadening) or relaxation during the pulse's action. The evolution of the atomic density matrix during each pulse is determined solely by the pulse area defined by

$$\theta = \int_{-\infty}^{\infty} \Omega_0(t)\mathrm{d}t \qquad [20]$$

In terms of density matrix elements in a standard interaction representation defined by

$$\rho_{12}^I = \rho_{12}e^{-i[kZ+\delta t]}, \quad \rho_{21}^I = \rho_{21}e^{i[kZ+\delta t]},$$
$$\rho_{22}^I = \rho_{22}, \quad \rho_{11}^I = \rho_{11}$$

the change in density matrix elements for an interaction occurring at time T_j is given by

$$\begin{pmatrix} \rho_{11}^I \\ \rho_{22}^I \\ \rho_{12}^I \\ \rho_{21}^I \end{pmatrix}^+ = \frac{1}{2}\begin{pmatrix} 1+\cos\theta_j & 1-\cos\theta_j & i\sin\theta_j e^{i\Phi(T_j)} & -i\sin\theta_j e^{-i\Phi(T_j)} \\ 1-\cos\theta_j & 1+\cos\theta_j & -i\sin\theta_j e^{i\Phi(T_j)} & i\sin\theta_j e^{-i\Phi(T_j)} \\ i\sin\theta_j e^{-i\Phi(T_j)} & -i\sin\theta_j e^{-i\Phi(T_j)} & 1+\cos\theta_j & (1-\cos\theta_j)e^{-2i\Phi(T_j)} \\ -i\sin\theta_j e^{i\Phi(T_j)} & i\sin\theta_j e^{i\Phi(T_j)} & (1-\cos\theta_j)e^{2i\Phi(T_j)} & 1+\cos\theta_j \end{pmatrix}\begin{pmatrix} \rho_{11}^I \\ \rho_{22}^I \\ \rho_{12}^I \\ \rho_{21}^I \end{pmatrix}^- \qquad [21]$$

where $\mp$ superscripts refer to times just before and after the pulse

$$\Phi(T_j) = \mathbf{k}\cdot\mathbf{R}(T_j) + \delta T_j$$

$$\mathbf{R}(T_j) = \mathbf{R} - \mathbf{v}(t - T_j)$$

θ_j is the pulse area, and $\mathbf{v}$ is the atomic velocity. Between pulses, or following the last pulse, the atoms evolve freely in the absence of any applied fields. The density matrix elements evolve as

$$\dot\rho_{11}^I = \gamma_2\rho_{22}^I; \quad \dot\rho_{22}^I = -\gamma_2\rho_{22}^I;$$
$$\dot\rho_{12}^I = -\gamma\rho_{12}^I; \quad \dot\rho_{21}^I = -\gamma\rho_{21}^I \qquad [22]$$

A coherent transient signal is constructed by piecing together field interaction zones and free evolution periods. There are many different types of coherent transient signals. A few illustrative examples are given below.

Free Polarization Decay

Free polarization decay (FPD), also referred to as optical FID, is the optical analog of free induction decay (FID) in NMR. This transient follows preparation of the atomic sample by any of three methods: (1) an optical pulse resonant with the atomic transition; (2) a Stark pulse that switches the transition frequency of a molecule (atom) into resonance with an incident *cw* laser beam; or (3) an electronic pulse that switches the frequency of a *cw* laser into coincidence with the molecular (atomic) transition frequency. In methods (2) and (3), the FPD emission propagates coherently in the forward direction along with the *cw* laser beam, automatically generating a heterodyne beat signal at a detector that can be orders of magnitude larger than the FPD signal. The FPD field intensity itself exiting the sample is equal to

$$I(L,t) = \left(\frac{k\mathcal{N}\mu L}{\varepsilon_0}\right)^2 |\langle\rho_{21}(t)\rangle|^2$$
$$= \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta\right)^2 \left|\int \mathrm{d}\mathbf{v}\, W_0(\mathbf{v}) e^{-[\gamma - i(\delta+\mathbf{k}\cdot\mathbf{v})]t}\right|^2 \qquad [23]$$

For a Maxwellian velocity distribution

$$W_0(\mathbf{v}) = \frac{1}{(\pi u^2)^{3/2}} e^{-(v/u)^2} \qquad [24]$$

where u is the most probable atomic speed, one finds

$$I(L,t) = \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta\right)^2 e^{-2\gamma t} e^{-(kut)^2/2} \qquad [25]$$

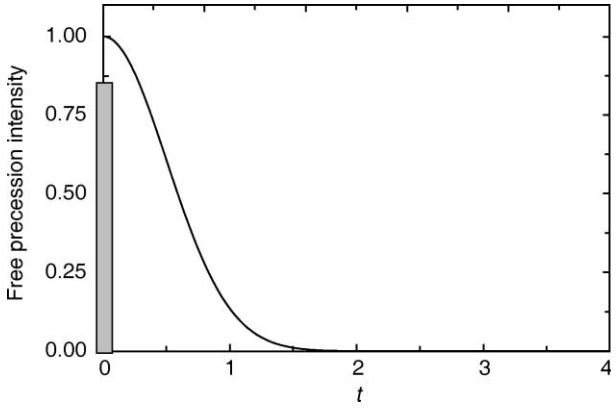

Figure 1 Pulse sequence and signal intensity for free precession decay. In this and subsequent figures, time is measured in units of $2/ku$.

If $ku \gg \gamma$, the signal decays mainly owing to inhomogeneous broadening, as shown in Figure 1. Owing to different Doppler shifts for atoms having different velocities, the optical dipoles created by the pulse lose their relative phase in a time of order $T_2^* = 2/ku$. The FPD signal can be used to measure T_2^*, which can be viewed as an inhomogeneous, transverse relaxation time. At room temperature ku/γ is typically of order of 100.

When FPD signals are observed using laser frequency switching, method 3 above, the *cw* field can modify the molecular velocity distribution, exciting only those atoms having $\mathbf{k}\cdot\mathbf{v} = -\delta \pm \gamma'$, where γ' is a power broadened homogeneous width. In the linear field regime, the FPD signal again decays on a time scale of order $(ku)^{-1}$, since the velocity distribution is unchanged to first order in the field amplitude. When one considers nonlinear interactions with the field, however, the *cw* field excites a narrow velocity subclass that is no longer subject to inhomogeneous broadening. These atoms give rise to a contribution to the FPD signal that decays with rate $T_2^{-1} = (\gamma + \gamma')$. Thus by using nonlinear atom-field interactions, one can extract homogeneous decay rates in situations where there is large inhomogeneous broadening. The price one pays is that only a small percentage of the atoms (those having velocities for which the applied field is resonant) contribute to the signal.

A FPD signal obtained on the D_2 transition in Cs is shown in Figure 2, where $T_2^* = 1.4$ ns. Oscillations in the signal originate from ground state hyperfine splitting. Figure 3 represents a FPD signal obtained in NH_2D at 10.6 μm using the method of Stark switching with *cw* state preparation. The oscillations are the heterodyne beat signal while the slowly varying increase in the signal is the result of optical nutation of molecules switched into resonance by the

Stark pulse. The FPD signal manifests itself as a reduction of the amplitude of the oscillation with time. This amplitude decays with the (power-broadened) homogeneous decay rate γ'.

Photon Echo

Although the FPD signal produced by short excitation pulses decays in a time of order $(ku)^{-1}$, the coherence of individual atoms decays in a much longer time, T_2.

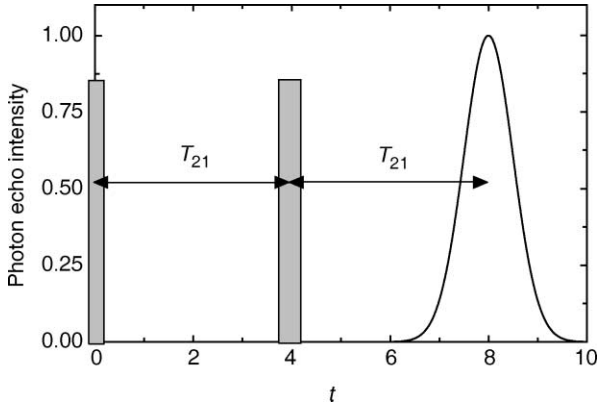

Figure 4 Pulse sequence and signal intensity for the photon echo.

The question arises as to whether it is possible to bring all the atomic dipoles back into phase so they can radiate a coherent signal. The photon echo accomplishes this goal, although it has very little to do with either photons or echoes. The pulse sequence and echo signal are shown in Figure 4. The first pulse creates a phased array of dipoles, which begin to dephase owing to inhomogeneous broadening. At time T_{21} the second pulse provides a nonlinear interaction that couples ρ_{12} and ρ_{21}. As a result of the second pulse, the dipoles begin a rephasing process that is completed at time $t = 2T_{21}$. The 'echo' appears at this time. The echo intensity exiting the sample is

$$\begin{aligned} I(L,t) &= \left(\frac{k\mathcal{N}\mu L}{\varepsilon_0}\right)^2 |\langle\rho_{21}(t)\rangle|^2 \\ &= \left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta_1 \sin^2(\theta_2/2)\right)^2 \\ &\quad \times e^{-4\gamma T_{21}} e^{-k^2u^2(t-2T_{21})^2/2} \end{aligned} \qquad [26]$$

If the echo intensity is measured as a function of T_{21}, one can extract the homogeneous decay rate $\gamma = T_{21}^{-1}$. It is interesting to note that the echo intensity near $t = 2T_{21}$ mirrors the FPD intensity immediately following the first pulse. For experimental reasons, it is often convenient to use a different propagation vector for the second pulse. If $\mathbf{k}_1$ and $\mathbf{k}_2$ are propagation vectors of the first and second pulses, the echo signal is in the direction $\mathbf{k} = 2\mathbf{k}_2 - \mathbf{k}_1$, provided $|\mathbf{k}_2 - \mathbf{k}_1|/k_1 \ll 1$.

The echo signal is sensitive only to $\rho_{21}(t)$ and $\rho_{12}(t)$ in the entire time interval of interest. Any interaction that results in a degradation of the dephasing–rephasing process for these density matrix elements leads to a decrease in the echo intensity. As such, echo signals can serve as a probe of transverse relaxation. Transverse relaxation generally falls into two broad categories. First, there are dephasing processes which produce an exponential damping of the coherences and contribute to γ. Second there is *spectral diffusion*; in a vapor, spectral diffusion is produced by velocity-changing collisions that change the effective field frequency seen by the atoms owing to the Doppler effect. Such terms enter the optical Bloch equations as *integral* terms, transforming the equations into differentio-integral equations. In general, the phase-changing and velocity-changing aspects of collisions are entangled; however, if the collisional interaction is *state-independent*, as it is for some molecular transitions, then collisions are purely velocity-changing in nature, leading to an echo that decays exponentially as T_{21}^3 for early times and T_{21} for later times. For electronic transitions, collisions are mainly phase-changing in nature, but there is a velocity-changing contribution that persists in the forward diffractive scattering cone. Photon echo techniques are sufficiently sensitive to measure the relaxation caused by such diffractive scattering.

The photon echo was first observed by NA Kurnit and co-workers, using a pulsed ruby laser (Figure 5). In Stark switching experiments, the photon echo follows two Stark pulses as shown in Figure 6. The effects of velocity-changing collisions on the photon echo signal in a CH_3F molecular vapor is represented in Figure 7. The signal exhibits exponential decay varying as T_{21}^3 for early times and T_{21} for later times. A theoretical interpretation of the observed echo decay permits a determination of the binary collision parameters for CH_3F, namely, the characteristic velocity jump $\Delta u_{\text{rms}} = 200\ \text{cm s}^{-1}$ and the cross section of $\sigma = 580\ \text{Å}^2$.

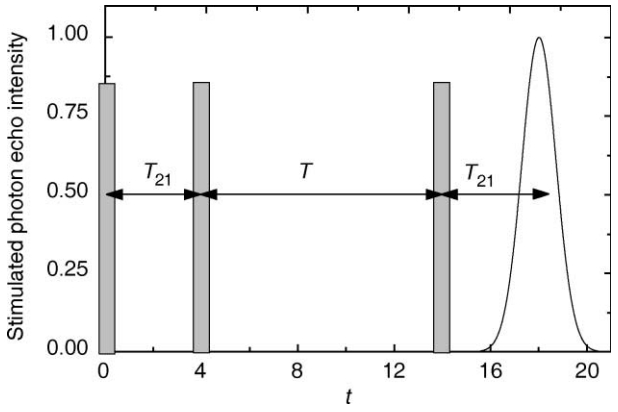

Figure 8 Pulse sequence and signal intensity for the stimulated photon echo.

Stimulated Photon Echo

In contrast to conventional photon echoes, *stimulated photon echoes* can be used to *simultaneously* measure both transverse and longitudinal relaxation times. Stimulated photon echoes have become an important diagnostic probe of relaxation in condensed matter systems as well as atomic vapors. The pulse sequence is shown in Figure 8 and consists of three pulses, having areas $\theta_1, \theta_2, \theta_3$, and equal propagation vectors $\mathbf{k}$. The time interval between the first two pulses is $T_{21} \gg T_2^*$ and pulse 3 occurs at time $t = T_{21} + T$. The maximum echo amplitude is given by

$$I(L, t_e) = \frac{1}{2}\left(\frac{k\mathcal{N}\mu L}{2\varepsilon_0}\sin\theta_1 \sin\theta_2 \sin\theta_3\right)^2 \times e^{-2\gamma_2 T} e^{-4\gamma T_{21}} \quad [27]$$

and occurs when $t_e - (T_{21} + T) = T_{21}$. The optimal pulse sequence consists of three $\pi/2$ pulses.

If slightly different $\mathbf{k}$ vectors are chosen such that $\mathbf{k}_1 = \mathbf{k}_3 \approx \mathbf{k}_2$ the echo intensity varies as

$$e^{-2\gamma_2 T} e^{-4\gamma T_{21}} e^{-|\mathbf{k}_1 - \mathbf{k}_2|^2 u^2 (T + 2T_{21})^2/2}$$

By varying the angle between $\mathbf{k}_1$and $\mathbf{k}_2$, one can determine the Doppler width ku. By monitoring the echo signal as a function of $T_{21}(T)$, one obtains information on the transverse (longitudinal) relaxation.

The situation changes dramatically if there is an *additional* ground state level (level 0) to which the excited state can decay. In that case, the system is 'open' since population can leave the 'two-level' subsystem. The total population of the 1–2 state subsystem is no longer conserved, requiring an *additional* decay rate to account for relaxation. Let us suppose that all states decay with rate Γ_t as a result of their finite time in the laser beams. Moreover, let $\Gamma_{2,1}$ and $\Gamma_{2,0}$ be the decay rates of level 2 to levels 1 and 0, respectively. Assuming that $\gamma_2 T \gg 1$, one finds that the factor $e^{-2\gamma_2 T}$ in eqn [27] must be replaced by $(\Gamma_{2,0}/(\Gamma_{2,1} + \Gamma_{2,0}))^2 e^{-2\Gamma_t T}$. If $\Gamma_{2,0} \neq 0$, there is a long-lived component in the ground state population that contributes to the echo signal. One can exploit this feature of open systems to study spectral diffusion or velocity-changing collisions with very high sensitivity. Echoes can occur for time separations T much greater than the excited state lifetime. The creation of such long-lived stimulated photon echoes can be attributed to the fact that, in open systems, a portion of the velocity modulation created by the first two pulses in the ground state remains following spontaneous decay from the excited state.

The stimulated photon echo observed on the D_1 transition in sodium is shown in Figure 9. This is

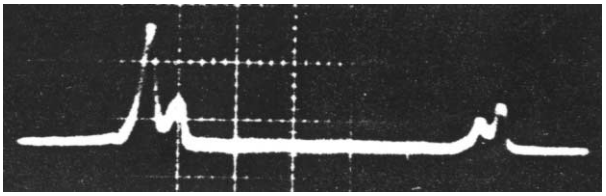

Figure 9 Stimulated photon echo observed on the D_1 transition in sodium. Reprinted with permission from Mossberg T, Flusberg A, Kachru R and Hartmann SR (1979) Total scattering cross section for Na on He measured by stimulated photon echoes. *Physical Review Letters* 42: 1665. Copyright (1979) by the American Physical Society.

an 'open' system, owing to ground state hyperfine structure. For the data shown, T is 17 times the 16 ns lifetime of the excited state. The first three pulses represent light scattered from the three input pulses and the fourth pulse is the echo. The echo appears at $t = T + 2T_{21}$.

Optical Ramsey Fringes

We have seen that coherent transients can be used to measure relaxation rates. With a slight modification of the stimulated photon echo geometry, it is also possible to use coherent transient signals to measure transition frequencies. If one chooses $\mathbf{k}_3$ in the $-\mathbf{k}_1$ direction instead of the $\mathbf{k}_1$ direction, it is possible to generate a phase matched signal in the

$$\mathbf{k} = \mathbf{k}_1 - \mathbf{k}_2 + \mathbf{k}_3 = -\mathbf{k}_2$$

direction. To simplify matters, it is assumed that $\mathbf{k}_1 \approx \mathbf{k}_2 = -\mathbf{k}$ and terms of order $|\mathbf{k}_1 - \mathbf{k}_2|u \times (T + 2T_{21})$ are neglected.

The averaged density matrix element in the vicinity of the echo is

$$\langle \rho_{21}(t) \rangle = (i/8) \sin\theta_1 \sin\theta_2 \sin\theta_3 e^{-\gamma_2 T} e^{-2\gamma T_{21}} \times e^{i\delta[(t-T_{21}-T)+T_{21}]} e^{-k^2u^2|(t-T_{21}-T)-T_{21}|^2/4} \quad [28]$$

An echo is formed at time $t_e = T + 2T_{21}$, just as for the stimulated photon echo, but there is an additional phase factor, given by $e^{2i\delta T_{21}}$ when $t = t_e$, that is absent for the nearly collinear geometry. This phase factor is the optical analog of the phase factor that is responsible for the generation of Ramsey fringes in the microwave domain. The phase factor can be measured directly by heterodyning the signal field with a reference field or, indirectly, by converting the off-diagonal density matrix element into a population by the addition of a *fourth* pulse in the $\mathbf{k}_3$ direction at time $t = T + 2T_{21}$. In either case, the signal varies as $\cos(2\delta T_{21})$. The central fringe, corresponding to $\delta = 0$ can be isolated using one of two methods. If the experiment is carried out using an atomic beam rather than atoms in a cell, $T_{21} = L/u_0$, will be different for atoms having different u_0 (L = spatial separation of the first two pulses and u_0 is the longitudinal velocity of the atoms). On averaging over a distribution of u_0, the fringe having $\delta = 0$ will have the maximum amplitude. Experiments of this type allow one to measure optical frequencies with accuracy of order T_{21}^{-1}. For experiments using temporally-separated pulses acting on atoms in a cell, it is necessary to take data as a function of δ for several values of T_{21}, and then average the data over T_{21}. It might seem remarkable that narrow pulses having large bandwidths can be used to measure optical frequencies with arbitrary accuracy as T_{21} is increased. Of course, it is the *total* duration of the pulse sequence rather than the duration of a single pulse that is the relevant time parameter. For the optical coherence, T_{21} is the appropriate time parameter (during the interval T, it is population rather than coherence that contributes to the signal). The price one pays by using large T_{21} is a signal that decays as $e^{-4\gamma T_{21}}$.

Figure 10 illustrates an optical Ramsey fringe signal on the 657 nm intercombination line in Ca. Four-field zones were used. The most probable value of T_{21} was about 10^{-5} s for an effusive beam having a most probable longitudinal speed equal to 800 ms^{-1}, giving a central fringe width of order 60 kHz.

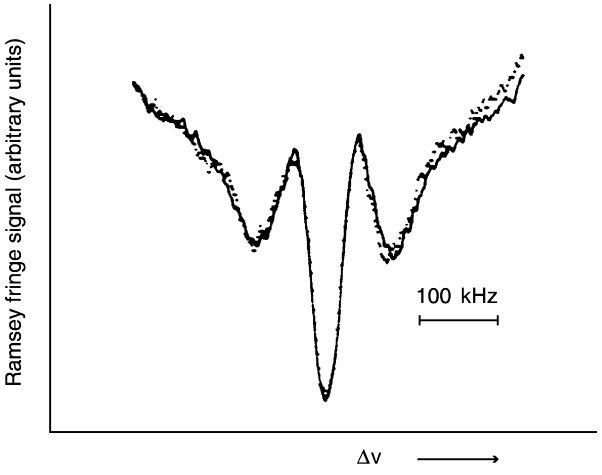

Figure 10 An optical Ramsey fringe signal on the 657 nm intercombination line in Ca. Four field zones were used. The solid and dotted lines represent runs with the directions of the laser field reversed, to investigate phase errors in the signals. Reprinted from Ito N, Ishikawa J and Moringa A (1994) Evaluation of the optical phase shift in a Ca Ramsey fringe stabilized optical frequency standard by means of laser-beam reversal. *Optics Communications* 109: 414, with permission from Elsevier.

Atom Interferometry

Matter wave atom interferometers rely on the wave nature of the center-of-mass motion for their operation. Such interferometers illustrate some interesting features of coherent optical transients not found in NMR. As an example, one can consider the response of a cold atomic ensemble to two, off-resonant standing-wave optical pulses separated in time by T. The electric field amplitude of pulse $j(j = 1, 2)$ is given by $\mathbf{E}_j(\mathbf{Z}, t) = \boldsymbol{\varepsilon} E_j(t)\cos(kZ)\cos(\omega t)$. The net effect of the field is to produce a spatially-modulated, ac Stark or light shift of the ground state energy. As a result, pulse j modifies the ground state amplitude by the phase factor $\exp[i\theta_j \cos(2kZ)]$. In other words, the standing wave field acts as a phase grating for the atoms. The phase factor can be interpreted in terms of momentum exchange between the two traveling wave components of the standing wave field. Owing to the fields' interaction with the atoms, all even integral multiples of $2\hbar k$ can be exchanged by the fields, imparting impulsive momenta of $2n\hbar k$ (n is a positive or negative integer) to the atoms. For an atom having momentum $\mathbf{P}$ and mass M, the frequency change associated with this momentum change is

$$E_{P,\mathbf{P}\pm 2n\hbar k\hat{Z}}/\hbar = \left(\frac{P^2}{2M} - \frac{|\mathbf{P} \pm 2n\hbar k\hat{Z}|^2}{2M}\right)\Big/\hbar = \mp\frac{2nP_Z k}{M} - \omega_{2nk} \qquad [29]$$

where

$$\omega_\kappa = \frac{\hbar\kappa^2}{2M}$$

There are two contributions to the frequency eqn [29]. The first part is independent of $\hbar$ and represents a classical Doppler shift, while the second part is proportional to $\hbar$ and represents a quantum, matter-wave effect. The quantum contribution will become important for times of order ω_{2nk}^{-1}. As with the echoes described previously, the Doppler effect results in a dephasing and rephasing of the optical response. However, in contrast to the previous echoes, the ground state density is no longer constant for times $t > \omega_{2nk}^{-1}$, when matter wave effects begin to play a role. At such times the phase grating created by the pulses can be transformed into amplitude gratings of the atomic density.

Long interaction times are possible, limited only by the time the atoms spend in the field. As such, atom interferometers offer exciting new possibilities for precision measurements of rotation rates, fundamental constants such as $\hbar$, gravitational acceleration, and gravitational gradients. Moreover, one can take advantage of the nonlinear atom-field interaction to create atomic density patterns having period $\lambda/2n$ from a standing wave optical field having wavelength λ. In this manner one has the possibility to construct atom interferometers and atom structures that operate on the nano-scale (spacings on the order of tens of nanometers).

Conclusion

Optical coherent transients are now used routinely as probes of atomic vapors, liquids, and condensed matter. Sophisticated techniques have been developed using fast and ultrafast pulses (having duration of 10 to 100 femtoseconds) to probe such systems and obtain the relevant relaxation rates. The manner in which optical coherent transients can be used to extract information on transition frequencies and relaxation rates in atomic and molecular vapors has been reviewed. In atomic vapors, optical coherent transients provide a means for obtaining both longitudinal and transverse relaxation rates. Moreover, echo experiments serve as an extremely sensitive probe of velocity changing collisions. Similar techniques are being rediscovered as an important tool in the analysis of cold atomic vapors and Bose–Einstein condensates. Only the most basic optical coherent transient phenomena have been described in this chapter. More elaborate, multi-pulse excitation schemes are joining established methods in attempts to understand the complex decay dynamics that one encounters in many branches of physics, chemistry and biology.

List of Units and Nomenclature

$\mathbf{E}(\mathbf{R}, t)$	Electric field vector
$E(t)$	Electric field amplitude
$E_s(Z, t)$	Complex signal electric field amplitude
$I(L, t)$	Signal intensity exiting the sample
$\mathbf{k}$	Field propagation vector
L	Sample length
$\mathcal{N}$	Atomic density
$\mathbf{P}$	Center-of-mass momentum
$\mathbf{P}(\mathbf{R}, t)$	Polarization vector
$P(Z, t)$	Complex polarization field amplitude
T_{21}, T	Time interval between pulses
u	Most probable atomic speed

(u, v, w)	Elements of Bloch vector
$\mathbf{U}(t)$	Bloch vector
$\mathbf{v}$	Atomic velocity
$W_0(\mathbf{v})$	Atomic velocity distribution
γ	Transverse relaxation rate
γ_2	Excited state decay rate or longitudinal relaxation rate
δ	Atom-field detuning
θ	Pulse area
μ	Dipole moment matrix element
ρ_{ij}^{I}	Density matrix element in 'normal' interaction representation
$\rho_{ij}(Z, t)$	Density matrix element in a field interaction representation
τ	Pulse durations
ω	Field frequency
ω_k	Recoil frequency
ω_0	Atomic transition frequency
$\Omega(t)$	Generalized Rabi frequency
$\mathbf{\Omega}(t)$	Pseudofield vector
$\Omega_0(t)$	Rabi frequency

Introduction

Electromagnetic irradiation of matter generates a coherent superposition of the excited quantum states. The attribute 'coherent' relates to the fact that the material excitations originally have a well defined phase dependence which is imposed by the phase of the excitation source, often a laser in the optical regime. Macroscopically, the generated superposition state can be described as an optical polarization which is determined by the transition amplitudes between the participating quantum states.

The optical polarization is a typical non-equilibrium quantity that decays to zero when a system relaxes to its equilibrium state. Coherent effects are therefore only observable in a certain time window after pulsed photo-excitation, or in the presence of a continuous-wave (cw) beam. As coherent transients one usually refers to phenomena that can be observed during or shortly after pulsed laser excitation and critically depend on the presence of the induced optical polarization.

Many materials such as atoms, molecules, metals, insulators, semiconductors including bulk crystals, heterostructures, and surfaces, as well as organic and biological structures are studied using coherent optical spectroscopy. Depending on the particular system, the states participating in the optical transitions, the interactions among them, and the resulting time-scale for the decay of the induced polarization may be very different. As a result, the time window during which coherent effects are

observable can be as long as seconds for certain atomic transitions, or it may be as short as a few femtoseconds (10^{-15}s), e.g., for metals, surfaces, or highly excited semiconductors.

Coherent spectroscopy and the analysis of coherent transients has provided valuable information on the nature and dynamics of the optical excitations. Often it is possible to learn about the interaction processes among the photoexcitations and to follow the temporal evolution of higher-order transitions which are only accessible if the system is in a non-equilibrium state.

The conceptually simplest experiment which one may use to observe coherent transients is to time resolve the transmission or reflection induced by a single laser pulse. However, much richer information can be obtained if one excites the system with several pulses. A pulse sequence with well-controlled delay times makes it possible to study the dynamical evolution of the photo-excitations, not only by time resolving the signal, but also by varying the delay. Prominent examples of such experiments are pump-probe measurements, which usually are performed with two incident pulses, or four-wave mixing, for which one may use two or three incident pulses.

Besides the microscopic interaction processes, the outcome of an experiment is determined by the quantum mechanical selection rules for the transitions and by the symmetries of the system under investigation. For example, if one wants to investigate coherent optical properties of surface states one often relies on phenomena, such as second-harmonic or sum-frequency generation, which give no signal in perfect systems with inversion symmetry. Due to the broken translational invariance, such experiments are therefore sensitive only to the dynamics of surface and/or interface excitations.

In this article the basic principles of coherent transients are presented and several examples are presented. The basic theoretical description and its generalization for the case of semiconductors are introduced.

Basic Principles

In the absence of free charges and currents, Maxwell's equations show that the electromagnetic field interacts with matter via the optical polarization. This polarization $\mathbf{P}$, or more precisely its second derivative with respect to time $(\partial^2/\partial t^2)\mathbf{P}$, appears as a source term in the wave equation for the electric field $\mathbf{E}$. Consequently, if the system is optically thin such that propagation effects within the sample can be ignored and if measurements are performed in the far field region, i.e., at distances exceeding the characteristic optical wavelength λ, the emitted electric field resulting from the polarization is proportional to its second time derivative, $\mathbf{E} \propto (\partial^2/\partial t^2)\mathbf{P}$. Thus the measurement of the emitted field dynamics yields information about the temporal evolution of the optical material polarization.

Microscopically the polarization is determined by the transition amplitudes between the different states of the system. These may be the discrete states of atoms or molecules, or the microscopic valence and conduction band states in a dielectric medium, such as a semiconductor. In any case, the macroscopic polarization $\mathbf{P}$ is computed by summing over all microscopic transitions p_{cv} via $\mathbf{P} = \sum_{c,v} (\boldsymbol{\mu}_{cv} p_{cv} + c.c.)$, where $\boldsymbol{\mu}_{cv}$ is the dipole matrix element which determines the strength of the transitions between the states v and c, and $c.c.$ denotes the complex conjugate. If ε_c and ε_v are the energies of these states, their dynamic quantum mechanical evolution is described by the phase factors $e^{-i\varepsilon_c t/\hbar}$ and $e^{-i\varepsilon_v t/\hbar}$, respectively. Therefore, each p_{cv} is evolving in time according to $e^{-i(\varepsilon_c - \varepsilon_v)t/\hbar}$. Assuming that we start at $t = 0$ with $p_{cv}(t = 0) = p_{cv,0}$, which may be induced by a short optical pulse, we have for the optical polarization $\mathbf{P}(t) = \sum_{c,v} (\boldsymbol{\mu}_{cv} p_{cv,0} e^{-i(\varepsilon_c - \varepsilon_v)t/\hbar} + c.c.)$. Thus $\mathbf{P}(t)$ is given by a summation over microscopic transitions which all oscillate with frequencies proportional to the energy differences between the involved states. Hence, the optical polarization is clearly a coherent quantity which is characterized by amplitude and phase. Furthermore, the microscopic contributions to $\mathbf{P}(t)$ add up coherently. Depending on the phase relationships, one may obtain either constructive superposition, interference phenomena like quantum beats, or destructive interference leading to a decay (dephasing) of the macroscopic polarization.

Optical Bloch Equations

The dynamics of photo-excited systems can be conveniently described by a set of equations, the optical Bloch equations, named after Felix Bloch (1905–1983) who first formulated such equations to analyze the spin dynamics in nuclear magnetic resonance. For the simple case of a two-level model, the Bloch equations can be written as

$$i\hbar \frac{\partial}{\partial t} p = \Delta\varepsilon p + \mathbf{E}\cdot\boldsymbol{\mu} I \qquad [1]$$

$$i\hbar \frac{\partial}{\partial t} I = 2\mathbf{E}\cdot\boldsymbol{\mu}(p - p^*) \qquad [2]$$

Here, $\Delta\varepsilon$ is the energy difference and I the inversion, i.e., the occupation difference between upper and lower state. The field $\mathbf{E}$ couples the polarization to the product of the Rabi energy $\mathbf{E}\cdot\boldsymbol{\mu}$

and the inversion I. In the absence of the driving field, i.e., $\mathbf{E} \equiv 0$, eqn [1] describes the free oscillation of p discussed above.

The inversion is determined by the combined action of the Rabi energy and the transition p. The total occupation N, i.e., the sum of the occupations of the lower and the upper states, remains unchanged during the optical excitation since light does not create or destroy electrons; it only transfers them between different states. If N is initially normalized to 1, then I can vary between -1 and 1. $I = -1$ corresponds to the ground state of the system, where only the lower state is occupied. In the opposite extreme, i.e., for $I = 1$, the occupation of the upper state is 1 and the lower state is completely depleted.

One can show that eqns [1]–[2] contain another conservation law. Introducing $\mathcal{P} = p + p^* = 2Re[p]$ and $J = i(p - p^*) = -2Im[p]$, which are real quantities and often named polarization and polarization current, respectively, one finds that the relation

$$\mathcal{P}^2 + J^2 + I^2 = 1 \qquad [3]$$

is fulfilled. Thus the coupled coherent dynamics of the transition and the inversion can be described on a unit sphere, the so-called Bloch sphere. The three terms $\mathcal{P}, J$, and I can be used to define a three-dimensional Bloch vector $\mathbf{S} = (\mathcal{P}, J, I)$. With these definitions, one can reformulate eqns [1]–[2] as

$$\frac{\partial}{\partial t}\mathbf{S} = \mathbf{\Omega} \times \mathbf{S} \qquad [4]$$

with $\mathbf{\Omega} = (-2\boldsymbol{\mu}\cdot\mathbf{E}, 0, \Delta\varepsilon)/\hbar$ and $\times$ denoting the vector product.

The structure of eqn [4] is mathematically identical to the equations describing either the angular momentum dynamics in the presence of a torque or the spin dynamics in a magnetic field. Therefore, the vector $\mathbf{S}$ is often called pseudospin. Moreover, many effects which can be observed in magnetic resonance experiments, e.g., free decay, quantum beats, echoes, etc. have their counterparts in photo-excited optical systems.

The vector product on the right-hand side of eqn [4] shows that $\mathbf{S}$ is changed by $\mathbf{\Omega}$ in a direction perpendicular to $\mathbf{S}$ and $\mathbf{\Omega}$. For vanishing field the torque $\mathbf{\Omega}$ has only a z-component. In this case the z-component of $\mathbf{S}$, i.e., the inversion, remains constant, whereas the x- and y-components, i.e., the polarization and the polarization current, oscillate with the frequency $\Delta\varepsilon/\hbar$ on the Bloch sphere around $\mathbf{\Omega}$.

Semiconductor Bloch Equations

If one wants to analyze optical excitations in crystallized solids, i.e., in systems which are characterized by a periodic arrangement of atoms, one has to include the continuous dispersion (bandstructure) into the description. In translationally invariant, i.e., ordered systems, this can be done by including the crystal momentum $\hbar\mathbf{k}$ as an index to the quantities which describe the optical excitation of the material, e.g., p and I in eqns [1]–[2]. Hence, one has to consider a separate two-level system for each crystal momentum $\hbar\mathbf{k}$. As long as all other interactions are disregarded, the bandstructure simply introduces a summation over the uncoupled contributions from the different $\mathbf{k}$ states, leading to inhomogeneous broadening due to the presence of a range of transition frequencies $\Delta\varepsilon(\mathbf{k})/\hbar$.

For any realistic description of optical processes in solids, it is essential to go beyond the simple picture of non-interacting states and to treat the interactions among the elementary material excitations, e.g., the Coulomb interaction between the electrons and the coupling to additional degrees of freedom, such as lattice vibrations (electron–phonon interaction) or other bath-like subsystems. If crystals are not ideally periodic, imperfections, which can often be described as a disorder potential, need to be considered as well.

All these effects can be treated by proper extensions of the optical Bloch equations introduced above. For semiconductors the resulting generalized equations are known as semiconductor Bloch equations, where the microscopic interactions are included at a certain level of approximation. For a two-band model of a semiconductor, these equations can be written schematically as

$$i\hbar\frac{\partial}{\partial t}p_{\mathbf{k}} = \Delta\varepsilon_{\mathbf{k}}p_{\mathbf{k}} + \Omega_{\mathbf{k}}(n^c_{\mathbf{k}} - n^v_{\mathbf{k}}) + i\hbar\frac{\partial}{\partial t}p_{\mathbf{k}}|_{\mathrm{corr}} \qquad [5]$$

$$i\hbar\frac{\partial}{\partial t}n^c_{\mathbf{k}} = (\Omega^*_{\mathbf{k}}p_{\mathbf{k}} - \Omega_{\mathbf{k}}p^*_{\mathbf{k}}) + i\hbar\frac{\partial}{\partial t}n^c_{\mathbf{k}}|_{\mathrm{corr}} \qquad [6]$$

$$i\hbar\frac{\partial}{\partial t}n^v_{\mathbf{k}} = -(\Omega^*_{\mathbf{k}}p_{\mathbf{k}} - \Omega_{\mathbf{k}}p^*_{\mathbf{k}}) + i\hbar\frac{\partial}{\partial t}n^v_{\mathbf{k}}|_{\mathrm{corr}} \qquad [7]$$

Here $p_{\mathbf{k}}$ is the microscopic polarization and $n^c_{\mathbf{k}}$ and $n^v_{\mathbf{k}}$ are the electron populations in the conduction and valence bands (c and v), respectively. Due to the Coulomb interaction and possibly further processes, the transition energy $\Delta\varepsilon_{\mathbf{k}}$ and the Rabi energy $\Omega_{\mathbf{k}}$ both depend on the excitation state of the system, i.e., they are functions of the time-dependent polarizations and populations. This leads, in particular, to a coupling among the excitations for all different values of the crystals momentum $\hbar\mathbf{k}$. Consequently, in the presence of interactions, the optical excitations can no longer be described as independent two-level systems but have to be treated

as a coupled many-body system. A prominent and important example in this context is the appearance of strong exciton resonances which, as a consequence of the Coulomb interaction, show up in the absorption spectra of semiconductors energetically below the fundamental bandgap.

The interaction effects lead to significant mathematical complications since they induce couplings between all the different quantum states in a system and introduce an infinite hierarchy of equations for the microscopic correlation functions. The terms given explicitly in eqns [5]–[7] arise in a treatment of the Coulomb interaction on the Hartree-Fock level. Whereas this level is sufficient to describe excitonic resonances, there are many additional effects, e.g., excitation-induced dephasing due to Coulomb scattering and significant contributions from higher-order correlations, like excitonic populations and biexcitonic resonances, which make it necessary to treat many-body correlation effects that are beyond the Hartree-Fock level. These contributions are formally included by the terms denoted as $|_{\mathrm{corr}}$ in eqns [5]–[7]. The systematic truncation of the many-body hierarchy and the analysis of controlled approximations is the basic problem in the microscopic theory of optical processes in condensed matter systems.

Examples

Radiative Decay

The emitted field originating from the non-equilibrium coherent polarization of a photo-excited system can be monitored by measuring the transmission and the reflection as function of time. If only a single isolated transition is excited, the dynamic evolution of the polarization and therefore of the transmission and reflection is governed by radiative decay. This decay is a consequence of the coupling of the optical transition to the light field described by the combination of Maxwell- and Bloch-equations. Radiative decay simply means that the optical polarization is converted into a light field on a characteristic time scale $2T_{\mathrm{rad}}$. Here, T_{rad} is the population decay time, often also denoted as T_1-time. This radiative decay is a fundamental process which limits the time on which coherent effects are observable for any photo-excited system. Due to other mechanisms, however, the non-equilibrium polarization often vanishes considerably faster.

The value of T_{rad} is determined by the dipole matrix element and the frequency of the transition, i.e., $T_{\mathrm{rad}}^{-1} \propto |\boldsymbol{\mu}|^2 \Delta\omega$, with $\Delta\omega = \Delta\varepsilon/\hbar$. The temporal evolution of the polarization and the emitted field are proportional to $e^{-i\Delta\omega t - t/(2T_{\mathrm{rad}})}$. Usually one measures the intensity of a field, i.e., its squared modulus, which evolves as $e^{-t/T_{\mathrm{rad}}}$ and thus simply shows an exponential decay, the so-called *free-induction decay* (see Figure 1). T_{rad} can be very long for transitions with small matrix elements. For semiconductor quantum wells, however, it is in the order of only 10 ps, as the result of the strong light-matter interaction.

The time constant on which the optical polarization decays is often called T_2. In the case where this decay is dominated by radiative processes, we thus have $T_2 = 2T_{\mathrm{rad}}$.

Superradiance

The phenomenon of superradiance can be discussed considering an ensemble of N two-level systems which are localized at certain positions $\mathbf{R}_i$. In this case

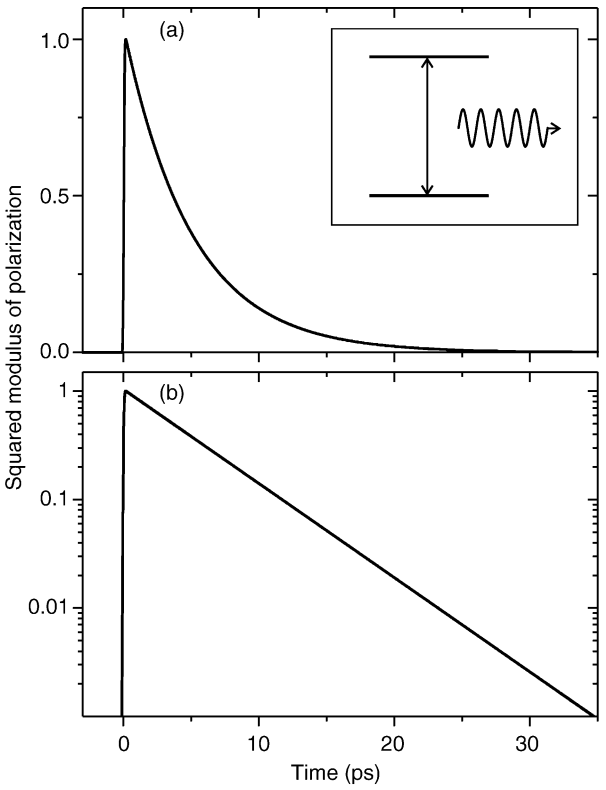

Figure 1 A two-level system is excited by a short optical pulse at $t = 0$. Due to radiative decay (inset) and possibly other dephasing mechanisms, the polarization decays exponentially as function of time with the time constant T_2, the dephasing time. The intensity of the optical field which is emitted as a result of this decay is proportional to the squared modulus of the polarization, which falls off with the time constant $T_2/2$. The decay of the squared modulus of the polarization is shown in (a) on a linear scale and in (b) on a logarithmic scale. The dephasing time was chosen to be $T_2 = 10$ ps which models the radiative decay of the exciton transition of a semiconductor quantum well.

Maxwell's equations introduce a coupling among all these resonances since the field emitted from any specific resonance interacts with all other resonances and interferes with their emitted fields. As a result, this system is characterized by N eigenmodes originating from the radiatively coupled optical resonances.

A very spectacular situation arises if one considers N identical two-level systems regularly arranged with a spacing that equals an integer multiple of $\lambda/2$, where λ is the wavelength of the system's resonance, i.e., $\lambda = c/\Delta\omega$, where c is the speed of light in the considered material (see Figure 2a). In this case all emitted fields interfere constructively and the system behaves effectively like a single two-level system with a matrix element increased by $\sqrt{N}$. Consequently, the radiative decay rate is increased by N and the polarization of the coupled system decays N-times faster than that of an isolated system (see Figure 2b). This effect is called superradiance.

It is possible to observe superradiant coupling effects, e.g., in suitably designed semiconductor heterostructures. Figure 2c compares the measured time-resolved reflection from a single quantum well (dashed line) with that of a Bragg structure, i.e., a multiple quantum-well structure which consists of 10 individual wells that are separated by $\lambda/2$ (solid line), where λ is the wavelength of the exciton resonance. For times greater than about 2 ps the direct reflection of the exciting pulse has decayed sufficiently and one is left with the exponential decay of the remaining signal. Figure 2c shows that this decay is much more rapid for the Bragg structure than for the single quantum well, due to superradiance introduced by the radiative coupling among the quantum wells.

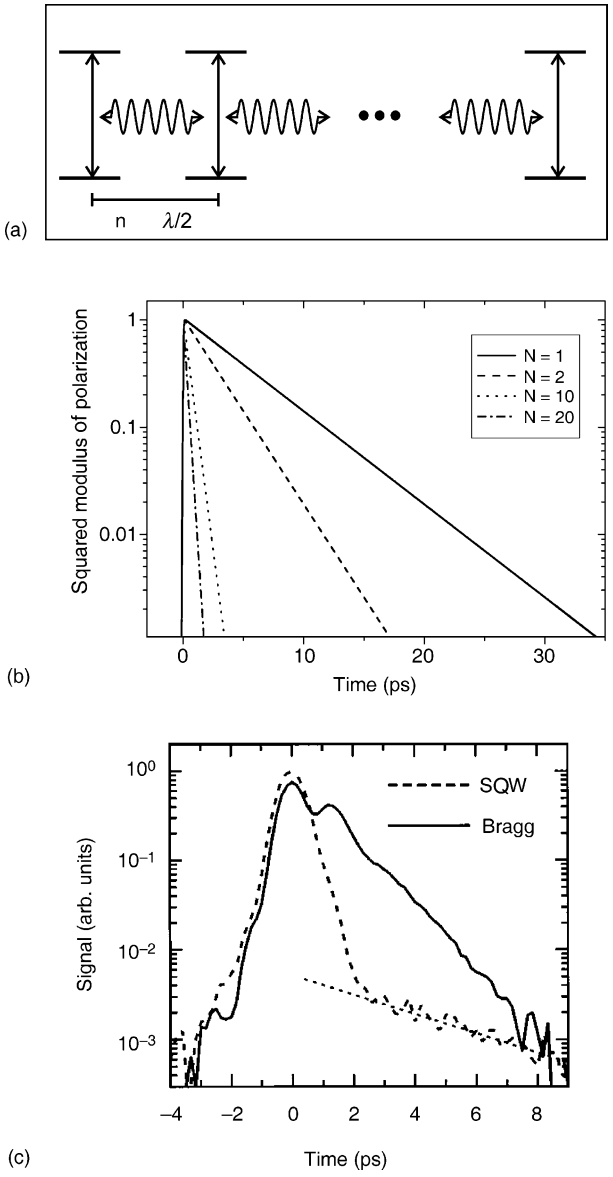

Figure 2 (a) N identical two-level systems are depicted which are regularly arranged with a spacing that equals an integer multiple of $\lambda/2$, where λ is the wavelength of the system's resonance. Due to their coupling via Maxwell's equations all fields emitted from the two-level systems interfere constructively and the coupled system behaves effectively like a single two-level system with an optical matrix element increased by $\sqrt{N}$. (b) The temporal decay of the squared modulus of the polarization is shown on a logarithmic scale. The radiative decay rate is proportional to N and thus the polarization of the coupled system decays N-times faster than that of an isolated system. This effect is called superradiance. (c) Measured time-resolved reflection of a semiconductor single quantum well (dashed line) and a $N = 10$ Bragg structure, i.e., a multi quantum well where the individual wells are separated by $\lambda/2$ (solid line), on a logarithmic scale. [Part (c) is reproduced with permission from Haas S, Stroucken T, Hübner M, *et al.* (1998) Intensity dependence of superradiant emission from radiatively coupled excitons in multiple-quantum-well Bragg structures. *Physical Review B* 57: 14860. Copyright (1998) by the American Physical Society].

Destructive Interference

As the next example we now consider a distribution of two-level systems which have slightly different transition frequencies characterized by the distribution function $g(\Delta\omega - \bar{\omega})$ of the transition frequencies which is peaked at the mean value $\bar{\omega}$ and has a spectral width of $\delta\omega$ (see Figure 3a). Ignoring the radiative coupling among the resonances, the optical polarization of the total system evolves after excitation with a short laser pulse at $t = 0$ proportional to $\int d\omega\, g(\Delta\omega - \bar{\omega}) e^{-i\Delta\omega t} \propto \tilde{g}(t) e^{-i\bar{\omega}t}$, where $\tilde{g}(t)$ denotes the Fourier transform of the frequency distribution function. $\tilde{g}(t)$ and thus the optical polarization decays on a time-scale which is inversely proportional to the spectral width of the distribution function $\delta\omega$. Thus the destructive interference of many different transition frequencies results in a rapid decay of the polarization (see Figure 3b).

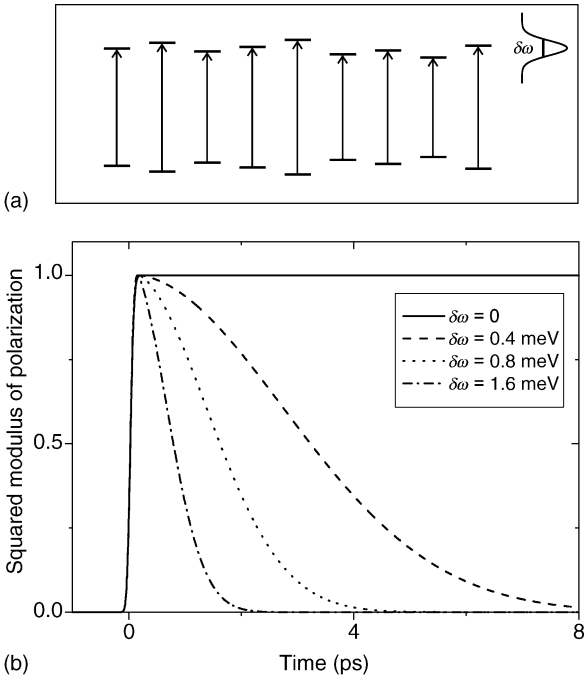

Figure 3 (a) An ensemble of two-level systems is shown where the resonance frequencies are randomly distributed according to a Gaussian distribution function of width $\delta\omega$ around an average value. (b) The temporal dynamics of the squared modulus of the polarization of ensembles of two-level systems after excitation with a short optical pulse at $t = 0$ is shown on a linear scale. Since the dephasing time is set to infinity, i.e., $T_2 \rightarrow \infty$, the polarization of an ensemble of identical two-level system ($\delta\omega = 0$) does not decay. However, for a finite width of the distribution, $\delta\omega > 0$, the individual polarizations of the ensemble oscillate with different frequencies and, therefore, due to destructive interference the polarization of the ensemble decays as function of time. Since the Fourier transform of a frequency-domain Gaussian is a Gaussian in the time domain, the dashed, dotted, and dashed dotted line have a Gaussian shape with a temporal width which is inversely proportional to $\delta\omega$.

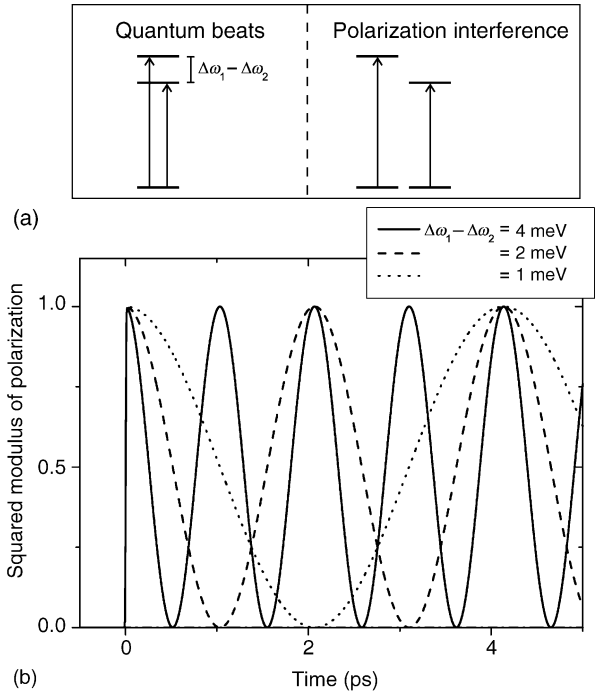

Figure 4 (a) Two optical resonances with frequency difference $\Delta\omega_1 - \Delta\omega_2$ may be realized by either a three-level system or by two uncoupled two-level systems. After impulsive excitation with an optical pulse the linear polarization of both types of systems show a modulation of the squared modulus of the polarization with the time period $2\pi/(\Delta\omega_1 - \Delta\omega_2)$. For the intrinsically coupled three-level system these modulations are called quantum beats, whereas for an interference of uncoupled systems they are named polarization interferences. Using nonlinear optical techniques, e.g., four-wave mixing and pump probe, it is possible to distinguish quantum beats and polarization interferences since coupled and uncoupled systems have different optical nonlinearities. (b) The temporal dynamics of the squared modulus of the polarization is shown for systems with two resonances and frequency difference $\Delta\omega_1 - \Delta\omega_2$, neglecting dephasing, i.e., setting $T_2 \rightarrow \infty$. After excitation with a short optical pulse at $t = 0$ the squared modulus of the polarization is periodically modulated with a time period $2\pi/(\Delta\omega_1 - \Delta\omega_2)$.

In the spectral domain this rapid decay shows up as inhomogeneous broadening. Depending on the system under investigation, there are many different sources for such an inhomogeneous broadening. One example is the Doppler broadening in atomic gases or disorder effects such as well-width fluctuations in semiconductor quantum wells or lattice imperfections in crystals.

In the nonlinear optical regime it is, under certain circumstances, possible to reverse the destructive interference of inhomogeneously broadened coherent polarizations. For example, in four-wave mixing, a second pulse may lead to a rephasing of the contributions with different frequencies, which results in the photon echo (see discussion below).

Quantum Beats

The occurrence of quantum beats can be understood most easily in a system where the total optical polarization can be attributed to a finite number of optical transitions. Let us assume for simplicity that all these transitions have the same matrix element. In this case, after excitation with a short laser pulse at $t = 0$ the optical polarization of the total system evolves proportional to $\sum_i e^{-i\Delta\omega_i t}$. The finite number of frequencies results in a temporal modulation with time periods $2\pi/(\Delta\omega_i - \Delta\omega_j)$ of the squared modulus of the polarization which is proportional to the emitted field intensity. For the case of two frequencies the squared modulus of the polarization is proportional to $[1 + \cos((\Delta\omega_1 - \Delta\omega_2)t)]$, i.e., due to the interference of two contributions the polarization varies between a maximum and zero (see Figure 4b).

In the linear optical regime it is impossible to distinguish whether the optical transitions are

uncoupled or coupled. As shown in Figure 4, the two uncoupled two-level systems give the same linear polarization as a three-level systems where the two transitions share a common state. It is, however, possible to decide about the nature of the underlying transitions if one performs nonlinear optical spectroscopy. This is due to the fact that the so-called quantum beats, i.e., the temporal modulations of the polarization of an intrinsically coupled system, show a different temporal evolution as the so-called polarization interferences, i.e., the temporal modulations of the polarization of uncoupled systems. The former ones are also much more stable in the presence of inhomogeneous broadening than the latter ones.

In semiconductor heterostructures, quantum-beat spectroscopy has been widely used to investigate the temporal dynamics of excitonic resonances. Also the coupling among different optical resonances has been explored in pump-probe and four-wave-mixing measurements.

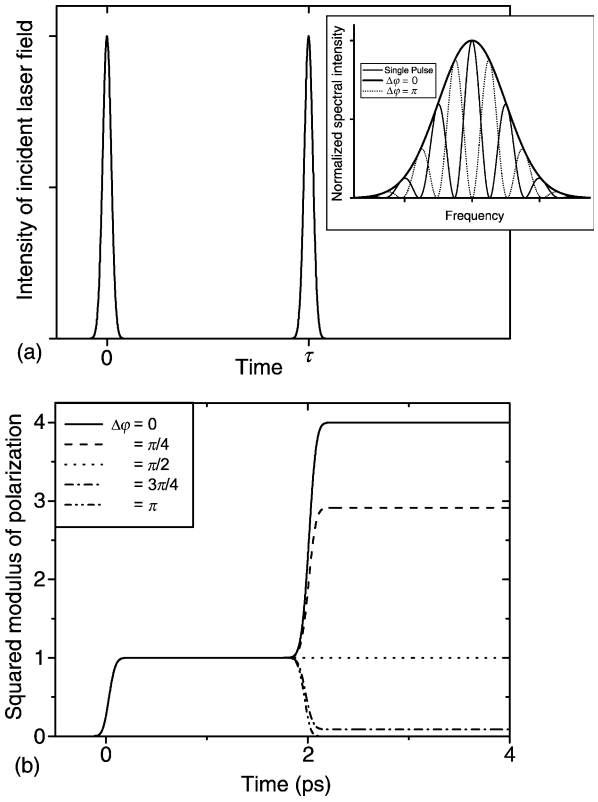

Figure 5 (a) Two Gaussian laser pulses separated by the time delay τ can lead to interferences. As shown by the thick solid line in the inset, the spectral intensity of a single pulse is a Gaussian with a maximum at the central frequency of the pulse. The width of this Gaussian is inversely proportional to the duration of the pulse. The spectral intensity of the field consisting of both pulses shows interference fringes, i.e., is modulated with a spectral period that is inversely proportional to τ. As shown by the thin solid and the dotted lines in the inset, the phase of the interference fringes depends on the phase difference $\Delta\varphi$ between the two pulses. Whereas for $\Delta\varphi = 0$ the spectral intensity has a maximum at the central frequency, it vanishes at this position for $\Delta\varphi = \pi$. (b) The temporal dynamics of the squared modulus of the polarization is shown for a two-level system excited by a pair of short laser pulses neglecting dephasing, i.e., setting $T_2 \to \infty$. The first pulse excites at $t = 0$ an optical polarization with a squared modulus normalized to 1. The second pulse, which has the same intensity as the first one, also excites an optical polarization at $t = 2$ ps. For $t > 2$ ps the total polarization is given by the sum of the polarizations induced by the two pulses. Due to interference, the squared modulus of the total polarization depends sensitively on the phase difference $\Delta\varphi$ between the two pulses. For constructive interference the squared modulus of the total polarization after the second pulse is four times bigger than that after the first pulse, whereas it vanishes for destructive interference. One may achieve all values in between these extremes by using phase differences $\Delta\varphi$ which are no multiples of π. It is thus shown that the second pulse can be used to coherently control the polarization induced by the first pulse.

Coherent Control

In the coherent regime the polarization induced by a first laser pulse can be modified by a second, delayed pulse. For example, the first short laser pulse incident at $t = 0$ induces a polarization proportional to $e^{-i\Delta\omega t}$ and a second pulse arriving at $t = \tau > 0$ induces a polarization proportional to $e^{-i\varphi}e^{-i\Delta\omega(t-\tau)}$. Thus for $t \geq \tau$ the total polarization is given by $e^{-i\Delta\omega t}(1 + e^{-i\Delta\varphi})$ with $\Delta\varphi = \varphi - \Delta\omega\tau$. If $\Delta\varphi$ is an integer multiple of 2π, the polarizations of both pulses interfere constructively and the amplitude of the resulting polarization is doubled as compared to a single pulse. If, on the other hand, $\Delta\varphi$ is an odd multiple of π, the polarizations of both pulses interfere destructively and the resulting polarization vanishes after the action of both pulses. Thus by

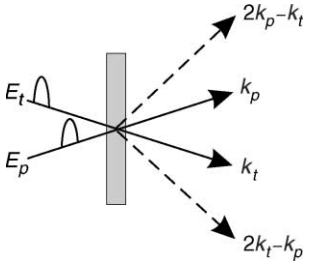

Figure 6 Transient optical nonlinearities can be investigated by exciting the system with two time delayed optical pulses. The pump pulse (E_p) puts the system in an excited state and the test (probe) pulse (E_t) is used to measure its dynamics. The dynamic nonlinear optical response may be measured in the transmitted or reflected directions of the pump and test pulses, i.e., $\pm k_p$ and $\pm k_t$, respectively. In a pump-probe experiment one often investigates the change of the test absorption induced by the pump pulse, by measuring the absorption in the direction k_t with and without E_p. One may also measure the dynamic nonlinear optical response in scattering directions like $2k_p - k_t$ and $2k_t - k_p$ as indicated by the dashed lines. This is what is done in a four-wave-mixing or photon-echo experiment.

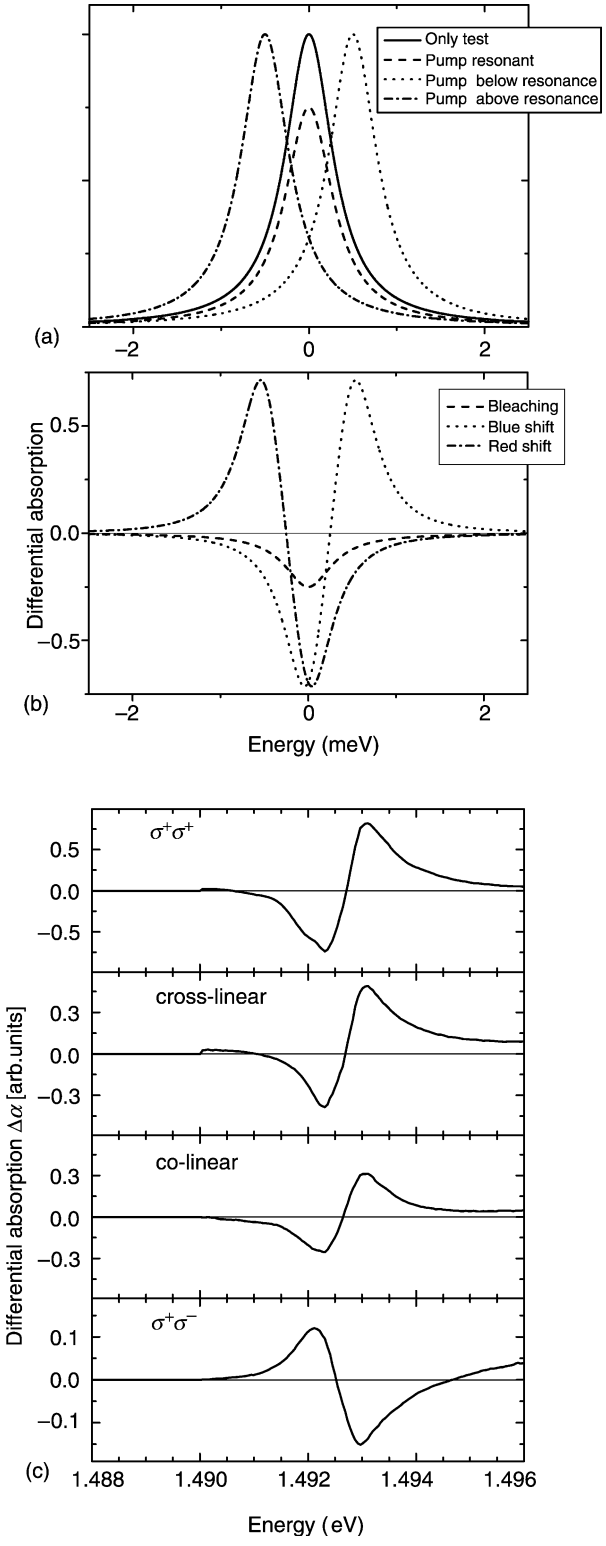

Figure 7 (a) Absorption spectra of a two-level system. The solid line shows the linear optical absorption spectrum as measured by a weak test pulse. It corresponds to a Lorentzian line that is centered at the transition frequency $\Delta\omega$, which has been set to zero. The width of the line is inversely proportional to the dephasing time T_2. In the presence of a pump pulse which resonantly excited the two-level system, the absorption monitored by the test pulse is reduced in amplitude, i.e., bleached, since the pump puts the system in an excited state (dashed line). In the optical Stark effect the frequency of the pump is nonresonant with the transition frequency. If the pump is tuned below (above) the transition frequency, the absorption is shifted to higher (lower) frequencies, i.e., shifted to the blue (red) part of the spectrum, see dotted (dashed-dotted) line. (b) The differential absorption obtained by taking the difference between the absorption in the presence of the pump and the absorption without pump. The dashed line shows the purely negative bleaching obtained using a resonant pump. The dotted and the dashed-dotted lines correspond to the dispersive shape of the blue and red shift obtained when pumping below and above the resonance, respectively. (c) Measured differential absorption spectra of a semiconductor quantum well which is pumped off resonantly 4.5 *meV* below the 1s heavy-hole exciton resonance. The four lines correspond to different polarization directions of the pump and probe pulses as indicated. [Part (c) is reproduced with permission from Sieh C, Meier T, Jahnke F, *et al.* (1999) Coulomb memory signatures in the excitonic optical Stark effect. *Physical Review Letters* 82: 3112. Copyright (1999) by the American Physical Society.]

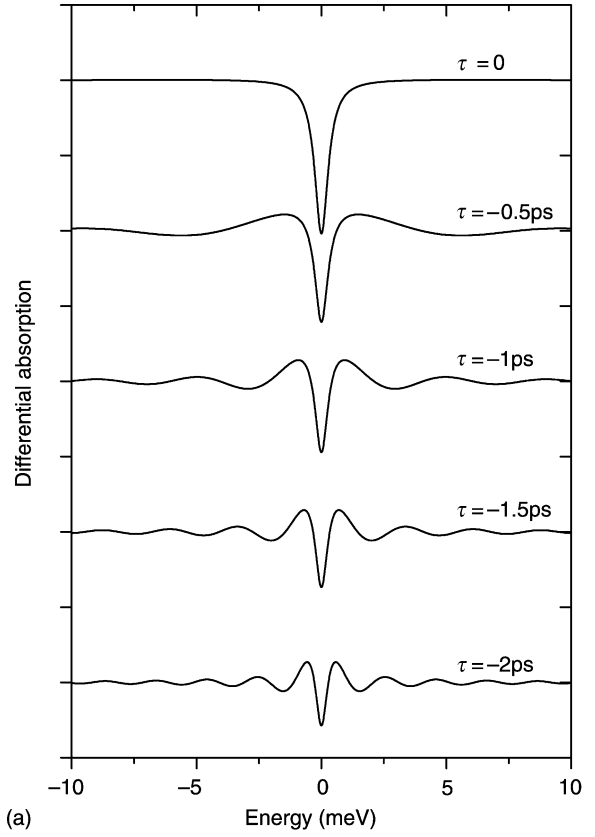
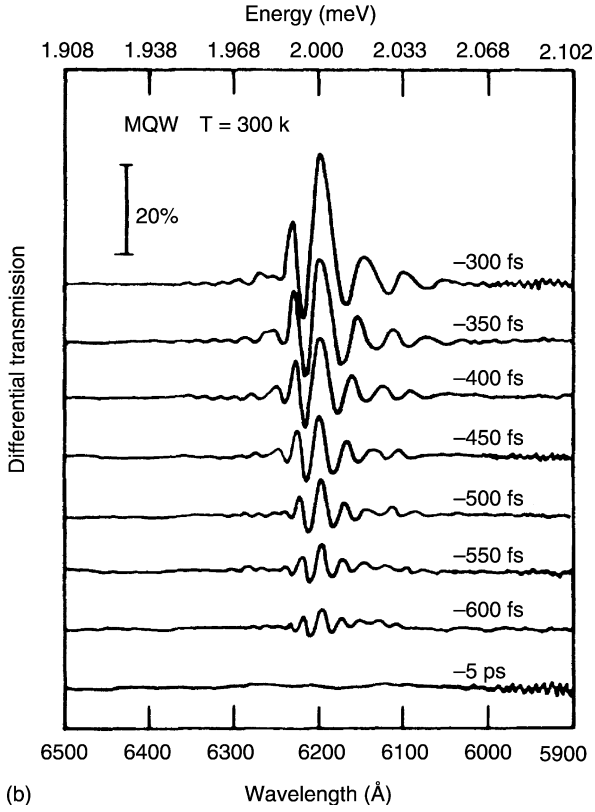


varying the phase difference of the two pulses it is possible to coherently enhance or destroy the optical polarization (see Figure 5b).



One can easily understand the coherent control in the frequency domain by considering the overlap between the absorption of the system and the pulse spectrum. For excitation with two pulses that are temporally delayed by τ, the spectrum of the excitation shows interference fringes with a spectral oscillation period that is inversely proportional to τ. The positions of the maxima and the minima of the fringes depend on the phase difference between the two pulses. For constructive interference, the excitation spectrum is at a maximum at the resonance of the system, whereas for destructive interference the excitation spectrum vanishes at the resonance of the system (see Figure 5a).

Coherent control techniques have been applied to molecules and solids to control the dynamical evolution of electronic wavepackets and also the coupling to nuclear degrees of freedom. In this context, it is sometimes possible to steer certain chemical reactions into a preferred direction by using sequences of laser pulses which can be chirped, i.e., have a time-dependent frequency. Furthermore, in semiconductors and heterostructures, coherent control has been used to optically inject electronic currents on an ultrafast time-scale.

Transient Absorption Changes

In a typical pump-probe experiment one excites the system with a pump pulse (E_p) and probes its dynamics with a weak test pulse (E_t) (see Figure 6). With such experiments one often measures the differential absorption $\Delta\alpha(\omega)$ which is defined as

the difference between the probe absorption in the presence of the pump $\alpha_{\text{pump on}}(\omega)$ and the probe absorption without the pump $\alpha_{\text{pump off}}(\omega)$.

For resonant pumping and for a situation where the pump precedes the test (positive time delays $\tau > 0$), the absorption change is usually negative in the vicinity of the resonance frequency $\Delta\omega$, indicating the effect of absorption bleaching (see Figure 7a,b). There may be positive contributions spectrally around the original absorption line due to resonance broadening and, at other spectral positions, due to excited state absorption, i.e., optical transitions to energetically higher states which are only possible if the system is in an excited state. The bleaching and the positive contributions are generally present in coherent, and also in incoherent situations, where the polarization vanishes but occupations in excited states are present.

For detuned pumping, the resonance may be shifted by the light field as for example, in the optical Stark effect. Depending on the excitation configuration and the system, this transient shift may be to higher (blue shift) or lower energies (red shift) (see Figure 7a,b). With increasing pump-probe time delay the system gradually returns to its unexcited state and the absorption changes disappear.

As an illustration we show in Figure 7c experimentally measured differential absorption spectra of a semiconductor quantum well which is pumped spectrally below the exciton resonance. For a two-level system one would expect a blue shift of the absorption, i.e., a dispersive shape of the differential absorption with positive contributions above and negative contributions below the resonance frequency. This is indeed observed for most polarization directions of the pump and probe pulses. However, if both pulses are oppositely circularly polarized, the experiment shows a resonance shift in the reverse direction, i.e., a red shift. For the explanation of this behavior one has to consider the optical selection rules of the quantum well system. One finds that the signal should actually vanish for oppositely circularly

Figure 8 (a) Differential absorption spectra are shown for resonant pumping of a two-level system for various time delays τ between the pump and the test pulse. When the pump precedes the test, i.e., $\tau < 0$, the differential absorption exhibits spectral oscillations with a period which is inversely proportional to the time delay. When τ approaches zero, these spectral oscillations vanish and the differential absorption develops into purely negative bleaching. (b) Measured differential transmission spectra of a multi quantum well for different negative time delays as indicated. [Part (b) is reproduced with permission from Sokoloff JK, Joffre M, Fluegel B, *et al.* (1988) Transient oscillations in the vicinity of excitons and in the band of semiconductors. *Physics Review B* 38: 7615. Copyright (1988) by the American Physical Society.]

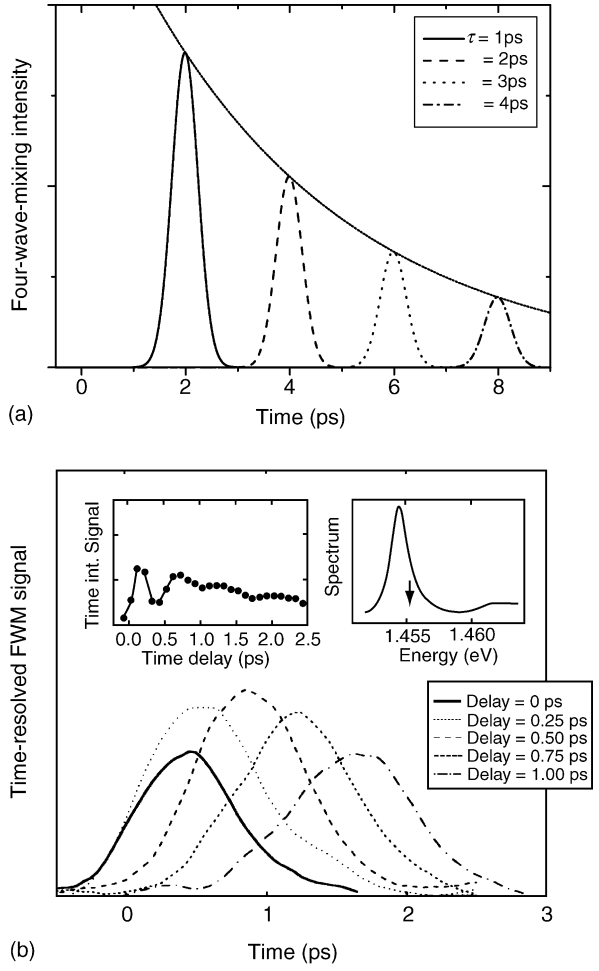


Figure 9 (a) The intensity dynamics as measured in a four-wave-mixing experiment on an ensemble of inhomogeneously broadened two-level systems for various time delays τ of the two incident pulses. The first pulse excites the system at $t = 0$. In the time period $0 < t < \tau$ the individual polarizations of the inhomogeneously broadened system oscillate with their respective frequencies and due to destructive interference the total polarization decays, cp. **Figure 3**. The second pulse arriving at $t = \tau$ leads to a partial rephasing of the individual polarizations. Due to phase conjugation all individual polarizations are in phase at $t = 2\tau$ which results in a macroscopic measurable signal, the photon echo. Due to dephasing processes the magnitude of the photon echo decays with increasing τ, see solid, dashed, dotted and dashed-dotted lines. Describing the dephasing via a T_2 time corresponds to an exponential decay as indicated by the thin dotted line. By measuring the decay of the echo with increasing τ, one thus gets experimental information on the dephasing of the optical polarization. (b) Time-resolved four-wave-mixing signal measured on an inhomogeneously broadened exciton resonance of a semiconductor quantum well structure for different time delays as indicated. The origin of the time axis starts at the arrival of the second pulse, i.e., for a non-interacting system the maximum of the echo is expected at $t = \tau$. The insets show the corresponding time-integrated four-wave-mixing signal and the linear absorption. [Part (b) is reproduced with permission from Jahnke F, Koch M, Meier T, *et al.* (1994) Simultaneous influence of disorder and Coulomb interaction on photon echoes in semiconductors. *Physics Review B* 50: 8114. Copyright (1994) by the American Physical Society.]

polarized pulses, as long as many-body correlations are neglected. Thus in this case the entire signal is due to many-body correlations and it is their dynamics which gives rise to the appearance of the red shift.

Spectral Oscillations

For negative time delays $\tau < 0$, i.e., if the test pulse precedes the pump, the absorption change $\Delta\alpha(\omega)$ is characterized by spectral oscillations around $\Delta\omega$ which vanish as τ approaches zero (see **Figure 8a**). The spectral period of the oscillations decreases with increasing $|\tau|$. **Figure 8b** shows measured differential transmission spectra of a multiple quantum-well structure for different negative time delays. As with the differential absorption, also the differential transmission spectra are dominated by spectral oscillations around the exciton resonance whose period and amplitude decrease with increasing $|\tau|$.

The physical origin of the coherent oscillations is the pump-induced perturbation of the free-induction decay of the polarization generated by the probe pulse. This perturbation is delayed by the time τ at which the pump arrives. The temporal shift of the induced polarization changes in the time domain leads to oscillations in the spectral domain, since the Fourier transformation translates a delay in one domain into a phase factor in the conjugate domain.

Photon Echo

In the nonlinear optical regime one may (partially) reverse the destructive interference of a coherent, inhomogeneously broadened polarization. For example, in four-wave mixing, which is often performed with two incident pulses, one measures the emitted field in a background-free scattering direction (see **Figure 5**). The first short laser pulse excites all transitions at $t = 0$. As a result of the inhomogeneous broadening the polarization decays due to destructive interference (see **Figure 3**). The second pulse arriving at $t = \tau > 0$ is able to conjugate the phases ($e^{i\varphi} \rightarrow e^{-i\varphi}$) of the individual polarizations of the inhomogeneously broadened system. The subsequent unperturbed dynamical evolution of the polarizations leads to a measurable macroscopic signal at $t = 2\tau$. This photon echo occurs since at this point in time all individual polarizations are in phase and add up constructively (see **Figure 9a**). Since this rephasing process leading to the echo is only possible as long as the individual polarizations remain coherent, one can analyze the loss of coherence (dephasing) by measuring the decay of the photon echo with increasing time delay.

Echo experiments are frequently performed using more complicated geometries, e.g., more than

two laser pulses. Further echo phenomena can also be observed as the result of the coupling of the photo-excitation to nuclear degrees of freedom and also due to spatial motion of the electrons, i.e., electronic currents.

Time-resolved four-wave-mixing signal, measured on an inhomogeneously broadened exciton resonance of a semiconductor quantum well structure for different time delays, is presented in Figure 9b. Compared to Figure 9a, the origin of the time axis starts at the arrival of the second pulse, i.e., for a non-interacting system the maximum of the echo is expected at $t = \tau$. Due to the inhomogeneous broadening the maximum of the signal is shifting to longer times with increasing delay. Further details of the experimental results, in particular, the exact position of the maximum and the width of the signal, cannot be explained on the basis of non-interacting two-level systems, but require the analysis of many-body effects in the presence of inhomogeneous broadening.

Introduction

Linear optical spectroscopy, using the techniques of absorption, transmission, reflection and light scattering, has provided invaluable information about the electronic and vibrational properties of atoms, molecules, and solids. Optical techniques also possess some additional unique strengths: the ability to

1. generate nonequilibrium distributions functions of electrons, holes, excitons, phonons, etc. in solids;
2. determine the distribution functions by optical spectroscopy;
3. determine the nonequilibrium distribution functions on femtosecond timescales;
4. determine femtosecond dynamics of carrier and exciton transport and tunneling; and
5. investigate interactions between various elementary excitations as well as many-body processes in semiconductors.

Researchers have exploited these unique strengths to gain fundamental new insights into nonequilibrium, nonlinear, and transport physics of semiconductors and their nanostructures over the past four decades.

A major focus of these efforts has been devoted to understanding how a semiconductor in

thermodynamic equilibrium, excited by an ultrashort optical pulse, returns to the state of thermodynamic equilibrium. Four distinct regimes can be identified:

(a) the coherent regime in which a well-defined phase relationship exists between the excitation created by the optical pulse and the electromagnetic (optical) field creating it;
(b) the nonthermal regime in which the coherence (well-defined phase relationships) has been destroyed by various collision and interference processes but the distribution function of excitations is nonthermal (i.e., cannot be described by a Maxwell–Boltzmann distribution or its quantum (degenerate) counterparts);
(c) the hot carrier regime in which the distributions for various excitations are thermal, but with different characteristic temperatures for different excitations and thermal bath; and
(d) the isothermal regime in which the excitations and the thermal bath are at the same temperature but there is an excess of excitation (e.g., electron–hole pairs) compared to thermodynamic equilibrium.

Various physical processes take the semiconductor from one regime to the next, and provide information not only about the fundamental physics of semiconductors but also about the physics and ultimate performance limits of electronic, optoelectronic, and photonic devices.

In addition to coherent and relaxation dynamics, ultrafast studies of semiconductors provide new insights into tunneling and transport of carriers, and demonstrate novel quantum mechanical phenomena and coherent control in semiconductors.

The techniques used for such studies have also advanced considerably over the last four decades. Ultrafast lasers with pulse widths corresponding to only a few optical cycles (1 optical cycle ≈ 2.7 fs at 800 nm) have been developed. The response of the semiconductor to an ultrafast pulse, or a multiple of phase-locked pulses, can be investigated by measuring the dynamics of light emitted by the semiconductor using a streak camera (sub-ps time resolution) or a nonlinear technique such as luminescence up-conversion (time resolution determined by the laser pulse width for an appropriate nonlinear crystal). The response of the semiconductor can also be investigated using a number of two or three beam pump-probe techniques such as transmission, reflection, light scattering or four-wave mixing (FWM). Both the amplitude and the phase of the emitted radiation or the probe can be measured by phase-sensitive techniques such as spectral interferometry. The lateral transport of excitation can be investigated by using time-resolved spatial imaging and the vertical transport and tunneling of carriers can be investigated using the technique of 'optical markers'. Electro-optic sampling can be used for transmission/reflection studies or for measuring THz response of semiconductors. More details on these techniques, and indeed many topics discussed in this brief article, can be found in the Further Reading.

Coherent Dynamics

The coherent response of atoms and molecules is generally analyzed for an ensemble of independent (noninteracting) two-level systems. The statistical properties of the ensemble are described in terms of the density matrix operator whose diagonal components relate to population of the eigenstates and off-diagonal components relate to coherence of the superposition state. The time evolution of the density matrix is governed by the Liouville variant of the Schrödinger equation $i\hbar\dot{\rho} = [H, \rho]$ where the system Hamiltonian $H = H_0 + H_{\text{int}} + H_R$ is the sum of the unperturbed, interaction (between the radiation field and the two-level system), and relaxation Hamiltonians, respectively. Using a number of different assumptions and approximations, this equation of motion is transformed into the optical Bloch equations (OBE), which are then used to predict the coherent response of the system, often using iterative procedures, and analyze experimental results.

Semiconductors are considerably more complex. Coulomb interaction profoundly modifies the response of semiconductors, not only in the linear regime (e.g., strong exciton resonance in the absorption spectrum) but also in the coherent and nonlinear regime. The influence of Coulomb interaction may be introduced by renormalizing the electron and hole energies (i.e., introducing excitons), and by renormalizing the field–matter interaction strength by introducing a renormalized Rabi frequency. These changes and the relaxation time approximation for the relaxation Hamiltonian lead to an analog of the optical Bloch equations, the semiconductor Bloch equations which have been very successful in analyzing the coherent response of semiconductors.

In spite of this success, it must be stressed that the relaxation time approximation, and the Boltzmann kinetic approach on which it is based, are not valid under all conditions. The Boltzmann kinetic approach is based on the assumption that the duration of the collision is much shorter than the interval between the collisions; i.e., the collisions are instantaneous. In the non-Markovian regime where these assumptions are not valid, each collision does not strictly

conserve the energy and momentum and the quantum kinetic approach becomes more appropriate. This is true for photo-excited semiconductors as well as for the quantum transport regime in semiconductors. Also, semiconductor Bloch equations have been further extended by including four-particle correlations. Finally, the most general approach to the description of the nonequilibrium and coherent response of semiconductors following excitation by an ultrashort laser pulse is based on nonequilibrium Green's functions.

Experimental studies on the coherent response of semiconductors can be broadly divided into three categories:

1. investigation of novel aspects of coherent response not found in other simpler systems such as atoms;
2. investigation of how the initial coherence is lost, to gain insights into dephasing and decoherence processes; and
3. coherent control of processes in semiconductors using phase-locked pulses.

Numerous elegant studies have been reported. This section presents some observations on the trends in this field.

Historically, the initial experiments focused on the decay of the coherent response (time-integrated FWM as a function of delays between the pulses), analyzed them in terms of the independent two-level model, and obtained very useful information about various collision processes and rates (exciton–exciton, exciton–carrier, carrier–carrier, exciton–phonon, etc.). It was soon realized, however, that the noninteracting two-level model is not appropriate for semiconductors because of the strong influence of Coulomb interactions. Elegant techniques were then developed to explore the nature of coherent response of semiconductors. These included investigation of time- and spectrally resolved coherent response, and of both the amplitude and phase of the response to complement intensity measurements. These studies provided fundamental new insights into the nature of semiconductors and many-body processes and interactions in semiconductors. Many of these observations were well explained by the semiconductor Bloch equations. When lasers with <10 fs pulse widths became laboratory tools, the dynamics was explored on a time-scale much shorter than the characteristic phonon oscillation period (≈ 115 fs for GaAs longitudinal optical phonons), the plasma frequency (≈ 150 fs for a carrier density of $5 \times 10^{17}\,\mathrm{cm}^{-3}$), and the typical electron–phonon collision interval (≈ 200 fs in GaAs). Some remarkable features of quantum kinetics, such as reversal of the electron–phonon collision, memory effects, and energy nonconservation, were demonstrated. More recent experiments have demonstrated the influence of four-particle correlations on coherent nonlinear response of semiconductors such as GaAs in the presence of a strong magnetic field.

The ability to generate phase-locked pulses with controllably variable separation between them provides an exciting opportunity to manipulate a variety of excitations and processes within a semiconductor. If the separation between the two phase-locked pulses is adjusted to be less than the dephasing time of the system under investigation, then the amplitudes of the excitations produced by the two phase-locked pulses can interfere either constructively or destructively depending on the relative phase of the carrier waves in the two pulses. The nature of interference changes as the second pulse is delayed over an optical period. A number of elegant experiments have demonstrated coherent control of exciton population, spin orientation, resonant emission, and electrical current. Phase-sensitive detection of the linear or nonlinear emission provides additional insights into different aspects of semiconductor physics.

These experimental and theoretical studies of ultrafast coherent response of semiconductors have led to fundamental new insights into the physics of semiconductors and their coherence properties. Discussion of novel coherent phenomena is given in a subsequent section. Coherent spectroscopy of semiconductors continues to be a vibrant research field.

Incoherent Relaxation Dynamics

The qualitative picture that emerges from investigation of coherent dynamics can be summarized as follows. Consider a direct gap semiconductor excited by an ultrashort laser pulse of duration τ_L (with a spectral width $h\Delta\nu_L$) centered at photon energy $h\nu_L$ larger than the semiconductor bandgap E_g. At the beginning of the pulse the semiconductor does not know the pulse duration so that coherent polarization is created over a spectral region much larger than $h\Delta\nu_L$. If there are no phase-destroying events during the pulse (dephasing rate $1/\tau_D \ll 1/\tau_L$), then a destructive interference destroys the coherent polarization away from $h\nu_L$ with increasing time during the excitation pulse. Thus, the coherent polarization exists only over the spectral region $h\Delta\nu_L$ at the end of the pulse. This coherence will be eventually destroyed by collisions and the semiconductor will be left in an incoherent (off-diagonal elements of the density matrix are 0) nonequilibrium state with peaked electron and hole population distributions whose central energies and energy widths are

determined by $h\nu_L$, $h\Delta\nu_L$ and E_g, if the energy and momentum relaxation rates $(1/\tau_E, 1/\tau_M)$ are much smaller than the dephasing rates.

The simplifying assumptions that neatly separate the excitation, dephasing and relaxation regimes are obviously not realistic. A combination of all these (and some other) physical parameters will determine the state of a realistic system at the end of the exciting pulse. However, after times $\sim \tau_D$ following the laser pulse, the semiconductor can be described in terms of electron and hole populations whose distribution functions are not Maxwell–Boltzmann or Fermi–Direct type, but nonthermal in a large majority of cases in which the energy and momentum relaxation rates are much smaller than the dephasing rates. This section discusses the dynamics of this incoherent state.

Extensive theoretical work has been devoted to quantitatively understand these initial athermal distributions and their further temporal evolution. These include Monte Carlo simulations based on the Boltzmann kinetic equation approach (typically appropriate for time-scales longer than $\sim$100 fs, the carrier–phonon interaction time) as well as the quantum kinetic approach (for times typically less than $\sim$100 fs) discussed above. We present below some observations on this vast field of research.

Nonthermal Regime

A large number of physical processes determines the evolution of the nonthermal electron and hole populations generated by the optical pulse. These include electron–electron, hole–hole, and electron–hole collisions, including plasma effects if the density is high enough, intervalley scattering in the conduction band and intervalence band scattering in valence bands, intersub-band scattering in quantum wells, electron–phonon, and hole–phonon scattering processes. The complexity of the problem is evident when one considers that many of these processes occur on the same time-scale. Of these myriad processes, only carrier–phonon interactions and electron–hole recombinations (generally much slower) can alter the total energy in electronic systems. Under typical experimental conditions, the redistribution of energy takes place before substantial transfer of energy to the phonon system. Thus, the nonthermal distributions first become thermal distributions with the same total energy. Investigation of the dynamics of how the nonthermal distribution evolves into a thermal distribution provides valuable information about the nature of various scattering processes (other than carrier–phonon scattering) described above.

This discussion of separating the processes that conserve energy in the electronic system and those that transfer energy to other systems is obviously too simplistic and depends strongly on the nature of the problem one is considering. The challenge for the experimentalist is to devise experiments that can isolate these phenomena so each can be studied separately. If the laser energy is such that $h\nu_L - E_g < \hbar\omega_{LO}$, the optical phonon energy, then majority of the photo-excited electrons and holes do not have sufficient energy to emit an optical phonon, the fastest of the carrier–phonon interaction processes. The initial nonthermal distribution is then modified primarily by processes other than phonon scattering and can be studied experimentally without the strong influence of the carrier–phonon interactions. Such experiments have indeed been performed both in bulk and quantum well semiconductors. These experiments have exhibited spectral hole burning in the pump-probe transmission spectra and thus demonstrated that the initial carrier distributions are indeed nonthermal and evolve to thermal distributions. Such experiments have provided quantitative information about various carrier–carrier scattering rates as a function of carrier density. In addition, experiments with $h\nu_L - E_g > \hbar\omega_{LO}$ and $h\nu_L - E_g >$ intervalley separation have provided valuable information about intravalley as well as intervalley electron–phonon scattering rates. Experiments have been performed in a variety of different semiconductors, including bulk semiconductors and undoped and modulation-doped quantum wells. The latter provide insights into intersub-band scattering processes and quantitative information about the rates.

These measurements have shown that under typical experimental conditions, the initial nonthermal distribution evolves into a thermal distribution in times $<$ or $\sim$1 ps. However, the characteristic temperatures of the thermal distributions can be different for electrons and holes. Furthermore, different phonons may also have different characteristic temperatures, and may even be nonthermal even when the electronic distributions are thermal. This is the hot carrier regime that is discussed in the next subsection.

Hot Carrier Regime

The hot carriers, with characteristic temperatures T_c (T_e and T_h for electrons and holes, respectively), have high energy tails in the distribution functions that extend several kT_c higher than the respective Fermi energies. Some of these carriers have sufficient energy to emit an optical phonon. Since the carrier–optical phonon interaction rates and the phonon energies are

rather large, this may be the most effective energy loss mechanism in many cases even though the number of such carriers is rather small. The emitted optical phonons have relatively small wavevectors and nonequilibrium populations larger than expected for the lattice temperature. These optical phonons are often referred to as hot phonons although nonequilibrium phonons may be a better term since they probably have nonthermal distributions. The dynamics of hot phonons will be discussed in the next subsection, but we mention here that in case of a large population of hot phonons, one must consider not only phonon emission but also phonon absorption. Acoustic phonons come into the picture at lower temperatures when the fraction of carriers that can emit optical phonons is extremely small or negligible, and also in the case of quantum wells with sub-band energy separation smaller than optical phonons.

The dynamics of hot carriers have been studied extensively to obtain a deeper understanding of carrier–phonon interactions and to obtain quantitative measures of the carrier–phonon interaction rates. Time resolved luminescence and pump-probe transmission spectroscopy are the primary tools used for such studies. For semiconductors like GaAs, the results indicate that polar optical phonon scattering (longitudinal optical phonons) dominates for electrons whereas polar and nonpolar optical phonon scattering contribute for holes. Electron–hole scattering is sufficiently strong in most cases to maintain a common electron and hole temperature for times $> \sim 1$ ps. Since many of these experiments are performed at relatively high densities, they provide important information about many-body effects such as screening. Comparison of bulk and quasi-two-dimensional semiconductors (quantum wells) has been a subject of considerable interest. The consensus appears to be that, in spite of significant differences in the nature of electronic states and phonons, similar processes with similar scattering rates dominate both types of semiconductors. These studies reveal that the energy loss rates are influenced by many factors such as the Pauli exclusion principle, degenerate (Fermi–Dirac) statistics, hot phonons, and screening and many-body aspects.

Hot carrier distribution can be generated not only by photo-excitation, but also by applying an electric field to a semiconductor. Although the process of creating the hot distributions is different, the processes by which such hot carriers cool to the lattice temperature are the same in two cases. Therefore, understanding obtained through one technique can be applied to the other case. In particular, the physical insights obtained from the optical excitation case can be extremely valuable for many electronic devices that operate at high electric fields, thus in the regime of hot carriers. Another important aspect is that electrons and holes can be investigated separately by using different doping. Furthermore, the energy loss rates can be determined quantitatively because the energy transferred from the electric field to the electrons or holes can be accurately determined by electrical measurements.

Isothermal Regime

Following the processes discussed above, the excitations in the semiconductor reach equilibrium with each other and the thermal bath. Recombination processes then return the semiconductor to its thermodynamic equilibrium. Radiative recombination typically occurs over a longer time-scale but there are some notable exceptions such as radiative recombination of excitons in quantum wells occurring on picosecond time-scales.

Hot Phonons

As discussed above, a large population of nonequilibrium optical phonons is created if a large density of hot carriers has sufficient energy to emit optical phonons. Understanding the dynamics of these nonequilibrium optical phonons is of intrinsic interest.

At low lattice temperatures, the equilibrium population of optical phonons is insignificant. The optical phonons created as a result of photoexcitation occupy a relatively narrow region of wavevector (k) space near $k = 0$ ($\sim 1\%$ of the Brillouin zone). This nonequilibrium phonon distribution can spread over a larger k-space by various processes, or anharmonically decay into multiple large-wavevector acoustic phonons. These acoustic phonons then scatter or decay into small-wavevector, low-energy acoustic phonons that are eventually thermalized.

Pump-probe Raman scattering provides the best means of investigating the dynamics of nonequilibrium optical phonons. Such studies, for bulk and quantum well semiconductors, have provided invaluable information about femtosecond dynamics of phonons. In particular, they have provided the rate at which the nonequilibrium phonons decay. However, this information is for one very small value of the phonon wavevector so the phonon distribution function within the optical phonon branch is not investigated. The large-wavevector acoustic phonons are even less accessible to experimental techniques. Measurements of thermal phonon propagation provide some information on this subject. Finally, the nature of phonons is considerably more complex in

quantum wells, and some interesting results have been obtained on the dynamics of these phonons.

Tunneling and Transport Dynamics

Ultrafast studies have also made important contributions to tunneling and transport dynamics in semiconductors. Time-dependent imaging of the luminescing region of a sample excited by an ultrashort pulse provides information about spatial transport of carriers. Such a technique was used, for example, to demonstrate negative absolute mobility of electrons in p-modulation-doped quantum wells. The availability of near-field microscopes enhances the resolution of such techniques to measure lateral transport to the subwavelength case.

A different technique of 'optical markers' has been developed to investigate the dynamics of transport and tunneling in a direction perpendicular to the surface (vertical transport). This technique relies heavily on fabrication of semiconductor nanostructures with desired properties. The basic idea is to fabricate a sample in which different spatial regions have different spectral signatures. Thus if the carriers are created in one spatial region and are transported to another spatial region under the influence of an applied electric field, diffusion, or other processes, the transmission, reflection, and/or luminescence spectra of the sample change dynamically as the carriers are transported.

This technique has provided new insights into the physics of transport and tunneling. Investigation of perpendicular transport in graded-gap superlattices showed remarkable time-dependent changes in the spectra, and analysis of the results provided new insight into transport in a semiconductor of intermediate disorder. Dynamics of carrier capture in quantum wells from the barriers provided information not only about the fundamentals of capture dynamics, but also about how such dynamics affects the performance of semiconductor lasers with quantum well active regions.

The technique of optical markers has been applied successfully to investigate tunneling between the two quantum wells in an a-DQW (asymmetric double quantum well) structure in which two quantum wells of different widths (and hence different energy levels) are separated by a barrier. The separation between the energy levels of the system can be varied by applying an electric field perpendicular to the wells. In the absence of resonance between any energy levels, the wavefunction for a given energy level is localized in one well or the other. In this nonresonant case, it is possible to generate carriers in a selected quantum well by proper optical excitation. Dynamics of transfer of carriers to the other quantum well by tunneling can then be determined by measuring dynamic changes in the spectra. Such measurements have provided much insight into the nature and rates of tunneling, and demonstrated phonon resonances. Resonant tunneling, i.e., tunneling when two electronic levels are in resonance and are split due to strong coupling, has also been investigated extensively for both electrons and holes. One interesting insight obtained from such studies is that tunneling and relaxation must be considered in a unified framework, and not as sequential events, to explain the observations.

Novel Coherent Phenomena

Ultrafast spectroscopy of semiconductors has provided valuable insights into many other areas. We conclude this article by discussing some examples of how such techniques have demonstrated novel physical phenomena.

The first example once again considers an a-DQW biased in such a way that the lowest electron energy level in the wide quantum well is brought into resonance with the first excited electron level in the narrow quantum well. The corresponding hole energy levels are not in resonance. By choosing the optical excitation photon energy appropriately, the hole level is excited only in the wide well and the resonant electronic levels are excited in a linear superposition state such that the electrons at $t = 0$ also occupy only the wide quantum well. Since the two electron eigenstates have slightly different energies, their temporal evolutions are different with the result that the electron wavepacket oscillates back and forth between the two quantum wells in the absence of damping. The period of oscillation is determined by the splitting between the two resonant levels and can be controlled by an external electric field. Coherent oscillations of electronic wavepackets have indeed been experimentally observed by using the coherent nonlinear technique of four-wave mixing. Semiconductor quantum wells provide an excellent flexible system for such investigations.

Another example is the observation of Bloch oscillations in semiconductor superlattices. In 1928 Bloch demonstrated theoretically that an electron wavepacket composed of a superposition of states from a single energy band in a solid undergoes a periodic oscillation in energy and momentum space under certain conditions. An experimental demonstration of Bloch oscillations became possible only recently by applying ultrafast optical techniques to semiconductor superlattices. The large period of a superlattice (compared to the atomic period in a

solid) makes it possible to satisfy the assumptions underlying Bloch's prediction. The experimental demonstration of Bloch oscillations was also performed using four-wave mixing techniques. This provides another prime example of the power of ultrafast optical studies.

Summary

Ultrafast spectroscopy of semiconductors and their nanostructures is an exciting field of research that has provided fundamental insights into important physical processes in semiconductors. This article has attempted to convey the breadth of this field and the diversity of physical processes addressed by this field. Many exciting developments in the field have been omitted out of necessity. The author hopes that this brief article inspires the readers to explore some of the Further Reading.

COLOR AND THE WORLD

G N Rao, Adelphi University, Garden City, NY, USA

© 2005, Elsevier Ltd. All Rights Reserved.

The human visual system is capable of detecting a small part of the electromagnetic spectrum which is called light. The visible region has a typical wavelength range of about 380–780 nm. Under optimal conditions the range is 360–830 nm. The most important point is that color is a perception. It is how human beings perceive the visual part of the electromagnetic spectrum. The color of an object perceived depends on the physical characteristics of the radiation illuminating the object, spectral scattering and reflectivity of the object, physiology of the eye, photochemistry of the sensors in the retina, the complex data processing that takes place in the visual system, and the psychology of color perception. In this review, we present an overview of color in nature and the world. Initially, color and wavelength is presented, then the human visual system and color perception. Then we go on to discuss measuring color and colorimetry and then color in nature, followed by a brief account of color in art and holography and the structural colors in nature.

Color and Wavelength (Spectral and Nonspectral Colors)

The ingenious yet simple experiments performed by Isaac Newton in the year 1666 and his ideas presented

in his famous treatise 'Opticks', are the foundations of our understanding of color and color perception. Based on his experiments, Newton showed that different regions of the visible spectrum are perceived as different colors and the solar radiation (white light) consists of spectral colors violet, blue, cyan, green, yellow, orange, and red. Thus, natural day light is quite colorful though we perceive it as colorless. Table 1 gives approximate wavelength ranges of the spectral colors. Superposition of all the spectral colors results in a perception of white.

Colors can be produced in a number of ways:

1. *Gas discharges* emit characteristic radiation in the visible region. For example, neon discharge is red in color, argon discharge blue, sodium discharge yellow, helium-neon laser gives red radiation and argon ion laser blue-green radiation. A variety of fluorescent lamps are available and they provide continuous spectral power distribution with characteristic lines of mercury in the blue-green region. Gas-filled sodium and fluorescent lamps offer long life and high efficiency and are popular for indoor and outdoor lighting.
2. *Transition metal* (Cr, Mn, Fe, Co, Ni, Cu) compounds or transition metal impurities are responsible for the colors of the minerals, paints, gems, and pigments. They involve inorganic compounds of transition metal or rare earth ions with unpaired d or f orbitals. About 1% chromium sesquioxide (Cr_2O_3) in colorless aluminum oxide results in beautiful red ruby, a gemstone. The Cr^{3+} impurity in pure beryllium aluminum silicate gives a beautiful emerald green resulting in sapphire, another gemstone. Transition metal impurities are added to glass in the molten state to prepare colored glass. For example, adding Cr^{3+} gives green, Mn^{3+} purple, Fe^{3+} pale yellow, Co^{3+} reddish blue, Ni^{2+} brown, and Cu^{2+} greenish blue color.
3. *Color in Organic Compounds* – Most natural and synthetic dyes and biological (vegetable and animal origin) colorants are complicated organic molecules. They absorb light, exciting molecular orbitals. The dyes are used for food coloration, clothing, photographic, and sensitizer purposes.
4. *Colors of metals, semiconductor materials and color centers* – The colors of these materials are caused by the electronic transitions involving the energy bands.

   Diode lasers emit radiation corresponding to the bandgap of the semiconductor materials used for their fabrication. They are inexpensive, compact, and can be operated using dry cell batteries. They are extensively used in compact disks, barcode readers, and optical communications.

   Light emitting diodes (LED) are also prepared using semiconductor materials and they emit radiation corresponding to the bandgap of the semiconductor materials used for their fabrication. LEDs are available in a variety of colors, red (GaAsP), orange (AlInGaP), yellow (InGaAs), green (CdSSe), blue (CdZnS) and are widely used in clocks, toys, tuners, displays, electronic billboards, and appliances.

   Color centers may be produced by irradiating some alkali halides and glass materials with electromagnetic radiation (gamma rays, X-rays, ultraviolet, and visible radiation) or with charged or uncharged particles (electrons, protons, neutrons). The irradiation produces an electron hole pair and the electron is trapped forming an electron center. The electron or hole, or both, form a color center absorbing part of the visible radiation. The color centers can be reversed by heating to high temperatures.
5. *Optical Phenomenon* lead to spectacular colors in nature and in biological materials. Scattering of light by the atmosphere is responsible for colors of the sky, beautiful sunsets and sunrise, twilight, blue moon, and urban glows. Dispersion and polarization cause rainbows and halos. Interference gives rise to the beautiful colors of thin films on water, foam, bubbles, and some biological colors (butterflies). Diffraction is responsible for the colors of liquid crystals, coronae, color of gems (opal), color of animals (sea mouse), the colors of butterfly (*Morpho rhetenor*), and diffraction gratings.

Table 1 Approximate wavelength ranges of different spectral colors

Color	*Wavelength range (nm)*
Violet	380–435
Blue	435–500
Cyan	500–520
Green	520–565
Yellow	565–597
Orange	597–625
Red	625–780

The Human Visual System and Color Perception

Photoreceptors in the Eye: Rods and Cones

As light enters the eye, the cornea and the eye lens focus the image on the retina. The retina has two kinds of photoreceptors: rods and cones so named

because of their shapes. Typically, there are about 7 million cones and 110–125 million rods. Cones are activated during photopic (daylight) conditions and the rods during scotopic (night) conditions. Cones are responsible for color perception whereas rods can perceive only white and gray shades. Cones are predominantly located near the fovea, the central region of the retina. When light falls on the rods and the cones, the photosensitive material in them, namely rhodopsin, is activated, generating an electrical signal which is further processed in the visual system and transmitted to the visual cortex. Considerable data processing takes place within the retina.

Color Perception

Subjective nature of color

Color is a perception and is subjective. There is no way one can define color in an absolute or quantitative means, even though it can be precisely characterized by the spectral power distribution (SPD) of the radiation. For monochromatic light of different wavelengths we see the spectral colors detailed in Table 1. In general, the SPD of light from an object is complex and to predict the exact color of such a spectrum is quite difficult. However, in the following we discuss some simple color schemes.

Additive color mixing

Newton's experiments demonstrated that using the three primary color light sources, blue, green, and red and by varying their relative intensities, one can generate most of the colors by additive color mixing. Additive color mixing is employed in stage lighting, and large screen color television projection systems. If we are concerned only with the hue and ignore saturation and brightness, the superposition of colored light beams of equal brightness on a white screen gives the following simple additive color scheme:

$$\text{Green} + \text{Red} \Rightarrow \text{Yellow}$$

$$\text{Blue} + \text{Red} \Rightarrow \text{Magenta}$$

$$\text{Blue} + \text{Green} \Rightarrow \text{Cyan}$$

$$\text{Blue} + \text{Green} + \text{Red} \Rightarrow \text{White}$$

Subtractive color mixing

When white light passes through, say, a red filter, the radiation corresponding to the red radiation is transmitted and all other parts of the visible spectrum are absorbed. If we insert more red filters the brightness of the light transmitted becomes less though the hue is likely to be more saturated. If you insert red and blue filters together in a white beam, you will see no light transmitted because the red filter blocks the entire spectrum except the radiation corresponding to red color which in turn is blocked by the blue filter.

Subtractive color scheme is also applicable when paints of various colors are mixed together. The subtractive primary colors are magenta, yellow, and cyan. The artists often call them red, yellow, and blue. By appropriately mixing the primary colored paints one can, in principle, generate most of the colors.

How many colors can we differentiate?

If we do a simple experiment beginning from the lowest wavelength of the visible spectrum, say 380 nm, and gradually move to the long wavelength end of the visible spectrum, one can differentiate about 150 spectral colors. For each spectral color there will be a number of colors that vary in brightness and saturation. Additionally, we can have additive mixtures of these spectral colors, which in turn have variations in brightness and saturation. It is estimated that under optimal conditions we can differentiate as many as 7 to10 million different colors and shades.

Temporal Response of the Human Visual System

Positive afterimages

The visual system responds to changes in the stimulation in time. However, the response of the visual system is both delayed and persists for some time after the stimulation is off. Because of the persistence of vision, one would see positive afterimages. The afterimages last about 1/20 s under normal conditions but are shorter at high light conditions. A rapid succession of images show results in a perception of continuous motion which is the basis for movies and TV.

Close your eyes for about five minutes so that any after images of the objects you have seen before are cleared. Open your eyes to see a bright colored object and then close your eyes again; you will see positive afterimages of the object in its original colors. Even though the positive afterimage at the initial stages will be of the same colors as the original, they gradually change color showing that different cones recover at different rates.

Negative afterimages

If you stare at a color picture intensely for about a minute and look at a white background, such as a sheet of white paper, you will see the complementary colors of the picture. The image of the object falls on a particular part of the retina and if we look at a green colored object, the cones that are more sensitive to the mid-wavelength region are activated

and are likely to be saturated. If you look at a bright sheet of white paper immediately, the cones that are sensitive to the middle wavelength region are inactivated since they need some time to replenish the active chemical whereas the cones that have maximum sensitivity for the low and high wavelengths are active, therefore you will see the object in complementary colors. Yellow will be seen after looking at blue image, cyan after looking at red image and vice versa.

Spatial Resolution of the Human Visual System

Lateral inhibition (color constancy)

By and large the perceived color of an object is independent of the nature of the illuminating white light source. The color of the object does not change markedly under different white light sources of illumination. For example, we see basically the same color of the object in the daytime in the light of the blue sky or under an incandescent light source even though the spectral power distributions of these sources are different and the intensity of light reaching the eye in both cases is also drastically different. The color constancy is a result of chromatic lateral inhibition. The human visual system has a remarkable way of comparing the signals from the object and manipulating them with the signals generated from the surroundings and picking up the correct color independent of the illuminating source. The color constancy and simultaneous lightness contrast are due to lateral inhibition. Lateral inhibition was exploited by a number of artists to provide certain visual effects that would not have been possible otherwise. For example, Georges Seurat in his famous painting 'La Poseuse en Profil' improved the light intensity contrast in different regions of his painting by employing edge enhancement effects resulting from lateral inhibition. Victor Vasarely's art work 'Arcturus' demonstrates the visual effects of lateral inhibition in different colors.

Spatial assimilation

The color of a region assimilates the color of the neighboring region, thus changing the perception of its color. Closely spaced colors, when viewed from a distance, tend to mix partitively and are not seen as distinct colors but as a uniform color due to additive color mixing. Georges Seurat in his painting 'Sunday Afternoon on the Island of La Grande Jatte', uses thousands of tiny dots of different colors to produce a variety of color sensations, a technique which is known as pointillism. The visual effects of spatial assimilation were clearly demonstrated by Richard Anuszkiewicz in his painting 'All Things Do Live in the Three'.

Color Perception Models

Thomas Young, in 1801, postulated that there are three types of sensors thus proposing trichromacy to explain the three attributes of color perception: hue, saturation, and brightness. Data on microspectrophotometry of excised retinas, reflection densitometry of normal eyes, and psychophysical studies of different observers confirm the existence of three types of cones. As shown in Figure 1, the three types of cones have different responsivities to light. The cones that have maximum responsivity in the short wavelength region are often refereed as S-cones, the cones that have maximum in the intermediate wavelength range as I-cones, and the cones that have maximum in the long wavelength region as L-cones.

The three response curves have considerable overlap. The overlap of the response curves and the complex data processing that takes place in the visual system enable us to differentiate as many as 150 spectral colors and about seven to ten million different colors and shades. An important consequence of the existence of only three types of color sensors is that different spectral power distributions can produce identical stimuli resulting in the perception of the same color. Such spectral power distributions are called metamers.

The neural impulses generated by the cones are processed through a complex cross-linking of bipolar cells, horizontal cells, amacrine cells, and communicated to ganglion cells leading to the optic chiasmas through the optic nerve. Information gathered by about 100 million photoreceptors, after considerable processing, is transmitted by about a million ganglion cells.

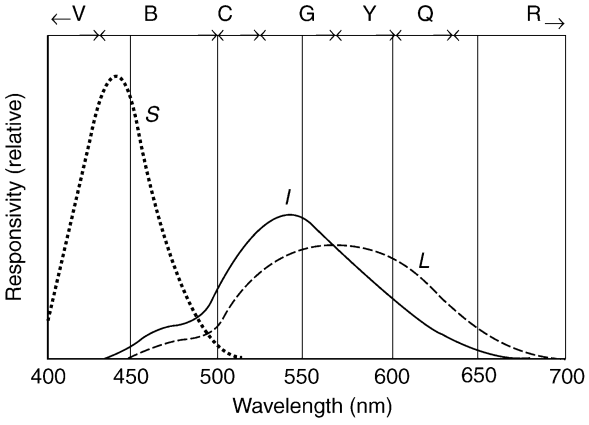

Figure 1 Relative spectral absorption of the three types of cones. *S*, *I*, and *L* respectively stand for the cones that have maximum responsivity for the short, intermediate, and long wavelength regions.

The zone theory of color vision assumes two separate zones where the signals are sequentially processed. In the first zone the signals are generated by the cones and in the second zone, the signals are processed to generate one achromatic and two opponent chromatic signals. Possibly other zones exist where the signals generated in the first and the second zones are further processed and communicated to the visual cortex where they are processed and interpreted based on the temporal and spatial response and comparisons with the information already available in the memory.

Measuring Color and Colorimetry

Since color is a human perception, how do we measure color? Colorimetry is based on the human visual system and how different observers perceive color. Though, the spectral power distribution of light is helpful for characterizing spectral hues, it is very difficult to infer the color from the spectral power distribution.

The three attributes of color perception are hue, saturation, and brightness. Hue is the color such as red, green, and blue. Saturation refers to the purity of the color. A color is said to be more saturated if the whiteness in the color is less and vice versa. Brightness is related to the intensity of light. For the sun at sunrise the hue is red, saturated, and low brightness. About half an hour after sunrise, the hue is yellow, less saturated, and higher brightness. Though a variety of color schemes are available in the literature, in the following we discuss the Munsell system and the C.I.E. diagram only.

Munsell Color System

Albert Munsell, a painter and art teacher, devised a color atlas in 1905 by arranging different colors in an ordered three-dimensional space. He used the three color attributes hue, chroma, and value corresponding to hue, saturation, and brightness. In this system there are 10 basic hues, each of which is divided into 10 equal gradations, resulting in 100 equally spaced hues. Each hue has a chart with a number of small chips arranged in rows and columns. Under daylight illumination, the chips in any column are supposed to have colors of equal chroma and the chips in any row are supposed to be of equal brightness. The brightness increases from the bottom of the chart to the top in steps that are perceptually equal. The saturation of the color increases from the inside edge to the outside edge of the chart in steps that are also perceptually equal. Each chip is identified by hue, value/chroma. In the Munsell scale, black is given a value of 0 and white 10, and the nine grays are uniformly placed in between. Though the Munsell system has gone through many revisions, typically it has a total of about 1450 chips. The Munsell color scheme, though subjective in nature, is widely used because of its simplicity and ease.

The Commission Internationale de l'Echlairage (C.I.E.) Diagram

Even though the visible light reaching the eye has a very complex SPD, color perception is mostly dependent on the signals generated by the three different types of cones. However, we do not know precisely the absorption and sensitivity of the cones and therefore are not in a position to calculate the signal strengths generated by the three different cones. Additionally, the response of the cones is specific to the individual. Therefore, the C.I.E. system is based on the average response of a large sample of normal observers. The C.I.E. system employs three color matching functions $\bar{x}(\lambda), \bar{y}(\lambda)$, and $\bar{z}(\lambda)$ (Figure 2), based on the psychological observations of a large number of standard observers to calculate the 'tristimulus values' X, Y, and Z defined as

$$X = c \int S(\lambda)\bar{x}(\lambda)\mathrm{d}\lambda \qquad [1]$$

$$Y = c \int S(\lambda)\bar{y}(\lambda)\mathrm{d}\lambda \qquad [2]$$

$$Z = c \int S(\lambda)\bar{z}(\lambda)\mathrm{d}\lambda \qquad [3]$$

Here, λ is the wavelength, $S(\lambda)$ the spectral power distribution, and c is the normalization constant. The integration is carried out over the visible region, normally 380 to 780 nm. The system is based on the assumption of additivity and linearity. The sum of the tristimulus values $(X + Y + Z)$ is normalized to 1. We choose $y(\lambda)$ so that the Y tristimulus value is proportional to the luminance which is a quantitative measure of the intensity of light leaving the surface. We further calculate x and y which are called chromaticity coordinates:

$$x = \frac{X}{(X + Y + Z)} \qquad [4]$$

$$y = \frac{Y}{(X + Y + Z)} \qquad [5]$$

The psychological color is then specified by the coordinates (Y, x, y). Relationship between colors is usually displayed by plotting the x and y values on

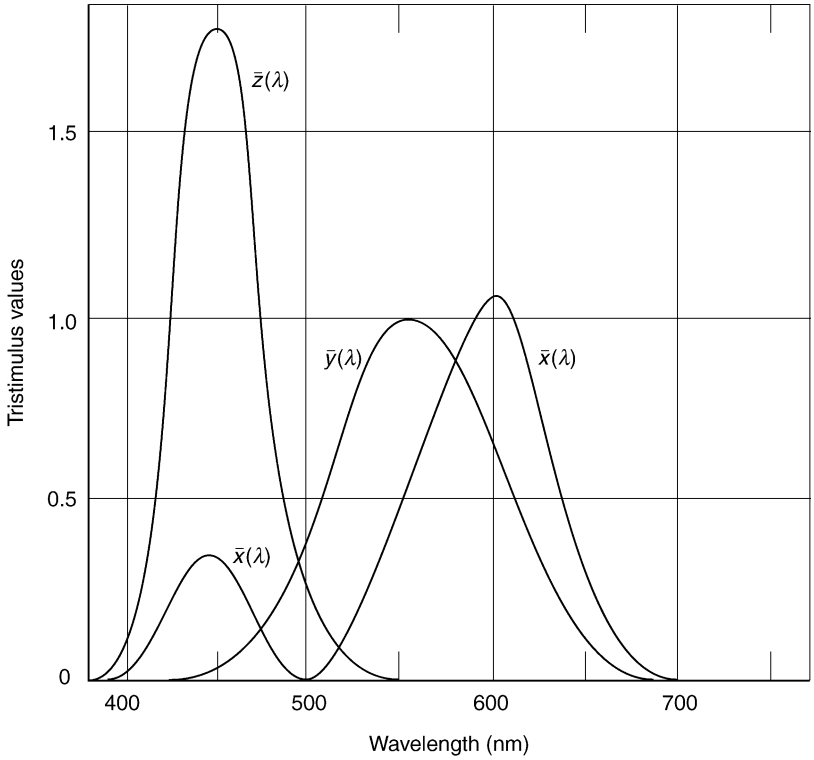

Figure 2 Color-matching functions $\bar{x}(\lambda)$,$\bar{y}(\lambda)$, and $\bar{z}(\lambda)$ of the C.I.E. 1931 standard observer.

a two-dimensional Cartesian Coordinate system with z as an implicit parameter ($z = 1 - x - y$) which is known as the C.I.E. chromaticity diagram (Figure 3). In this plot, the monochromatic hues are on the perimeter of a horseshoe shaped curve and is called spectrum locus. A straight line joining the ends of the spectrum is called the line of purples. Every chromaticity is represented by means of two coordinates (x, y) in the chromaticity diagram. The point corresponding to $x = 1/3$ and $y = 1/3$ (also $z = 1/3$) is the point of 'equal energy' and represents achromatic point. The complementary colors are on the opposite sides of the achromatic point. Complementary wavelength of a color is obtained by drawing a line from the color through the achromatic point to the perimeter on the other side.

Continuum (white) sources

A perfect white source is the one that has constant SPD over the entire visible region. Such a source will not distort the color of the objects they illuminate. A number of sources in general are considered as white sources; they include incandescent lamps, day skylight, a variety of fluorescent lamps, etc. It should be noted that the SPD of these sources is not constant and varies with the source. Typical SPDs of commonly used light sources are given in Figure 4.

Color temperature

The thermal radiation emitted by a black body has a characteristic SPD which depends solely on its temperature. The wavelength λ of the peak of this distribution is inversely proportional to its absolute temperature. As the absolute temperature of the blackbody increases, the peak shifts towards shorter wavelengths (blue region) and also the width of the distribution decreases. Since the peak of the black body radiation is dependent on the absolute temperature, the color of the blackbody can be approximately defined by its temperature.

The color temperature of a body is that temperature at which the SPD of the body best matches with that of the blackbody radiation at that temperature. The concept of color temperature is often used to characterize the sources. Low color temperature sources have a reddish tinge and high color temperature sources tend to be slightly bluish. For example, the color temperature of red looking star Antares is about 5000 K and that of the bluish white looking Sirius is about 11 000 K. One should note that the color temperature of a body is different from its actual temperature. The fluorescent lamps have a

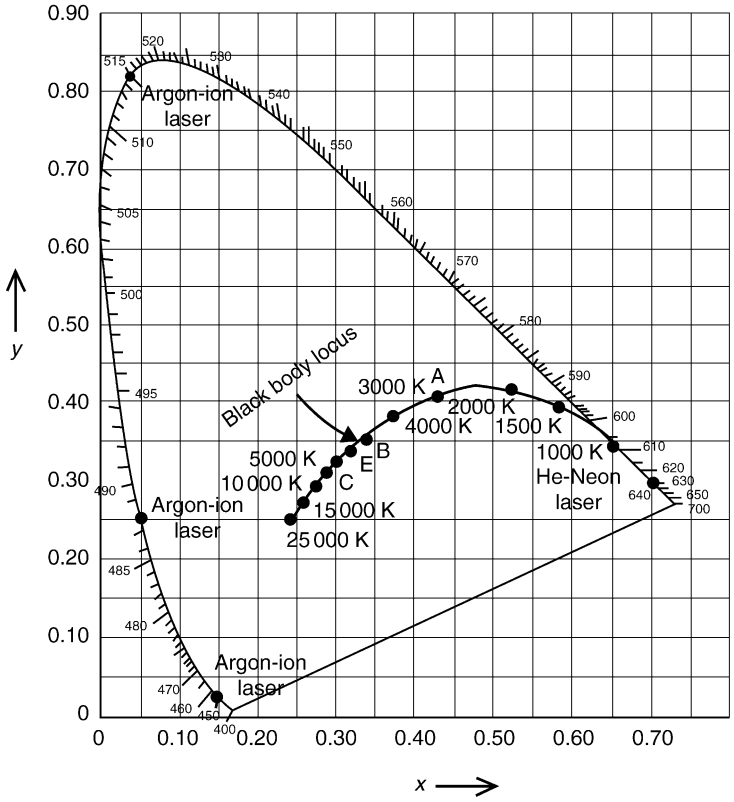

Figure 3 Chromaticity diagram of the C.I.E. 1931 standard observer. The chromaticities of the incandescent sources and their color temperatures are given inside the curve. A, B, and C are the C.I.E. standard illuminants. The chromaticities of the helium-neon laser (red, 633 nm) and the argon-ion laser (green 515 nm, blue 488 nm, and indigo, 458 nm) are also shown.

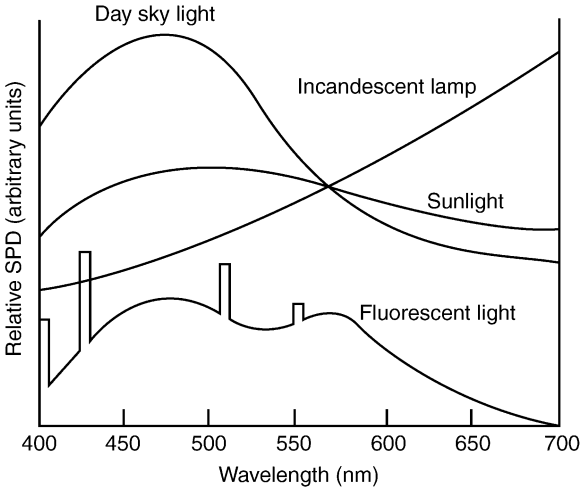

Figure 4 Relative SPDs of commonly used white light sources.

color temperature range of 5000–7500 K, incandescent lamps about 3000 K, direct sunlight ~4870 K and overcast skylight has a color temperature of ~7000 K.

The C.I.E. chromaticity diagram along with the color temperatures of the commonly employed sources, is shown in Figure 3.

Color in the Nature

As the solar radiation passes through the atmosphere, it is partly absorbed and partly scattered by the atmospheric constituents: air, water vapor, and dust particles. Absorption depends on the molecular properties of the air molecules, water vapor, and the dust particles, and is strongly wavelength dependent. Absorbed energy increases the internal energy of the molecule finally manifesting itself as thermal energy. When the sun is at the zenith, the solar radiation passes through one air mass loosing approximately 32% of its power. The SPD of the solar radiation above the atmosphere and at the Earth's surface at air mass 1 is shown in Figure 5. Scattering and absorption of the solar radiation by the atmosphere are responsible for a variety of interesting colorful views in the nature and they are briefly discussed in this section.

Atmospheric Colors

1. *Colors of the sky.* Scattering occurs over most of the visible part of the electromagnetic spectrum and is a function of the frequency of

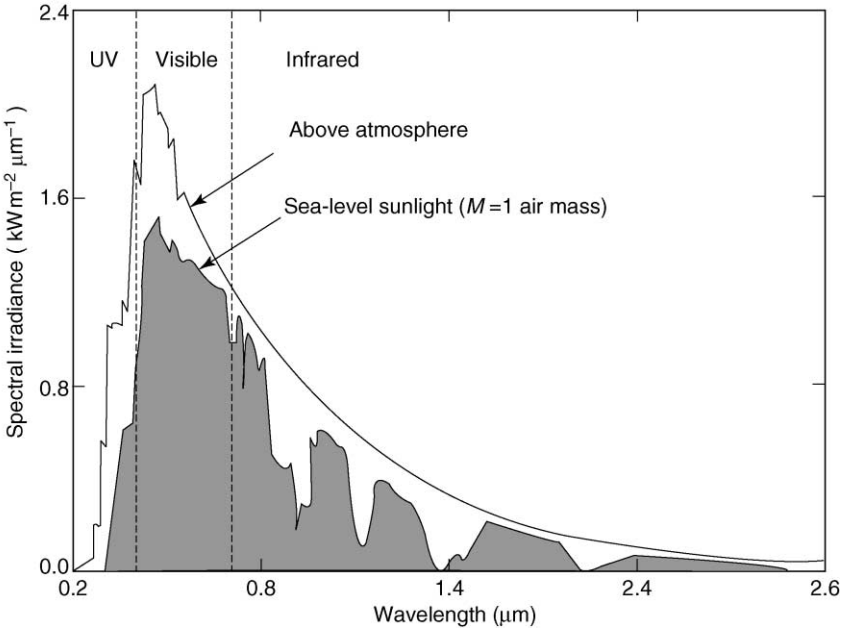

Figure 5 Spectral irradiance (kW m^{-2} μm^{-1}) of the solar radiation measured above the atmosphere and at the Earth's surface at sea level on a clear day and the sun at the zenith.

the radiation. According to Lord Raleigh's theory of scattering, the scattering probability varies inversely as a function of the fourth power of the wavelength of the radiation. If we consider the radiation corresponding to blue (400 nm) and the radiation corresponding to say red (700 nm), the photons corresponding to blue radiation are scattered by about 9.4 times that of photons corresponding to the red radiation. During noontime, when we look at the sky, not directly at the sun, the sky looks unsaturated blue because of the predominant scattering experienced by the high frequency radiation corresponding to blue color. However, it should be noted that the daytime skylight contains all the spectral colors of the solar radiation though the spectral power distribution has changed resulting in an increase in the intensity of the high frequency (blue) radiation. During noontime at the horizon, the sky looks close to white in color with a bluish tinge, because the solar radiation has passed through many air masses. As the thickness of the atmosphere increases, the intensity of the blue radiation decreases and ultimately as the radiation reaches the horizon, all the spectral colors are scattered about the same level resulting in white or bluish white sky.

2. *Polarization of the solar radiation by the atmosphere*. Light scattered by a molecule is polarized. The blue skylight is polarized with a maximum polarization of about 75% to 85% at 90° from the sun.
3. *Distant mountains seem bluish in color.* When an artist wishes to paint a distant mountain in perspective, he/she paints it blue; why? This is called airlight. The low wavelength part of the solar radiation is scattered more prominently, giving it a blue perspective when observed from a distance. However, it should be mentioned that the distant mountains may look any color depending on the scattering and absorption of the solar radiation sometimes resulting in 'Purple Mountain's majesty.'
4. *Sun looks red at the sunrise and sunset*. At sunset as the sun approaches the horizon, the sun changes its color from dazzling white to yellow, orange, bright red, and dull red and the order is reversed at sunrise. At the sunsets and sunrise, the solar radiation travels through many airmasses compared to approximately one airmass when the sun is at the zenith. Because of the large mass of air the radiation has to pass through, first the blue part of the spectrum is removed and the transmitted green to red spectral colors give the appearance of yellow. As this spectrum passes through more airmass, green is scattered most, leaving spectral yellow, orange, and red. As the radiation further passes through air, yellow and orange are also scattered, leaving only red.

5. *Twilight*. After sunset (dusk), or before the sunrise (dawn), the sky is illuminated by light which in turn illuminates the landscape. At sunsets and sunrise the solar radiation passes through a large mass of air. At a solar depression of about 0°, most of the blue is lost by scattering, resulting in a yellow arch and bright sky, and as the solar depression increases to about 10°, the arch will be reddish and the brightness of the sky reduced.
6. *Alpenglow*. Snow-covered mountains glow orange yellow from the low sun and after the sunset the same mountains look purple because of the reflection of the twilight.
7. *Twinkling of stars*. The stars twinkle. The local variations in the density of air are responsible for the twinkling of stars. As the density of air changes, so does the index of refraction and the starlight is continually refracted and dispersed. Twinkling is more prominent when the stars are on the horizon or on cold clear and windy nights.
8. *Mirages*. Mirages are refracted images produced because of the existence of refractive index gradients in the atmosphere. This results in the sight of shimmering water on a highway, inverted view of a car, etc.
9. *Aurora Borealis*. Aurorae are diffused slowly moving lights seen at high latitudes. They are often greenish yellow with different shapes. The lights in the northern hemisphere are called 'Aurora Borealis' and the lights in the southern hemisphere 'Aurora Australis.' They are caused primarily by the high-energy electrons deflected by the Earth's magnetic field towards the Earth's magnetic poles interacting with the atmospheric molecules resulting in molecular excitation and ionization. When the molecules de-excite, the characteristic electromagnetic radiation is commonly emitted. The commonly seen yellow-green light is due to the molecular emission of oxygen at 557 nm.
10. *Urban glows*. The scattered light from cities can be observed from space. The metropolitan Los Angeles can be observed from about 250 km in space. Extensively used sodium lamps with strong spectral yellow and blue-green mercury and fluorescent lights have unique color spectra of their own.

Colors due to Water and Water Droplets

1. *What is the color of pure water?* The transmission coefficient of pure water as a function of wavelength for different thicknesses of water column is shown in Figure 6. Our perception of the color of water changes with the thickness of water. For 1 mm thick water column, all the wavelengths are transmitted, resulting in the perception of white; 1 m thick water column looks unsaturated bluish green. As the thickness of water increases, the bluish green color will get more and more saturated. The color of water perceived by us depends on: (i) light reflected from the water surface; (ii) the light refracted at the water surface and diffused and scattered by the water molecules; and (iii) the refracted light reaches the bottom and gets reflected, which is further diffused and scattered and refracted at the water surface again. What we see is an additive sum of all these components.

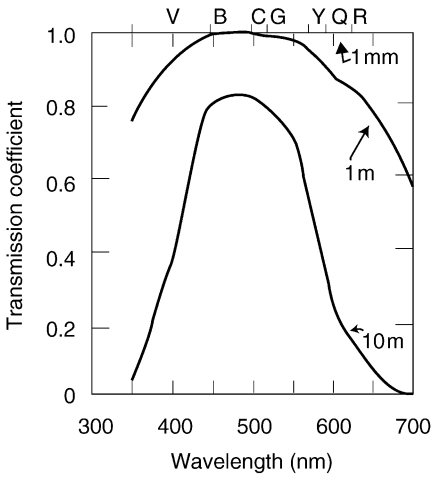

Figure 6 Transmission coefficient of water as a function of wavelength for different thicknesses of water (1 mm, 1 m, and 10 m).

2. *Refraction through water–air interface*. When light travels from an optically denser medium to an optically lighter medium, the light is deviated away from the normal. This is the reason why the apparent depth of a fish located in a pond is less than the true depth and a pencil struck in water seems to bend. If you are a diver when you look at the horizon from under water, the hemisphere seems to be compressed into a circle of diameter 97.2° instead of 180° which is known as 'Optical Manhole.'
3. *Glitter*. When you look at the reflection of the sun or the moon in wavy water, you notice a bright elongated reflected light known as glitter. It has a brilliant reddish orange color when the sun is above the horizon. Since the water is wavy, light reflected by a certain part of the wave at a certain time has the correct angle of reflection to reach your eye, which is known as glint. An ensemble of a large number of glints

coming from different waves and different parts of the waves results in glitter. Since you are looking at the reflected light, it will be polarized.

4. *Sky pools and landpools*. The light coming from a wavy water surface of a lake consists of oval shaped bright colored patterns that continually change in shape. This results from the reflection of skylight by the wavy water. If the waves are not turbulent the reflected light reaching your eye continually changes resulting in bright colored patterns. Landpools are caused by a nearby sloping landscape and the reflected light pattern from the landscape.
5. *Thin films*. Oil floats on water and spreads into thin films because of its low surface tension. When viewed in reflected natural white light, the light reflected from the top surface of the oil and the light reflected from the interfacial surface of oil and water interfere to produce colorful patterns. Brilliant colored patterns are commonly seen on the roads after rain because of gasoline on water. Foam ordinarily consists of bubbles ranging typically 10^{-4} mm to several mm. Even though each bubble produces colorful light due to the interference effects, the light coming out of the foam adds up to white light.
6. *Wet surfaces look darker*. A water spot on a concrete road looks darker. Since concrete is not porous a thin layer of water sticks to the surface. At the water surface part of the light incident is reflected, and a large part is transmitted. The transmitted light is diffusively scattered, part of which goes through total internal reflection and only a small part reaches the eye, making the surface look darker.

   When a fabric is wet it looks darker because of a slightly different mechanism. The surface of the fabric gets coated with a thin layer of water (refractive index = 1.33) which is smaller than the refractive index of the fabric. When the cloth is wet more light is transmitted, and less gets reflected than before. The transmitted light penetrates the fabric and gets scattered, resulting in a darker appearance.
7. *Rainbows*. Water with a refractive index of 1.33 is a dispersive medium. White light consisting of different wavelengths travel at different speeds in the medium and emerge at different directions. If the dispersion is adequate, different spectral colors can be seen by the naked eye. The dew covered lawn on a sunny day displays the spectral colors. If you stand close to the dew drop without blocking the sun's radiation falling on the drop, at some angle one should see the spectral colors. The primary rainbow is produced by the water droplets in the atmosphere after rain. The radius of the primary rainbow is about 42° with a width of about 2°. The color of the primary rainbow would be blue to red from the center of the rainbow. A rainbow is observed at the antisolar point. The brightness of the rainbow depends on the ambient sunlight, the size of the droplets, and whether the sun is low or high in the sky. The secondary rainbow, which is fainter, is often seen outside the primary rainbow at about 51°. The secondary rainbow will have red to blue from the center of the secondary rainbow. The secondary rainbow is approximately half as bright as the primary rainbow. The secondary rainbow is caused by two total internal reflections within the droplet whereas the primary rainbow is the result of one total internal reflection only. Because of the total internal reflection process, light is about 95% tangentially polarized in the primary rainbow.
8. *Heiligenschein*. Heiligenschein or the 'holy light' can be seen around the shadow of your head on a lawn on a sunny morning when dew drops are present. Usually, the dew drops are held by the tiny hairs of the grass at some distance from the blade of the grass. As light falls on the droplet, the spherical drop converges light at its focus and if the grass blade is located at that point, the light gets retroreflected approximately towards the sun resulting in holy light around your shadow.
9. *Coronae*. Colored concentric patchy rings seen around the moon and the sun are called coronae. They are primarily produced by the water droplets in the thin clouds. Even though the water droplets are randomly located, the diffracted light from the droplets has a defined angle and the superposition of the diffraction patterns from different water droplets results in colored ring structures. Coronae can be easily seen around the full moon viewed through thin clouds.
10. *The Glory*. On a foggy day with the sun at your back, one may see bright colored rings in the form of arches of about 5° to 10° at the solar point. The light in the glory is polarized and the ring structure is produced by reflection of the solar radiation by the fog.
11. *Clouds*. Clouds contain suspended water droplets or ice crystals. The size of the droplets ranges from less than a micrometer to about 100 micrometers (10^{-6} m). When the air is supersaturated with water vapor, the water condenses into water droplets, resulting in a definite shape to the cloud. When the sun's radiation falls on

the cloud, the light is scattered by the water droplets. Even though one would expect that the scattered light may have some color distribution, since we look at the scattered light from a very large number of droplets, the summation of all the colors results in white. Some clouds look dark or gray because, either they are in the shadow of other clouds or they are so thick that most of the light is absorbed. During sunset and sunrise, the clouds look bright orange because of the colored light illuminating them. Even though all the clouds are basically white, they may appear colored because of the selective absorption of certain colors in the atmosphere or due to the colored background radiation. Often, you see a silver lining at the edges of a cloud, because at the edges the density of water is low and when the sun illuminates it from the back, the radiation is scattered in the forward direction quite efficiently, resulting in a bright and shiny 'silver lining' to the cloud.

12. *Lightning*. Lightning is caused by an intense electrical discharge due to the high potential differences developed. On a cloudy and rainy day, as the water droplets grow in size, the falling drops get distorted to ellipsoidal shape and get polarized. The top smaller portion becoming negative and the lower larger part becoming positive. As the deformation increases, the drop ultimately breaks and the smaller drops being negatively charged and the larger ones positively charged. The wind currents easily lift the buoyant small drops to higher altitudes and the heavier positively charged droplets fall towards the Earth. The final result is that the upper region of the cloud is negatively charged whereas the lower region of the cloud is positively charged. The portion of the Earth under the cloud becomes negatively charged due to induction. The localized ions in the positively charged cloud produce a strong electric field which is further augmented by the induced negative charges on the Earth below. The strong electric field ionizes the air molecules setting up a current discharge to the earth. This discharge is called stepped leader. Following the stepped leader, the charges in the upper region of the cloud also discharge resulting in what is called return stroke. The sequence of leader and return strokes occur typically about ten times in a second. Since the clouds are charged and they are closer to each other, lightening is more frequent between the oppositely charged clouds than cloud and Earth. It is estimated that the lightning between the clouds is about five times more frequent compared to the lightening events between a cloud and the Earth. In this process, the nitrogen and oxygen molecules in air are excited and ionized. The flash is produced by the de-excitation of these molecular species. Since the temperatures involved are quite high (30 000 K), the flash has a strong unsaturated bluish hue. Some hydrogen lines are also observed in the flash. Hydrogen is produced as a result of the dissociation of water molecules during the discharge process.
13. *Ice and Halos*. Snow reflects most of the light falling with a reflectivity of about 95%. Snowflakes are crystalline and have hexagonal structure. In nature they occur in assorted sizes and shapes. As white light falls on them, light may be simply reflected from their surfaces making them shining white, which are often called glints. The light may also pass through the crystalline material get dispersed and emerge with different colors, which are known as sparkles.

    The halos appear as thin rings around the sun or the moon. They are produced because of the minimum deviation of light in snow crystals. The 22° halo is most common and is often seen a number of times in a year. The halos are circular and have a faint reddish outer edge and a bluish white diffused spot at the center. They often look white because of the superposition of different colors resulting in a more or less white color.

Color in Art and Holography

Sources of Color

There are two major color sources, dyes and paint pigments. Dyes are usually dissolved in a solvent. The dye molecules have selective absorption resulting in selective transmission. Paint pigments are powdered and suspended in oil or acrylic. The paint particles reflect part of the radiation falling on them, selectively absorb part of the radiation and transmit the balance. Lakes are made of translucent materials such as tiny grains of alumina soaked in a dye of appropriate color.

In the case of water colors and printer's inks, part of the light incident is reflected from the surface and the remaining transmitted which is selectively absorbed by the dye. The transmitted light reflected by the paper, passes through the dye again and emerges. Each transmission produces color by subtractive color scheme and the emerging light is mixed partitively by the observer.

In the case of paints, the color depends on the size and concentration of the pigment particles and the

medium in which they are suspended. Part of the light incident on the artwork gets reflected at the surface and the remaining selectively absorbed and transmitted which in turn is further reflected and transmitted by other pigment particles each time following a subtractive color scheme. The light reaching the canvas gets reflected and passes through the medium and emerges. Again, all the emerging beams are partitively mixed by the observer.

Holograms may be broadly categorized as transmission and reflection holograms. Both transmission and reflection (volume) holograms are prepared by producing the interference pattern of the reference and object laser beams. Transmission holograms can be viewed in the presence of the reference laser beam that was employed for its preparation. Spectacular three-dimensional colored images are reconstructed by the reflection holograms depending on the angle of incidence of the white light and the direction of observation. Embossed holograms are popular for advertising, security applications (credit cards), display, and banknotes. Some studios prepare three-dimensional holographic portraits that can be viewed in natural light. In the future, three-dimensional videos and even holographic three-dimensional movies may be a reality.

Structural Colors in Nature

Nanoscale Photonic Lattices

Newton observed that iridescence (change in color with the direction of observation) is caused by optical interference. The colors are produced by the interference or the light diffracting characteristics of the microstructures and not by the selective reflection or absorption of light, as in the case of pigments. Photonic band structures consist of periodic arrangement of dielectric materials even though they are transparent, have a bandgap resulting in inhibition of certain wavelengths. Light with frequencies in the gaps between the bands get reflected resulting in the specific color.

The structural colors of light can be seen in the animal world and minerals. For example, opal, a sedimentary gem does not have crystalline structure, but consists of tiny spheres of silica packed together. The diffraction of light through these structures results in spectacular colors determined by the size of the spheres and their periodicity. The spines of the sea mouse Aphrodite are covered with natural photonic structures that produce iridescence resulting in brilliant colors depending on the direction of the incident light and the direction of observation.

In the case of the butterfly, *Morpho rhetenor*, the metallic blue color is produced by the periodic structure of its wings. Its wings have layers of scales, each of about 200 mm long and 80 mm wide and about 1300 thin parallel structures per mm which form a diffraction grating.

The bird feathers viewed through an optical microscope show the structural components which are responsible for their coloration. The structural details of the peacock's eye pattern employing the scanning electron microscopy show photonic structures on peacock barbules. Barbules are the strap like branches on the peacock feathers. The four principal colors on the peacock feathers blue, green, yellow, and brown were identified wth the specific structures. The interference between the light reflected from the front surface to that reflected from the back was shown to be responsible for the brown color in the peacock's eye. The photonic structure of the green barbule has a periodic structure of melanin cylinders with a spacing of about 150 nm whereas the blue barbule has a periodic structure of 140 nm, and yellow barbules have a periodicity of 165 nm.

Introduction

The growth in the fiber optic communications and optoelectronics industries has led to the development and commercialization of many types of optical components. Fiber sensor devices and systems are a major user of such technologies. This has resulted in the development of commercial fiber sensors that can compete with conventional sensors. Fiber sensors are capable of measuring a wide variety of stimuli including: mechanical (displacement, velocity, acceleration, strain, pressure); temperature; electromagnetic (electric field, magnetic field, current); radiation (X-ray, nuclear); chemical composition; flow and turbulence in liquids; and biomedical. The main advantages of fiber sensors are that they are low cost, compact and lightweight, robust, passive, immune to electromagnetic interference, and highly sensitive.

Fiber sensors can be grouped into two basic classes: intrinsic and extrinsic. In an intrinsic fiber sensor the sensing is carried out by the optical fiber itself. In an extrinsic sensor the fiber is simply used to carry light to and from an external optical device where the sensing takes place. Point fiber sensors are localized to discrete regions; quasi-distributed sensors utilize point sensors at various locations along a fiber and distributed sensors are capable of sensing over the entire length of fiber.

A basic fiber sensor system, as shown in Figure 1, consists of a light source, fiber sensor, optical detector, and signal processing electronics. A measurand causes some change (intensity, phase, polarization, spectrum, etc.) in the light propagating through the sensor. This change is detected and processed to give an output signal proportional to the measurand. A large part of fiber sensor research concerns the development of fiber sensors sensitive to particular measurands and appropriate signal processing techniques. We describe some of the most important fiber sensors and also consider quasi-distributed and distributed sensing, including the use of multiplexing techniques.

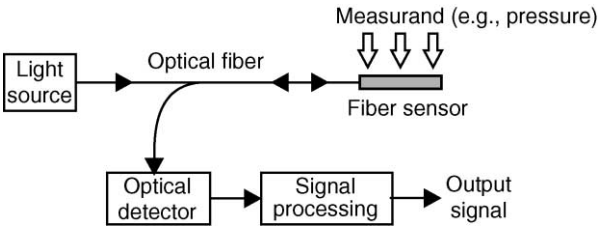

Figure 1 Basic fiber sensor system.

Intensity-Based Fiber Sensors

The intensity modulation (IM) of light is a simple method for optical sensing. There are several mechanisms that can produce a measurand-induced change in the optical intensity propagated by an optical fiber. Perhaps the simplest type of IM fiber sensor is the microbend sensor shown in Figure 2. The sensor consists of two grooved plates between which passes an optical fiber. The upper plate can move in response to pressure. When the fiber is bent sufficiently, light escapes into the fiber cladding and is lost. The greater the pressure on the plates the more loss occurs.

Coupling-based fiber sensors are useful for measurement of displacement or dynamic pressure. Transmission and reflective configurations are possible as shown in Figure 3. The transmission coupling-based sensor consists of two fibers with a small gap between them. The amount of light coupled to the second fiber depends on the fiber acceptance angles and the distance between the fibers. One of the fibers can move in response to vibration or pressure thereby changing the distance between the fibers and hence the coupling loss. The reflection-based sensor operates in a similar fashion, where light is reflected from a flexible diaphragm back into a collecting fiber. The reflected light intensity changes as the diaphragm is flexed. Once the coupling relationship between the input fiber, diaphragm and collecting fiber is known, intensity changes can be related to the applied displacement or pressure.

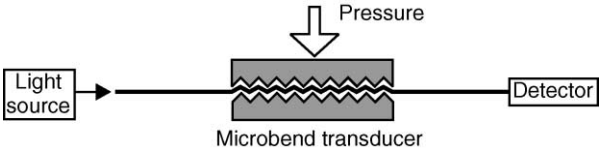

Figure 2 Microbend fiber sensor. The transducer moves in response to pressure and in doing so changes the bending radius of the fiber and thereby the fiber loss.

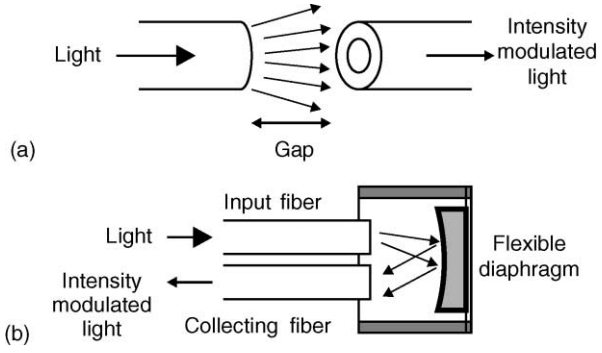

Figure 3 (a) Transmission and (b) reflective coupling-based fiber sensors.

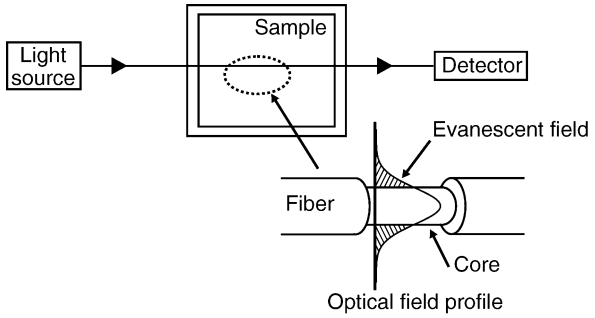

Figure 4 Evanescent wave fiber chemical sensor.

Evanescent wave fiber sensors exploit the fact that some of the energy in the guided mode of an optical fiber penetrates a short distance from the core into the cladding. The penetration of light energy into the cladding is called the evanescent wave. It is possible to design a sensor where energy is absorbed from the evanescent wave in the presence of certain chemicals as shown in Figure 4. This is achieved by stripping the cladding from a section of the fiber and using a light source having a wavelength that can be absorbed by the chemical that is to be detected. The resulting change in light intensity is a measure of the chemical concentration. Measurements can also be performed in a similar fashion by replacing the cladding with a material such as an organic dye whose optical properties can be changed by the chemical under investigation. Evanescent wave fiber sensors have found many applications in the biomedical field, such as blood component meters for detection of cholesterol and uric acid concentrations in blood.

A linear position sensor based on time division multiplexing is shown in Figure 5. It uses a square-wave modulated light source, optical delay loops and an encoded card. The delay loops separate the return signal from the encoded card by a time that is greater than the pulse duration. The encoded return signal can be decoded to determine the card position and velocity.

Interferometric Sensors

Interferometric fiber sensors operate on the principle of interference between two or more light beams to convert phase differences to intensity changes. Common configurations used include Michelson, Mach–Zehnder, and Sagnac interferometers, polarimetric systems, grating and etalon-based interferometers and ring resonators. Interferometric fiber sensors have extremely high sensitivity and are able to resolve path differences of the order of 10^{-6} of the light

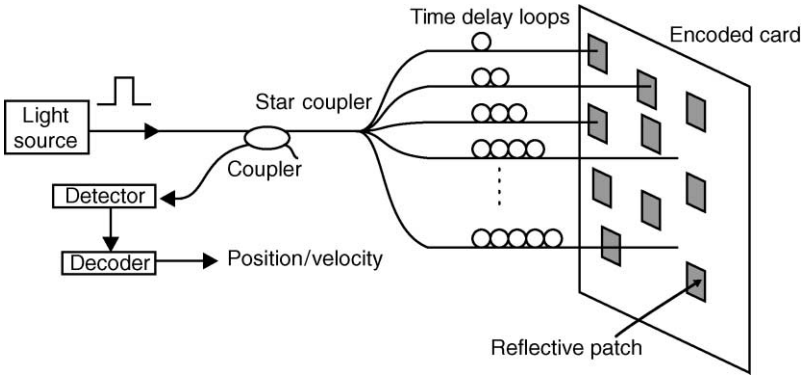

Figure 5 Linear position sensor using time division multiplexing.

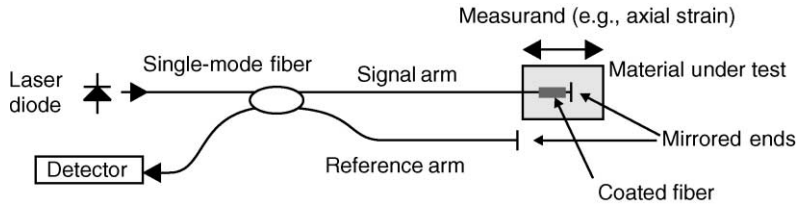

Figure 6 Michelson interferometric strain sensor. Part of the signal arm is embedded in a material, such as concrete (in civil engineering structures) or carbon composite (used in the aerospace industry).

source wavelength. To realize high sensitivity, spectrally pure light sources such as semiconductor lasers must be used. In addition, single mode fibers and components are used to maintain the spatial coherence of the light beams. Factors that affect the performance of interferometric sensors include the optical source phase noise and the polarization states of the interfering light beams.

In two-beam interferometric sensors, such as the Michelson interferometric strain sensor shown in Figure 6, one of the light beams travels through a fiber where its phase can be modulated by the measurand. The two reflected beams recombine on a detector, the output of which is of the form $1 + V \cos \phi$ as shown in Figure 7. ϕ is the relative phase shift between the return beams and V the interferometer visibility. Compensating techniques must be used to ensure that the interferometer sensitivity is maximized. Active techniques involve the insertion of an active device, such as a fiber stretcher, in one of the interferometer arms to control the mean phase difference between the beams. Passive schemes have the advantage in that no active components are required, but usually involve complex signal processing schemes such as active homodyne or synthetic heterodyne demodulation. The sensitivity of the fiber to the measurand can be further improved through the use of specialized coatings.

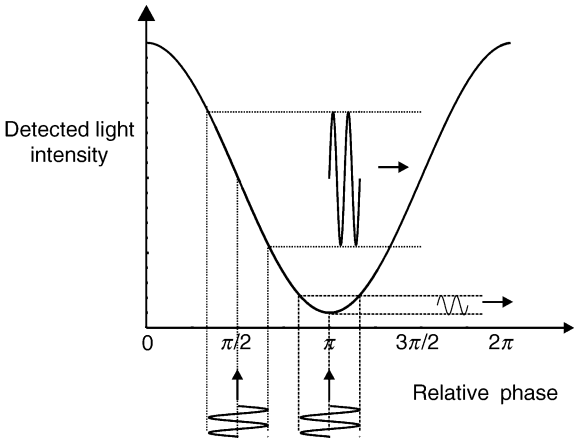

Figure 7 Two-beam interferometer transfer function. The sensitivity is maximized when the mean phase difference between the detected light beams is an odd integer multiple of $\pi/2$. When this is the case the interferometer is said to be operating in quadrature.

Compact interferometric sensors can be constructed using intrinsic or extrinsic Fabry–Perot type configurations, the most common of which are shown in Figure 8. If the Fabry–Perot cavity reflectivities are $\ll 1$, then it can be considered to be a two-beam interferometer.

Polarimetric fiber sensors relate changes induced in the polarization state of light to the measurand.

These sensors usually use high birefringence (Hi-Bi) fiber. The phase difference between the two orthogonally polarized modes of Hi-Bi fiber is given by

$$\phi = \Delta\beta l \qquad [1]$$

where $\Delta\beta$ is the fiber (linear) birefringence and l the fiber length. Both $\Delta\beta$ and l can be changed by the measurand. A polarimetric strain sensor using Hi-Bi fiber embedded in carbon fiber composite, is shown in Figure 9. Light from a linearly polarized He–Ne laser is launched into the Hi-Bi fiber, through a half-waveplate and lens. The waveplate is used to rotate the light plane of polarization so that it is at 45° to the principal axes of the fiber. This ensures that half of the input light power is coupled to each of the fast and slow modes of the Hi-Bi fiber. The output light from the Hi-Bi fiber is passed through a polarization beamsplitter. The beamsplitter separates the light into two orthogonally polarized beams, which are then detected. The output from each of the detectors is given by $V_1 = I_0 \sin^2\phi$ and $V_2 = I_0 \cos^2\phi$, respectively, where I_0 is the input light intensity. The state of polarization (SOP) of the output light from the Hi-Bi fiber is given by

$$\text{SOP} = \frac{V_1 - V_2}{V_1 + V_2} = \cos^2\phi + \sin^2\phi \qquad [2]$$

It is a simple matter to calculate the SOP, from which ϕ can be determined. The form of eqn [2] is very similar to the two-beam interferometer transfer function, shown in Figure 7.

A polarimetric electric current sensor based on the Faraday effect is shown in Figure 10. The Faraday effect provides a rotation of the light's polarization state when a magnetic field is parallel to the optical path in glass. If an optical fiber is closed around a current-carrying conductor, the Faraday rotation is directly proportional to the current. By detecting the polarization rotation of light in the fiber, the current can be measured.

Linearly polarized light is equivalent to a combination of equal intensity right and left circularly polarized components. The linear state of polarization of the polarized laser light rotates in the presence of a magnetic field because the field produces

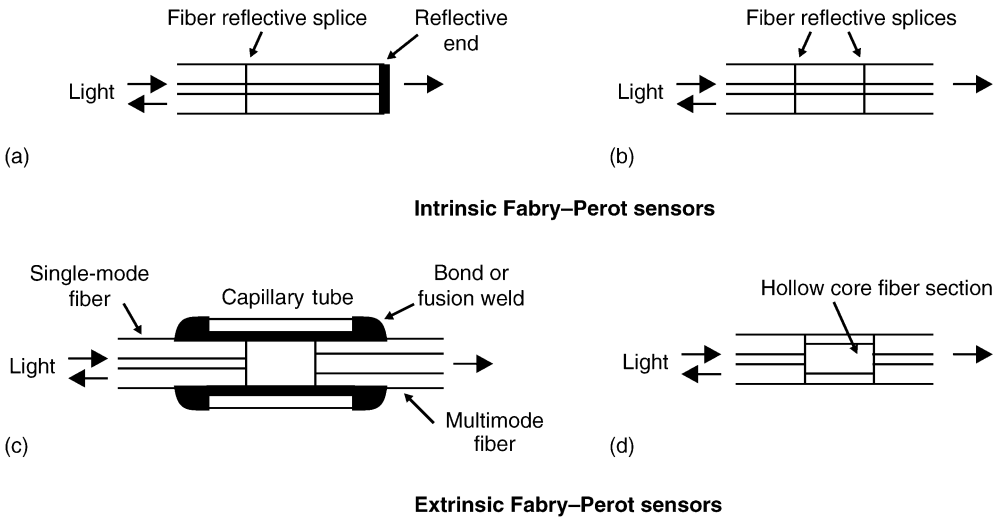

Figure 8 Interferometric fiber Fabry–Perot configurations.

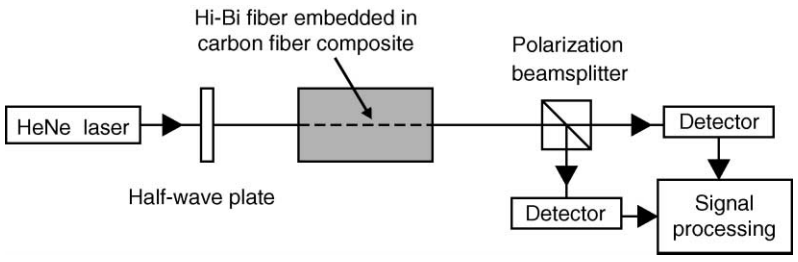

Figure 9 Polarimetric strain sensor system.

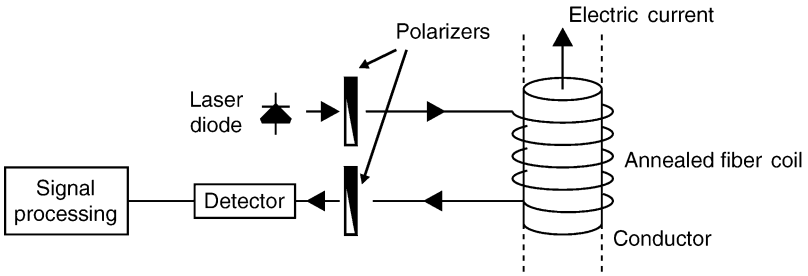

Figure 10 Polarimetric electric current sensor system.

circular birefringence in the fiber. This means that right and left circularly polarized light will travel at different speeds and accumulate a relative phase difference given by

$$\phi = VBl \qquad [3]$$

where V is the Verdet constant (rad Tesla^{-1} m^{-1}) of the glass, B the magnetic field flux density (Tesla), and l the length of the fiber exposed to the magnetic field. In the polarimetric current sensor, the polarization rotation is converted to an intensity change by the output polarizer. The output to the detector is proportional to $1 + \sin(2\phi)$, from which ϕ and the current can be determined.

The linear birefringence of conventional silica fiber is much greater than its circular birefringence. To make a practical current sensor, the linear birefringence must be removed from the fiber and this can be achieved by annealing the fiber. Annealing involves raising the temperature of the fiber, during manufacture, to a temperature above the strain point for a short period of time and slowly cooling back to room temperature. This reduces stresses in the glass, which are the principal cause of linear birefringence, and also cause physical and chemical changes to the glass. Waveguide-induced birefringence cannot be removed by annealing, but can be significantly reduced by twisting the fiber.

White light – or more accurately low-coherence – interferometry utilizes broadband sources such as LEDs and multimode lasers in interferometric measurements. Optical path differences (OPDs) are observed through changes in the interferometric fringe pattern. A processing interferometer is required in addition to the sensing interferometer to extract the fringe information.

The processing of white light interferometry signals relies on two principal techniques. The first technique involves scanning the OPD of the processing interferometer to determine regions of optical path balance. The second technique involves determination of the optical spectrum using an optical spectrum analyzer. The resulting fringe pattern fringe spacing is then related to the OPD of the sensing interferometer.

An example of the optical path scanning technique is shown in Figure 11a. The sensing interferometer is designed such that its OPD is much greater than the coherence length of the light source, so at its output no interference fringes are observed. The output of the sensing interferometer is fed to the processing interferometer. The OPD of the processing interferometer is scanned using a piezoelectric fiber stretcher driven by a suitable scanning voltage. As the processing interferometer is scanned, interference fringes are observed at two distinct points as shown in Figure 11b. The first set of fringes occurs when the OPD of the processing interferometer is within the coherence length of the optical source (close to zero). The second set of fringes occurs when the OPDs in the two interferometers are equal. The OPD in the sensing interferometer can be determined by measuring the OPD in the processing interferometer between the two positions of maximum visibility in the output signal from the detector. This, in turn, can be related to OPD changes due to the action of the measurand, in this case strain.

Sagnac interferometric sensors can be used to create highly sensitive gyroscopes that can be used to sense angular velocity (e.g., in aircraft navigation systems). It is based on the principle that the application of force (e.g., centrifugal force) will alter the wavelength of light as it travels around a coil of optical fiber. A basic open-loop fiber gyroscope is shown in Figure 12. The broadband source (e.g., superluminescent diode) is split into two counter propagating light beams traveling in the clockwise and anticlockwise directions. The polarizer is used to ensure the reciprocity of the counter propagating waves. The inherent nonlinear response of the gyroscope can be overcome by using a phase modulator and signal processing techniques. In the ideal case the detector output is proportional to $1 + \cos\phi_s$. The Sagnac phase shift ϕ_s between the

two returning beams is given by

$$\phi_s = \frac{8\pi AN\Omega}{c\lambda_0} \quad [4]$$

A is the area enclosed by a single loop of the fiber, N the number of turns, Ω the component of the angular velocity perpendicular to the plane of the loop, λ_0 the free-space wavelength of the optical source, and c the speed of light in a vacuum. Sensitivities greater than 10^{-8} rad/s and dynamic ranges in excess of 40 dB have been achieved with open-loop fiber gyroscopes. More advanced gyroscopes can greatly improve on this performance.

Fiber Grating Sensors

Many types of fiber gratings can be used in sensing applications including Bragg, long-period, and

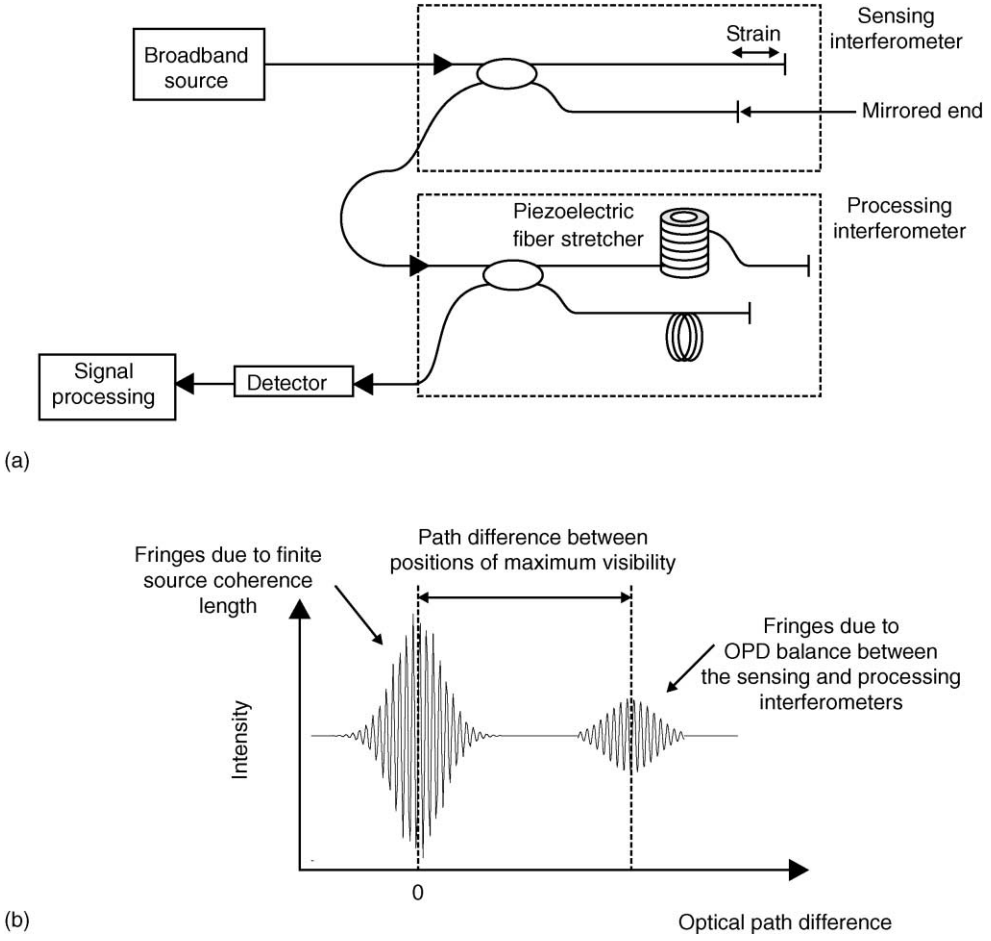

Figure 11 Low-coherence interferometric sensor. (a) Schematic diagram. (b) Output of the scanned processing interferometer.

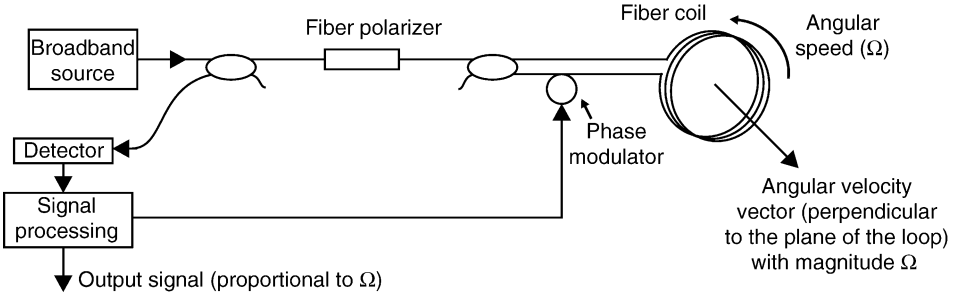

Figure 12 Basic open-loop fiber gyroscope.

chirped gratings. Because fiber gratings are small and have a narrow wavelength response, they can be used for both point and quasi-distributed sensing. They can be embedded in composite materials for smart structure monitoring and also in civil engineering structures such as bridges.

Fiber Bragg gratings (FBGs) are the most popular type of grating sensor. A typical FBG consists of a short section (typically a few mm) of single-mode fiber with a periodic modulation (typically 100s of nm) of the core refractive index. The index modulation causes light in the forward propagating core mode to be coupled into the backward core mode. This causes the FBG to act as a highly wavelength-selective rejection filter. The wavelength of peak reflectivity is the Bragg wavelength $\lambda_B = 2n_{eff}\Lambda$, where n_{eff} is the effective refractive index of the guided mode in the fiber and Λ the index modulation period. Both n_{eff} and Λ can be changed by an external measurand, resulting in a shift in λ_B.

The basic principle of FBG sensors is the measurement of an induced shift in the wavelength of an optical source due to a measurand, such as strain or temperature. A basic reflective FBG sensor system is shown in Figure 13. A broadband light source is used to interrogate the grating, from which a narrowband slice is reflected. The peak wavelength of the reflected spectrum can be compared to λ_B, from which strain or temperature can be inferred. The shift in the Bragg wavelength $\Delta\lambda_B$ with applied microstrain $\Delta(\mu\varepsilon)$ and change in temperature ΔT, for silica fiber is given approximately by

$$\frac{\Delta\lambda_B}{\lambda_B} \approx 0.78 \times 10^{-6}\Delta(\mu\varepsilon) + 6.67 \times 10^{-6}\Delta T \qquad [5]$$

A wavelength resolution of ~1 pm is required (at 1.3 μm) to resolve a temperature change of 0.1 °C or a strain change of 1 $\mu\varepsilon$. The response of the grating to strain can be improved through the use of specialized coatings. Polyimide coatings are commonly used as an efficient strain transducer for gratings embedded in composite materials. Because thermal effects in materials are usually very slow, it is relatively easy to measure dynamic strain (>1 Hz). However, in structural monitoring it can be necessary to distinguish between wavelength shifts due to static strain and those due to temperature. One technique is to use two collocated gratings whose response to strain and temperature is significantly different. In addition to strain and temperature measurement, grating sensors have also been used to measure flow, vibration, electromagnetic fields and chemical effects.

An example of quasi-distributed strain sensing, using a wavelength division multiplexed array of FBGs, is shown in Figure 14. Each FBG in the array has a unique Bragg wavelength. The return light from the FBG array is passed through a tunable narrowband Fabry–Perot filter. As the filter is tuned, the wavelengths returned by the individual FBGs can be analyzed and the strain present at each grating determined.

FBGs can be used as narrowband reflectors for creating fiber laser sensors, capable of measuring temperature, static strain, and very high-resolution dynamic strain. The basic form of an FBG laser sensor system shown in Figure 15 consists of a doped fiber section between two identical FBGs. The doped fiber is optically pumped to provide gain and thereby enable lasing to occur. Single-mode or multi-mode lasing is possible depending on the cavity length. In single-mode operation the FBG laser linewidth can be much smaller than the linewidth of diode lasers. This means that FBG laser sensors have greater sensitivities compared to passive FBG sensors.

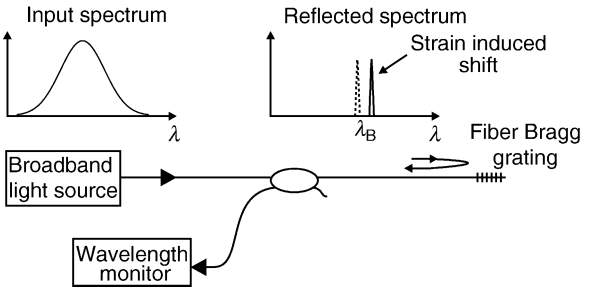

Figure 13 Basic reflective FBG sensor system.

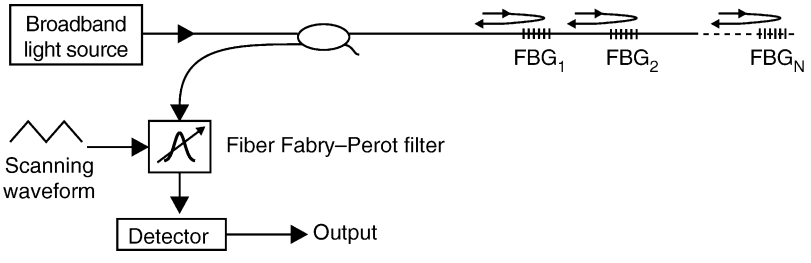

Figure 14 Quasi-distributed strain sensing using a wavelength division multiplexed array of FBGs.

When the cavity is subject to weak dynamic strain, the laser output is frequency modulated. This frequency modulation can be detected by using interferometric techniques. The main advantage of the FBG laser sensor over direct interferometry is that it is possible to obtain comparable strain sensitivities using a much shorter length of fiber.

Long-period fiber gratings (LPFGs) are attracting much interest for use in sensing applications. They are more sensitive to measurands than FBGs and easier to manufacture. A typical LPFG has a length of tens of mm with a grating period of 100s of μm. Its operation is different to an FBG in that coupling occurs between the forward propagating core mode and co-propagating cladding modes. The high attenuation of the cladding modes results in a series of minima occurring in the transmission spectrum of the fiber. This means that the spectral response is strongly influenced by the optical properties of the cladding and surrounding medium. This can be exploited for chemical sensing as shown in Figure 16, where a broadband source is used to interrogate an LPFG. The wavelength shifts of the output spectrum minima can be used to determine the concentration of particular chemicals in the substance surrounding the grating. The longest wavelength attenuation bands are the most sensitive to the refractive index of the substance surrounding the grating. This is because higher order cladding modes extend a greater distance into the external medium. LPFGs can also be used as strain, temperature, refractive index, bend, and load sensors.

Fiber Laser Doppler Velocimeter

Laser Doppler velocimetry (LDV) is a technique used for measuring velocity, especially of fluid flows. A fiber LDV system and associated scattering geometry is shown in Figure 17. In LDV two coherent laser beams intersect in a small measurement volume where they can interfere. The light reflected by a seed particle passing through the measurement volume is modulated at a frequency proportional to the spatial frequency (Doppler difference frequency Δf) of the interference fringes and the component of its velocity

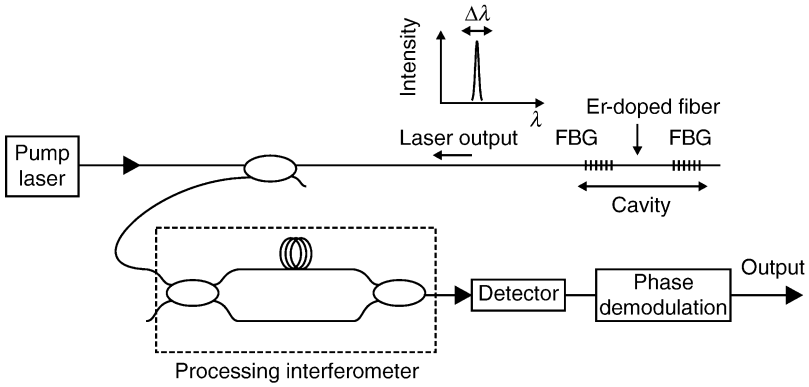

Figure 15 FBG laser sensor with interferometric detection.

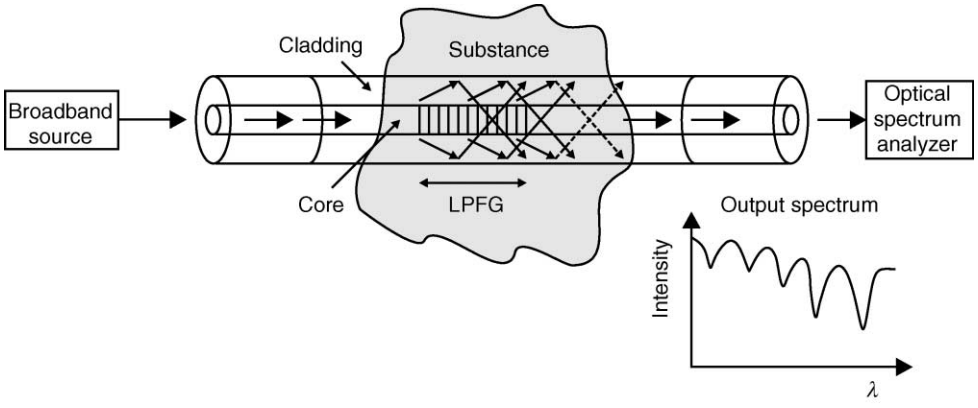

Figure 16 Detail of LPFG sensor.

normal to the interference fringes. Δf is given by

$$\Delta f = \frac{2nV\cos\beta}{\lambda_0}\sin(\theta/2) \qquad [6]$$

where n is the fluid refractive index, V the particle velocity and λ_0 the laser free-space wavelength. The output of the detector is processed to extract Δf and therefore $V\cos\beta$. Δf is independent of the scattered light direction so collection of the scattered light using a lens increases the system sensitivity. The form of eqn [6] indicates that the direction of flow cannot be ascertained. The simplest technique to resolve this ambiguity is to apply a frequency shift Δf_s to one of the input beams. This can be achieved by the use of a piezoelectric frequency shifter. The frequency shift causes a phase shift to appear between the two beams. The phase shift increases linearly with time. This results in a fringe pattern of spacing s, which moves with constant velocity $V_f = s\Delta f_s$. In this case the measured Δf will be less than or greater than Δf_s, depending on whether the particle is moving with or against the fringe motion. There will then be an unambiguous detectable range of velocities from zero to V_f.

Luminescence-Based Fiber Sensors

Luminescence-based fiber sensors are usually based on fluorescence or amplified spontaneous emission occurring in rare earth materials. They can be used in many applications such as chemical, humidity, and temperature sensing. It is possible to connect a fiber to luminescent material or to introduce luminescent dopants into the fiber. An example of the latter, used to detect chemical concentration is shown in Figure 18. A laser pulse causes the doped section of the fiber to luminesce at a longer wavelength than the

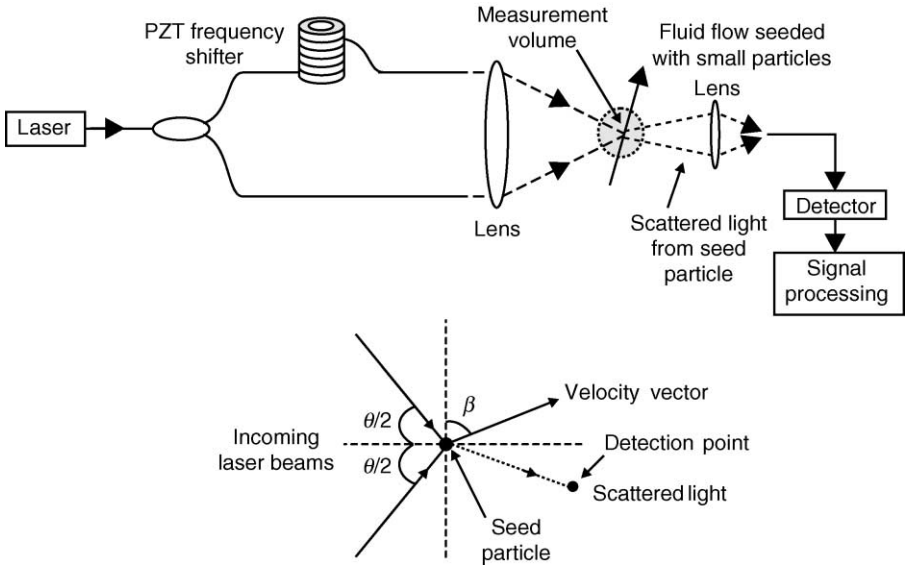

Figure 17 Fiber Doppler velocimeter and scattering geometry.

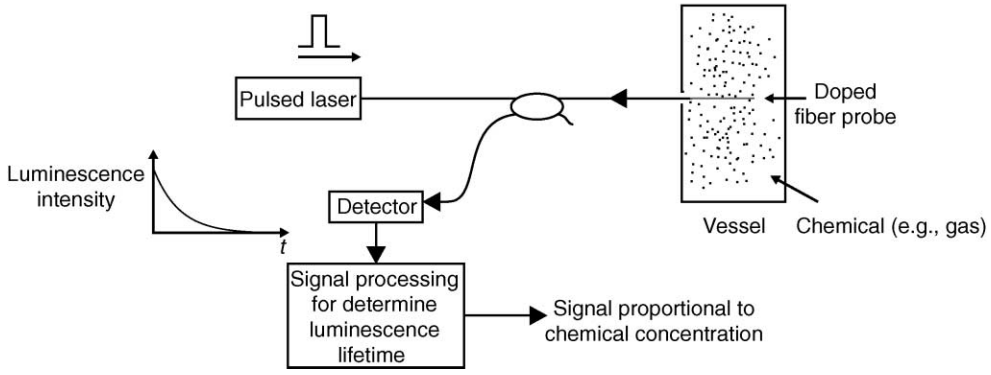

Figure 18 Chemical sensor based on fluorescence in doped optical fiber.

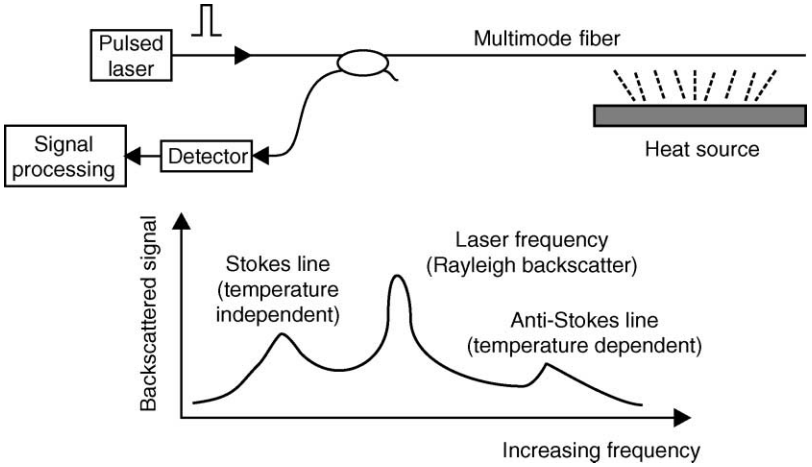

Figure 19 Anti-Stokes Raman thermometry system.

laser. The luminescence intensity $I(t)$ at the detector has an exponential decay profile given by

$$I(t) = I_0 \exp\left(-(k_1 + k_2 C)t\right) \qquad [7]$$

where I_0 is the initial luminescence intensity, t time, k_1, k_2 constants, and C the chemical concentration. The luminescence time constant $1/(k_1 + k_2 C)$ can be determined by comparing the luminescence intensity at various times after excitation by the laser pulse, from which C can be determined. The use of time division multiplexing allows quasi-distributed measurement of chemical concentration. The use of plastic optical fiber for luminescence-based sensors is attracting much interest.

Distributed Fiber Sensing

We have seen that both point and quasi-distributed sensing are possible using fiber sensors. Distributed sensing can be achieved through the use of linear or nonlinear backscattering or forward scattering techniques. In linear backscattering systems, light backscattered from a pulse propagating in an optical fiber is time resolved and analyzed to obtain the spatial distribution of the measurand field, e.g., polarization optical time domain reflectometry analyzes the polarization state of backscattered light to determine the spatial distribution of electromagnetic fields. Nonlinear backscattering schemes use effects such as Raman or Brillouin scattering. An important example of the former is the anti-Stokes Raman thermometry system shown in Figure 19. A light pulse is transmitted down the sensing fiber. Spontaneous Raman scattering causes Stokes and anti-Stokes photons to be generated along the fiber. Some of these photons travel back along the fiber to a fast detector. The intensity of the Stokes line is temperature independent. The anti-Stokes line intensity is a function of temperature. The ratio of the two intensities provides a very accurate measurement of temperature. The measurement location is determined by timing of the laser pulse.

Heterodyning

T-C Poon, Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Heterodyning, also known as frequency mixing, is a frequency translation process. Heterodyning has its root in radio engineering. The principle of heterodyning was discovered in the late 1910s by radio engineers experimenting with radio vacuum tubes. Russian cellist and electronic engineer Leon Theremin invented the so-called Thereminvox, which was one of the earliest electronic musical instruments that generates an audio signal by combining two different radio signals. American electrical engineer Edwin Armstrong invented the so-called super-heterodyne receiver. The receiver shifts the spectrum of the modulated signal, that is, the frequency contents of the modulated signal, so as to demodulate the audio information from it. Commercial amplitude modulation (AM) broadcast receivers nowadays are super-heterodyne type. After illustrating the basic principle of heterodyning by some simple mathematics, we will discuss some examples on how the principle of heterodyning is used in radio and in optics.

For a simple case, when signals of two different frequencies are heterodyned or mixed, the resulting signal produces two new frequencies, the sum and difference of the two original frequencies. Figure 1 illustrates how signals of two frequencies are mixed or heterodyned to produce two new frequencies, $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$, by simply multiplying the two signals $\cos(\omega_1 t + \theta_1)$ and $\cos(\omega_2 t)$, where ω_1 and ω_2 are radian frequencies of the two signals and θ_1 is the phase angle between the two signals. Note that when the frequencies of the two signals to be heterodyned are the same, i.e., $\omega_1 = \omega_2$, the phase information of $\cos(\omega_1 t + \theta_1)$ can be extracted to get $\cos\theta_1$ if we use an electronic lowpass filter (LPF) to filter out the term $\cos(2\omega_1 t + \theta_1)$. This is shown in Figure 2. Heterodyning is often referred to as homodyning for the mixing of two signals of the same frequency.

For a general case of heterodyning, we can have a signal represented by $s(t)$ with its spectrum $S(\omega)$, which is given by the Fourier transform of $s(t)$, and when it is multiplied by $\cos(\omega_2 t)$, the resulting spectrum is frequency-shifted to new locations in the frequency domain as:

$$\mathcal{F}\{s(t)\cos(\omega_2 t)\} = \frac{1}{2}S(\omega - \omega_2) + \frac{1}{2}S(\omega + \omega_2) \quad [1]$$

where $\mathcal{F}\{s(t)\} = S(\omega)$ and $\mathcal{F}\{\cdot\}$ denotes the Fourier transform of the quantity being bracketed. The spectrum of $s(t)\cos(\omega_2 t)$, along with the spectrum of $s(t)$, is illustrated in Figure 3. It is clear that multiplying $s(t)$ with $\cos(\omega_2 t)$ is a process of heterodyning, as we have translated the spectrum of the signal $s(t)$. This process is known as modulation in communication systems.

In order to appreciate the process of heterodyning let us now consider, for example, heterodyning in radio. In particular, we consider AM. While the frequency content of an audio signal (from 0 to around 3.5 kHz) is suitable to be transmitted over a pair of wires or coaxial cables, it is, however, difficult to be transmitted in air. By impressing the audio information onto a higher frequency, say 550 kHz, as one of the broadcast bands in AM radio, i.e., by

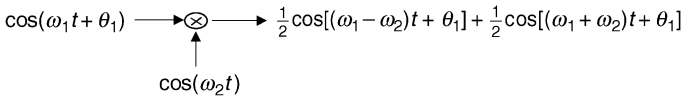

Figure 1 Heterodyning of two sinusoidal signals.

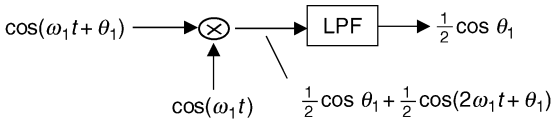

Figure 2 Heterodyning becomes homodyning when the two frequencies to be mixed are the same: homodyning allows the extraction of the phase information of the signal.

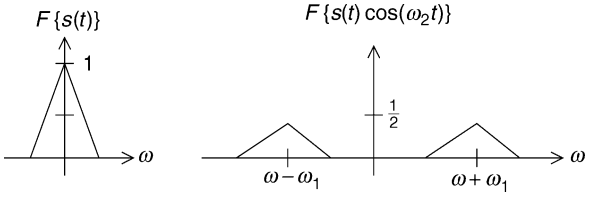

Figure 3 Spectrum of $s(t)$ and $s(t)\cos(\omega_2 t)$. It is clear that spectrum of $s(t)$ has been translated to new locations upon multiplying a sinusoidal signal.

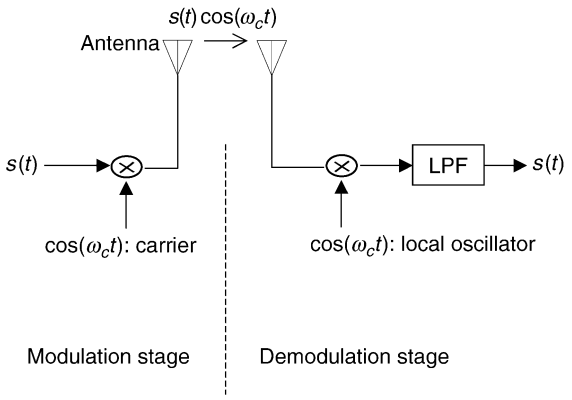

Figure 4 Radio link: heterodyning in the demodulation stage is often known as heterodyne detection.

modulating the audio signal, the resulting modulated signal can now be transmitted using antennas of reasonable dimensions. In order to recover (demodulate) the audio signal from the modulated signal, the modulated signal is first received by an antenna in a radio receiver, multiplied by the so-called local oscillator with the same frequency as the signal used to modulate the audio signal, then followed by a lowpass filter to eventually obtain the audio information back. The situation is illustrated in Figure 4. We shall now describe the process mathematically with reference to Figure 4.

We denote $s(t)$ as the audio signal. After multiplying by $\cos(\omega_c t)$, which is usually called a carrier in radio in the modulation stage, where ω_c is the radian frequency of the carrier. The modulated signal $s(t)\cos(\omega_c t)$. is transmitted via an antenna. When the modulated signal is received in the demodulation stage, the modulated signal is then multiplied by the local oscillator of signal waveform $\cos(\omega_c t)$. The output of the multiplier is given by

$$s(t)\cos(\omega_c t)\cos(\omega_c t) = s(t)\tfrac{1}{2}[1+\cos(2\omega_c t)] \qquad [2]$$

Note that the two signals in the demodulation stage, $s(t)\cos(\omega_c t)$ and $\cos(\omega_c t)$, are heterodyned to produce two new frequencies, the sum $\omega_c + \omega_c = 2\omega_c$ to give the term $\cos(2\omega_c t)$ and the difference $\omega_c - \omega_c = 0$ to give the term $\cos(0) = 1$. Since the two frequencies to be multiplied in the demodulation stage are the same, this is homodyning as explained above. Now by performing lowpass filtering (LPF), we can recover our original audio information $s(t)$. Note that if the frequency of the local oscillator in the demodulation stage within the receiver is higher than the frequency of the carrier used in the modulation stage, heterodyning in the receiver is referred to as superheterodyning, which most receivers nowadays use for amplitude modulation. In general, we have two heterodyning processes in the radio system just described, one in the modulation stage and the other in the demodulation stage. However, it is unusual to speak of heterodyning in the modulation stage, and so we just refer to the process in the demodulation stage as 'heterodyne detection.'

In summary, heterodyne detection can extract the information from a modulated signal and can also extract the phase information of a signal if homodyning is used. We shall see, in the next section, how optical heterodyne detection is employed.

Optical information is usually carried by coherent light such as a laser. Let $\psi_p(x, y)$ be a complex amplitude of the light field, which may physically represent a component of the electric field. We further assume that the light field is oscillating at temporal frequency ω_0. Therefore, we can write the light field as $\psi_p \exp(i\omega_0 t)$. By taking the real part of $\psi_p \exp(i\omega_0 t)$, i.e., $\mathrm{Re}[\psi_p \exp(i\omega_0 t)]$, we recover the usual physical real quantity. For a simple example, if we let $\psi_p = A\exp(-ik_0 z)$, where A is some constant and k_0 is the wavenumber of the light, $\mathrm{Re}[\psi_p \exp(i\omega_0 t)] = \mathrm{Re}[A\exp(-ik_0 z)\exp(i\omega_0 t)] = A\cos(\omega_0 t - k_0 z)$, which is a plane wave propagating along the positive z direction in free space. To detect light energy, we use a photodetector (PD), as shown in Figure 5. Assuming a plane wave for simplicity, as $\psi_p = A$, we have also taken $z = 0$ at the surface of the photodetector. As the photodetector responds to intensity, i.e., $|\psi_p|^2$, which gives the current, i, as output by spatially integrating the intensity:

$$i \propto \int_S |\psi_p \exp(i\omega_0 t)|^2 \mathrm{d}x\mathrm{d}y = A^2 S \qquad [3]$$

where S is the surface area of the photodetector. We can see that the photodetector current is proportional to the intensity, A^2, of the incident light. Hence the output current varies according to the intensity of the

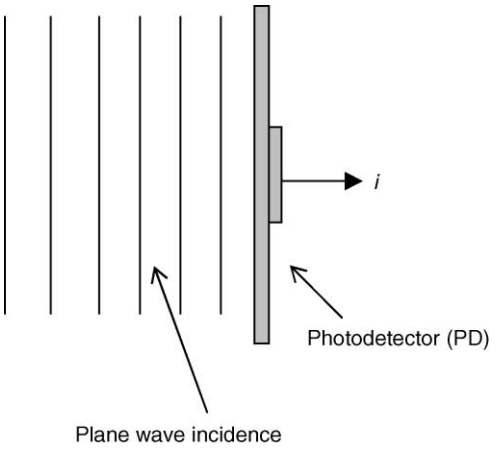

Figure 5 Optical direction detection or optical incoherent detection.

optical signal intensity. This mode of photodetection is called direct detection or incoherent detection in optics.

Let us now consider the heterodyning of two plane waves on the surface of the photodetector. We assume an information-carrying plane wave, also called the signal plane wave, $A_s \exp\{i[(\omega_0 + \omega_s)t + s(t)] \times \exp(-ik_0 x \sin\phi)\}$, and a reference plane wave, $A_r \exp(i\omega_0 t)$, or called a local oscillator in radio. The situation is shown in Figure 6.

Note that the frequency of the signal plane wave is ω_s higher than that of the reference signal, and it is inclined at an angle ϕ with respect to the reference plane wave, which is normal incident to the photodetector. Also, the information content $s(t)$ is in the phase of the signal wave. In the situation shown in Figure 6, we see that the two plane waves are interfered on the surface of the photodetector, giving the total light field ψ_t, given by

$$\psi_t = A_r \exp(i\omega_0 t) + A_s \exp\{i[(\omega_0 + \omega_s)t + s(t)]\} \times \exp(-ik_0 x \sin\phi) \quad [4]$$

Again, the photodetector responds to intensity, giving the current

$$i \propto \int_S |\psi_t|^2 \mathrm{d}x\mathrm{d}y = \int_{-a}^{a}\int_{-a}^{a} [A_r^2 + A_s^2 + 2A_r A_s \cos(\omega_s t + s(t) - k_0 x \sin\phi)]\mathrm{d}x\mathrm{d}y \quad [5]$$

where we have assumed that the photodetector has a $2a \times 2a$ square area. The current can be evaluated to be:

$$i(t) \propto 2a(A_r^2 + A_s^2) + 4A_r A_s \frac{\sin(k_0 a \sin\phi)}{k_0 \sin\phi} \cos(\omega_s t + s(t)) \quad [6]$$

The current output has two parts: the DC current and the AC current. The AC current at frequency ω_s is commonly known as the heterodyne current.

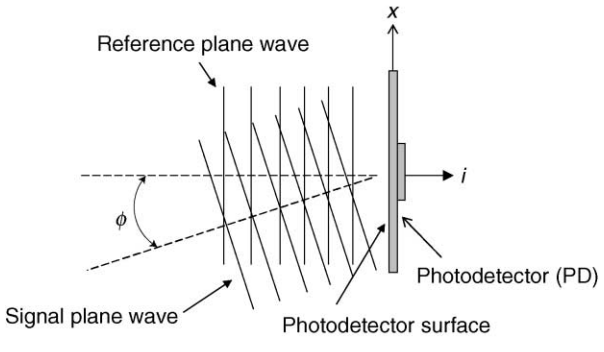

Figure 6 Optical heterodyne detection.

Note that the information content $s(t)$ originally embedded in the phase of the signal plane wave has now been preserved and transferred to the phase of the heterodyne current. The above process is called optical heterodyning. In optical communications, it is often referred to as optical coherent detection. In contrast, if the reference plane wave has not been used for the detection, we have the incoherent detection. The information content carried by the signal plane wave would be lost, as it is evident that for $A_r = 0$, the above equation gives only a DC current at a value proportional to the intensity of the plane wave, A_s^2.

Let us now consider some of the practical issues encountered in coherent detection. Again, the AC part of the current given by the above equation is the heterodyne current $i_{het}(t)$, given by

$$i_{het}(t) \propto A_r A_s \frac{\sin(k_0 a \sin\phi)}{k_0 \sin\phi} \cos(\omega_s t + s(t)) \quad [7]$$

We see that since the two plane waves propagate in slightly different directions, the heterodyne current output is degraded by a factor of

$$\frac{\sin(k_0 a \sin\phi)}{k_0 \sin\phi} = a\,\mathrm{sinc}(k_0 a \sin\phi)$$

where $\mathrm{sinc}(x) = \sin(x)/x$. For small angles, i.e., $\sin\phi \approx \phi$, the current amplitude falls off as $\mathrm{sinc}(k_0 a\phi)$. Hence, the heterodyne current is at a maximum when the angular separation between the signal plane wave and the reference plane wave is zero, i.e., the two plane waves are propagating exactly in the same direction. The current will go to zero when $k_0 a\phi = \pi$, or $\phi = \lambda_0/2a$, where λ_0 is the wavelength of the laser light. To see how critical it is for the angle ϕ to be aligned in order to have any heterodyne output, we assume the size of the photodetector $2a = 1$ cm and the laser used is red, i.e., $\lambda_0 \approx 0.6$ μm; ϕ is calculated to be about 2.3×10^{-3} degrees. Hence to be able to work with coherent detection, we need to have precise optomechanical mounts for angular rotation.

Finally we describe a famous application of heterodyning in optics – holography. As we have seen, the mixing of two light fields with different temporal frequencies will produce heterodyne current at the output of the photodetector. But we can record the two spatial light fields of the same temporal frequency with photographic films instead of using electrical devices. Photographic films respond to light intensity as well. We discuss holographic recording of a point source object as a simple example. Figure 7 shows a collimated laser split into two plane waves and recombined by the use of two mirrors (M) and two beamsplitters (BS). One plane wave is used to illuminate the pinhole aperture (our point source object), and the other

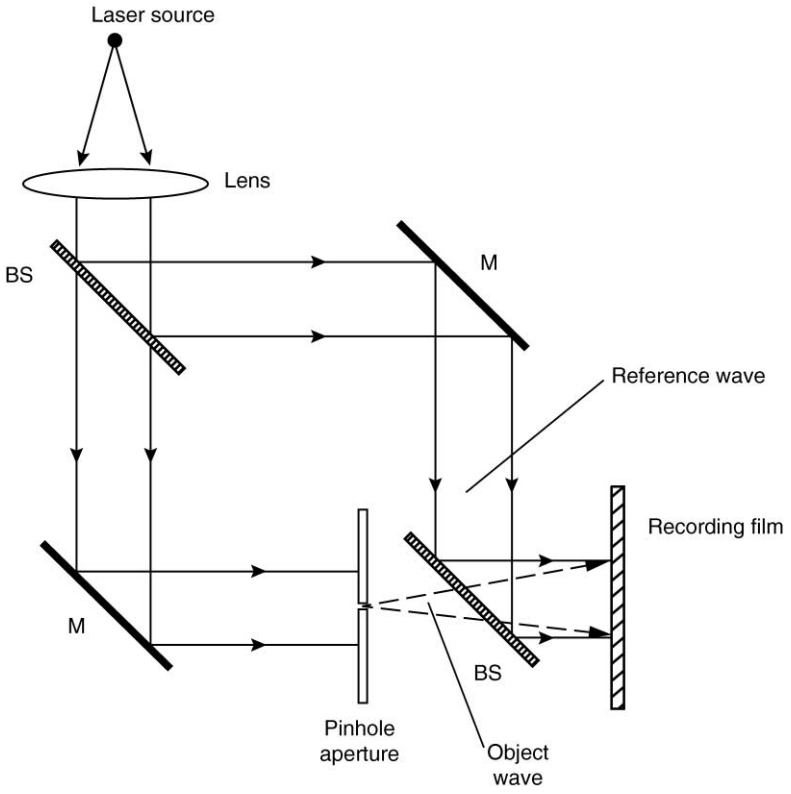

Figure 7 Holographic recording of a point source object.

illuminates the recording film directly. The plane wave that is scattered by the point source object, which is located z_0 away from the film, generates a diverging spherical wave. This diverging wave is known as an object wave in holography. The object wave arising from the point source object on the film is given by, according to Fresnel diffraction:

$$\psi_0 = A_0 \exp(-ik_0 z_0) \frac{ik_0}{2\pi z_0} \times \exp[-ik_0(x^2 + y)^2/2z_0] \exp(i\omega_0 t) \quad [8]$$

This object wave is a spherical wave, where A_0 is the amplitude of the spherical wave.

The plane wave that directly illuminates the photographic plate is known as a reference wave, ψ_r. For the reference plane wave, we assume that the plane wave has the same phase with the point source object at a distance z_0 away from the film. Its field distribution on the film is, therefore, $\psi_r = A_r \exp(-ik_0 z_0) \exp(i\omega_0 t)$, where A_r is the amplitude of the plane wave. The film now records the interference of the reference wave and the object wave, i.e., what is recorded on the film as a 2D pattern is given by $t(x, y) \propto |\psi_r + \psi_0|^2$. The resulting recorded 2D pattern, $t(x, y)$, is called the hologram of the object. This kind of recording is known as holographic recording, distinct from a photographic recording in which the reference wave does not exist and hence only the object wave is recorded. Now:

$$\begin{aligned} t(x,y) &\propto |\psi_r + \psi_0|^2 \\ &= \left| A_r \exp(-ik_0 z_0) \exp(i\omega_0 t) + A_0 \exp(-ik_0 z_0) \right. \\ &\quad \left. \times \frac{ik_0}{2\pi z_0} \exp[-ik_0(x^2 + y)^2/2z_0] \exp(i\omega_0 t) \right|^2 \\ &= A + B \sin\left\{ \frac{k_0}{2z_0} [(x^2 + y)^2/2z_0] \right\} \end{aligned} \quad [9]$$

where A and B are some inessential constants. Note that the result of recording two spatial light fields of the same temporal frequency preserves the phase information (noticeably the depth parameter z_0) of the object wave. This is considered optical homodyning as it is clear from the result shown in Figure 2.

The intensity distribution being recorded on the film, upon being developed, will have transmittance given by the above equation. This expression is called the Fresnel zone plate, which is the hologram of a point source object and we shall call it the point-object hologram. Figure 8 shows the hologram for a particular value of z_0 and k_0. The importance of this phase-preserving recording is that when we

illuminate the hologram with a plane wave, called the reconstruction wave, a point object is reconstructed at the same location of the original point source object if we look towards the hologram as shown in Figure 9, that is the point source is reconstructed at a distance z_0 from the hologram as if it were at the same distance away from the recording film. For an arbitrary 3D object, we can imagine the object as a collection of points, and therefore, we can see that we have a collection of Fresnel zone plates on the hologram. Upon reconstruction, such as the illumination of the hologram by a plane wave, the observer would see a 3D virtual object behind a hologram.

As a final example, we discuss a state-of-the-art holographic recording technique called optical scanning holography, which employs the use of optical heterodyning and electronic homodyning to achieve real-time holographic recording without the use of films. We will take the holographic recording of a point object as an example. Suppose we superimpose a plane wave and a spherical wave of different temporal frequencies and use the resulting intensity pattern as an optical scanning beam to raster scan a point object located z_0 away from the point source that generates the spherical wave. The situation is shown in Figure 10. Point C is the point source that generates the spherical wave (shown with dashed lines) on the pinhole object, our point object. This point source, for example, can be generated by a focusing lens. The solid parallel rays represent the plane wave. The interference of the two waves generates a Fresnel zone plate type pattern on the pinhole object:

$$
\begin{aligned}
&I_s(x, y;\ z_0, t) \\
&= \left| A_r \exp(-ik_0 z_0) \exp(i\omega_0 t) + A_0 \exp(-ik_0 z_0) \frac{ik_0}{2\pi z_0} \right. \\
&\quad \left. \times \exp[-ik_0 (x^2 + y)^2 / 2z_0] \exp[i(\omega_0 + \Omega)t] \right|^2 \\
&= 1 + \left(\frac{1}{\lambda_0 z_0} \right)^2 + \frac{1}{\lambda_0 z_0} \sin\left[\frac{\pi}{\lambda_0 z_0} (x^2 + y^2) - \Omega t \right]
\end{aligned}
\qquad [10]
$$

assuming $A_r = A_0 = 1$ for simplicity. Note that the plane wave is at temporal frequency ω_0, and the spherical wave is at temporal frequency $\omega_0 + \Omega$. The expression $I_s(x, y;\ z_0, t)$ is a temporally modulated Fresnel zone plate and is known as the time-dependent Fresnel zone plate (TDFZP). If we freeze time, say at $t = t_0$, we have the Fresnel zone plate pattern on the pinhole object as shown in Figure 10. However, if we let the time run in the above expression, physically we will have running zones that would be moving away from the center of the pattern. These running zones are the result of optical heterodyning of the plane wave and the spherical wave of different temporal frequencies. It is this TDFZP that is used to raster scan a 3D object to obtain holographic information of the scanned object and such technique is called optical scanning holography.

Upon scanning by the TDFZP, the photodetector, captures all the transmitted light and delivers a current, which consists of a heterodyne current at

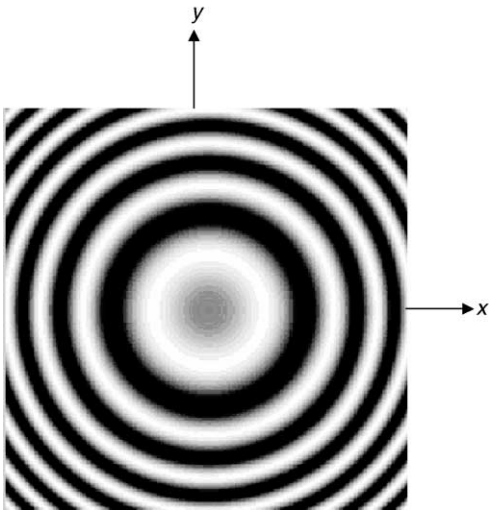

Figure 8 Point-object hologram.

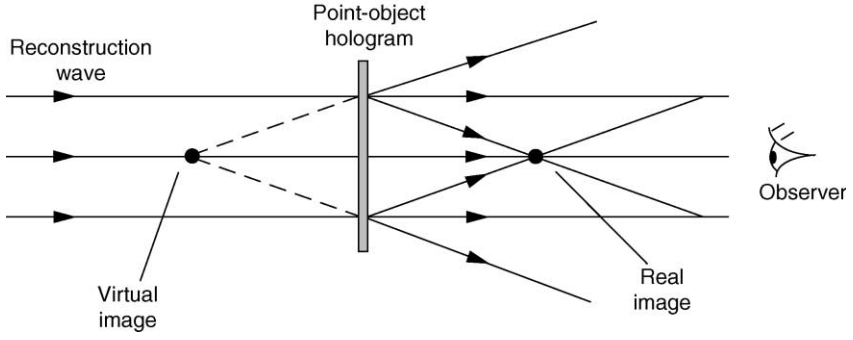

Figure 9 Reconstruction of a point-object hologram.

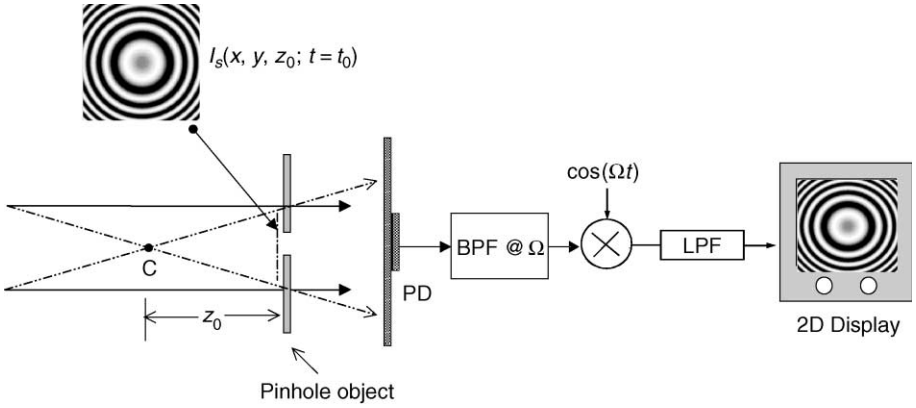

Figure 10 Optical scanning holography (use of optical heterodyning and electronic homodyning to record holographic information upon scanning the object in two dimensions).

frequency Ω. After electronic bandpass filtering (BPF) at Ω, the heterodyne current is homodyned electronically by cos(Ω*t*) and lowpass filtered (LPF) to extract the phase information of the current. When this final scanned and processed current is display in a 2D display, as shown in Figure 10, we have the Fresnel zone plate, which is the hologram of the pinhole object, on the display. We can photograph this 2D display to obtain a transparency and have it illuminated by a plane wave to have the reconstruction as shown in Figure 9, or, since the hologram is now in electronic form, we can store it in a PC and reconstruct it digitally. When holographic reconstruction is performed digitally, we have so-called digital holography.

Introduction

The spectacular development of imaging sensors, communication, and internet infrastructure has immensely facilitated the creation, processing, and distribution of electronic digital images. One nontrivial aspect of the digital image is its complete application dependence. The image may be created using a number of different acquisition methods and sensors. It is then processed in different ways, depending upon myriad of digital imaging applications. Consequently, the effectiveness of a useful electronic image processing engine may involve development of robust pre-processing techniques, different types of goal-directed processing such as detection, recognition, identification, classification, tracking, reconstruction and/or registration, as well as post-processing algorithms for different application areas such as multimedia, biomedical, astronomical, defense, consumer, industrial, etc. A notional schematic of this electronic image processing cycle is shown in Figure 1. Note that

while the goal-directed techniques may be different, based on problems at hand, the pre- and post-processing techniques and tools are very similar. Thus, most of the common image pre-processing techniques are also applicable for image post-processing purposes.

Electronic image post-processing techniques involve three broad domains such as: (i) spatial; (ii) frequency; and (iii) time-frequency. Each of these domain techniques may be grouped into different types of processing such as: (i) spatial domain technique to include filtering, spatial processing such as histogram modification, morphological processing, texture processing, etc.; (ii) frequency domain technique to include filter; and (iii) time-frequency domain technique to include short-time Fourier transform, wavelet, and Wigner-ville transforms.

On the other hand, it is useful to identify the typical lifecycle of a digital image from the distribution perspective as shown in Figure 2. The image may be created using a number of different acquisition methods and sensors as mentioned above. The processing block next combines all different types of processing, as mentioned in Figure 1. The image may then be transmitted over the internet or it can leave the digital world to go to the print world. It may then go through wear/tear, subsequently being scanned back to digital domain again. After some processing, it may again be distributed over the internet.

Consequently, the image may be copied legally or fraudulently, processed, and used by a user. Further, the threats and vulnerabilities of the internet have also increased proportionately. The rapid development and availability of high-end computers, printers, and scanners has made the tools of counterfeiting easily accessible and more affordable. With these products, one may counterfeit digital images, which are easy to distribute and modify. As a result, copyright ownership poses a formidable challenge to image post-processing and distribution.

In the subsequent sections, we briefly review relevant background in image post-processing and distribution techniques. We also present a few representative application examples of image post-processing and copyright protection in image distribution.

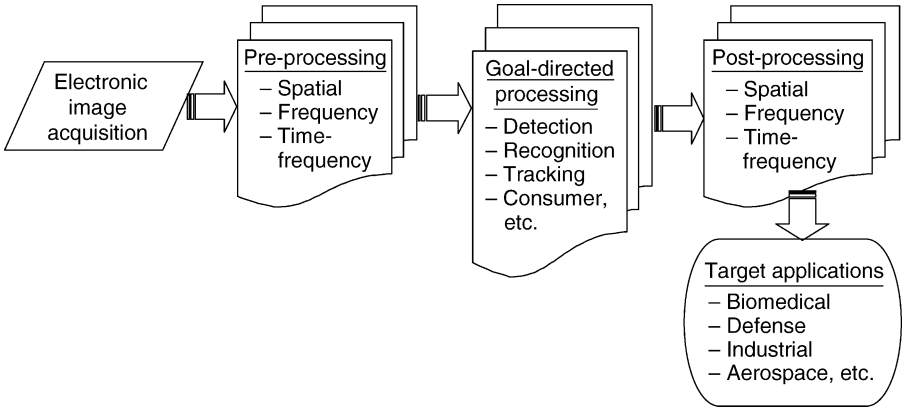

Figure 1 Notional schematic of electronic image processing.

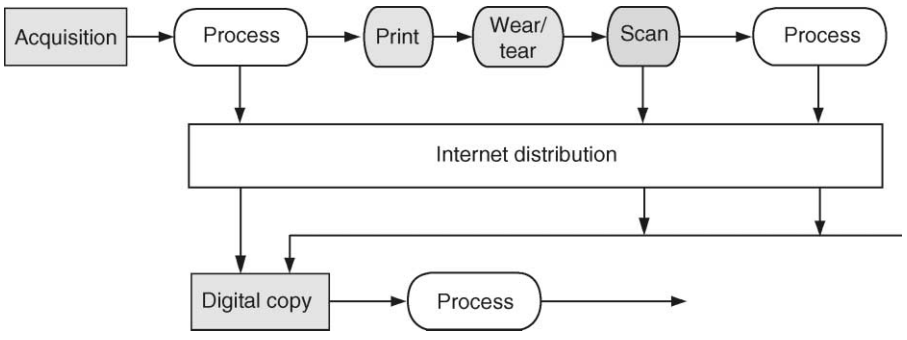

Figure 2 Typical lifecycle of a digital image distribution cycle.

Techniques in Image Post-Processing

Image Formation

We begin by describing the image formation technique briefly. Consider that a three-dimensional (3D) object or scene is imaged onto a 2D imaging plane by means of a recording system such as a camera. If the image formation process is linear, the recorded image may be modeled as the output of the system shown in Figure 3, which is given mathematically by

$$g(x,y) = s\left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(x,y;s,t)f(s,t)\mathrm{d}s\,\mathrm{d}t\right\} + n(x,y) \quad [1]$$

where $g(x,y)$ denotes the recorded output image, and $f(x,y)$ is the ideal electronic image. The function $h(x,y;s,t)$ is the 2D impulse response or the point-spread function (PSF) of the image formation system. The PSF determines the radiant energy distribution in the image plane due to a point source located in the object plane. Usually the PSF is normalized such that

$$\left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(x,y;s,t)\mathrm{d}s\,\mathrm{d}t\right\} = 1 \quad [2]$$

The noise contribution $n(x,y)$ is shown as an additive random process that is statistically uncorrelated with the image. This is a simplification because noises such as film-grain noise and the noise caused by photon statistics, which often corrupt images, are not uncorrelated with the input. This simplification nonetheless leads to reasonable and useful results. One of the primary goals of image pre-processing (and post-processing as well) is to devise techniques that reduce this additive random noise.

The PSF is a function of only the argument differences $x-s$ and $y-t$ for stationary image and object fields. Thus, it is possible to envision an image formation system that is space invariant; hence the PSF is independent of position. In this case, we may rewrite the superposition integral in eqn [1] into a more familiar convolution integral as follows:

$$g(x,y) = \left\{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(x-s,y-t)f(s,t)\mathrm{d}s\,\mathrm{d}t\right\} + n(x,y) \quad [3]$$

Equivalently, eqn [3] is written as

$$g(x,y) = \{h(x,y)^{*}f(x,y)\} + n(x,y) \quad [4]$$

where $(*)$ is used to denote 2D convolution. Converting from a continuous image $f(x,y)$ to its discrete representation $f(i,j)$ requires the process of sampling. In the ideal sampling system, $f(x,y)$ is multiplied by an ideal 2D impulse train given as

$$f(i,j) = \sum_{m=-\infty}^{+\infty}\sum_{m=-\infty}^{+\infty} f(mX_0,nY_0)\,\delta(x-mX_0,y-Y_0) \quad [5]$$

where X_0 and Y_0 are the sampling distances or intervals, $\delta(^{*},^{*})$ is the ideal impulse function. Note that the square sampling implies that $X_0 = Y_0$. Sampling with an impulse function corresponds to sampling with an infinitesimally small point. If one is interested in image processing, one should choose a sampling density based upon the classical Nyquist sampling theory. Thus, in discrete domain implementation, eqns [3] and [4] are expressed as

$$g(i,j) = \left\{\sum_{\forall(k,l)} h(i,j;k,l)f(k,l)\right\} + n(i,j),\ 0 \le i,j \le N-1 \quad [6]$$

and,

$$g(i,j) = s\left\{\sum_{\forall(k,l)} h(i-k,j-l)f(k,l)\right\} + n(i,j) \quad [7]$$

Thus, we may rewrite eqn [6] in discrete domain as follows:

$$g(i,j) = h(i,j)^{*}f(i,j) + n(i,j) \quad [8]$$

where $(*)$ represents convolution operation. Equation [8] also describes the spatial domain filtering wherein $h(x,y;s,t)$ may be considered as the spatial domain filter mask. The discrete Fourier transform may be used to yield the frequency domain model as follows:

$$G(u,v) = H(u,v)F(u,v) + N(u,v) \quad [9]$$

where G, H, F, and N are corresponding Fourier transforms and u and v are the dummy variables. In eqn [9], $H(u,v)$ is again the frequency domain filter.

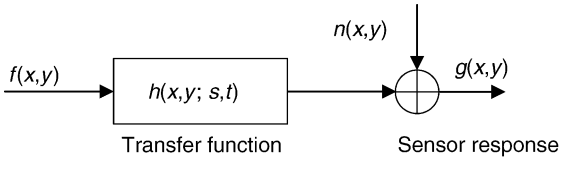

Figure 3 Model for image formation and recording.

We discuss the frequency domain filtering concept further, later in this article.

Spatial Domain Processing

The image pixel domain operations are frequently described as the spatial domain processing. These techniques are important for image pre- as well as post-processing operations. We describe two representative spatial domain processing techniques such as histogram processing and fractal processing for texture analysis below.

Histogram processing

One of the important issues in post-processing is image enhancement. Distortions in image may be introduced due to different noise factors, relative motion between a camera and the object, a camera that is out of focus, or atmospheric turbulence. Noise may be due to thermal measurement errors, recording medium, transmission medium, or digitization process. The histogram processing operation is one of the simplest techniques for enhancing the distorted image for certain type of noises. Histogram equalization is a contrast enhancement technique with the objective to obtain a new enhanced image with a uniform histogram. This can be achieved by using the normalized cumulative histogram as the gray scale mapping function. Histogram modeling is usually introduced using continuous domain functions. Consider that the images of interest contain continuous intensity levels in the interval [0,1] and that the transformation function τ which maps an input image $f(x, y)$ onto an output image $w(x, y)$ is continuous within this interval. We assume that the transfer function, $K_f = \tau(K_w)$, is single-valued and monotonically increasing such that it is possible to define the inverse law $K_w = \tau^{-1}(K_f)$. An example of such a transfer function is illustrated in Figure 4. All pixels in the input image, with densities in the interval D_f to $D_f + dD_f$, are mapped using the transfer function $K_f = \tau(K_w)$, such that they assume an output pixel density value in the interval from D_w to $D_w + dD_w$. Consider that if the histogram h is regarded as a continuous probability density function p, describing the distribution of the intensity levels, then we obtain:

$$p_w(w) = p_f(D_f)/d(D_f) \qquad [10]$$

where

$$D_f = du(f)/df \qquad [11]$$

In the case of histogram equalization, the output probability densities are all an equal fraction of the maximum number of intensity levels in the input image, thus generating a uniform intensity distribution. Sometimes it is desirable to control the shape of the output histogram in order to enhance certain intensity levels in an image. This can be accomplished by the histogram specialization operator which maps a given intensity distribution into a desired distribution using a histogram equalized image as an intermediate stage.

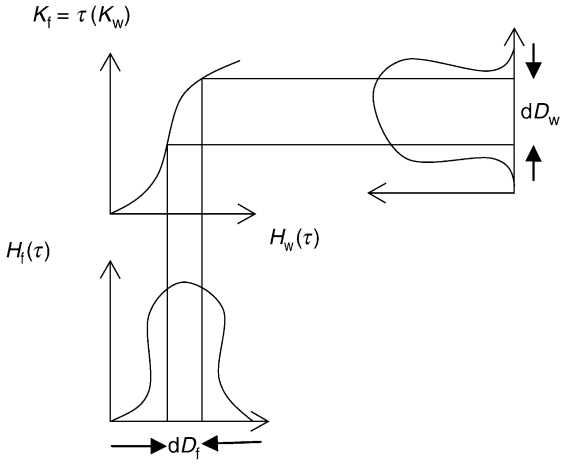

Figure 4 A histogram transformation function.

Fractals for Texture Analysis

The fractal aspect of an image has successfully been exploited for image texture analysis. The fractal concept developed by Mandelbrot, who coined the term fractal from the Latin 'fractus', provides a useful tool to explain a variety of naturally occurring phenomena. A fractal is an irregular geometric object with an infinite nesting of structure at all scales. Fractal objects can be found everywhere in nature such as coastlines, fern trees, snowflakes, clouds, mountains, and bacteria. Some of the most important properties of fractals are self-similarity, chaos, and noninteger fractal dimension (FD). The FD of an object can be correlated with the object properties. Object textures in images are candidates for characterization using fractal analysis because of their highly complex structure. The fractal theory developed by Mandelbrot is based, in part, on the work of mathematicians Hausdorff and Besicovitch. The Hausdorff–Besicovitch dimension, D_H, is defined as:

$$D_H = \lim_{\varepsilon \to 0^+} \frac{\ln N}{\ln 1/r} \qquad [12]$$

where N is the number of elements of box size r required to form a cover of the object. The FD can be defined as the exponent of the number of self-similar pieces (N) with magnification factor ($1/r$) into which a figure may be broken. The FD is a noninteger

value in contrast to objects that lie strictly in Euclidean space. The equation for FD is as follows:

$$\text{FD} = \frac{\ln(\text{number of self-similar pieces})}{\ln(\text{magnification factor})} = \frac{\ln N}{\ln(1/r)} \qquad [13]$$

Frequency Domain Image Filtering

Ignoring noise contribution, we may obtain the basic filtering expression using eqns [7] and [8] as follows:

$$f(i,j) = \Im^{-1}[G(u,v)/H(u,v)] \qquad [14]$$

where $\Im^{-1}$ is the inverse Fourier transform and $[1/H(u,v)]$ is the inverse frequency domain filter. The key importance of this result is that, instead of performing a convolution as shown in eqn [7] to obtain the output of the system, we obtain the inverse of the Fourier transform of the impulse response $h(x,y;s,t)$ and the output image $g(x,y)$, multiply them and then take the inverse Fourier transform of the product to obtain $f(x,y)$. This is the basis for all the filtering as well as other types of image post-processing such as image reconstruction works. The filter function in eqn [9] may have different forms and shapes based on different types of functions such as uniform, Gaussian, lowpass, highpass, etc. While these are all linear filters, there are examples of nonlinear filters such as median, mean, etc. that are equally applicable for image post-processing.

Time-Frequency Domain Processing

One of the fundamental aspects of early image representation is the notion of scale. An inherent property of objects in the world and details in image is that they only exist as meaningful entities over certain ranges of scale. Consequently, a multiscale representation is of crucial importance if one aims at describing the structure of the world, or more specially the structure of projections of the three-dimensional world onto two-dimensional electronic images. The multiscale image post-processing may be facilitated by the wavelet (WT) computation.

A wavelet is, by definition, an amplitude-varying short waveform with a finite bandwidth. Naturally, wavelets are more effective than the sinusoids of Fourier analysis for matching and reconstructing signal features. In wavelet transformation and inversion, all transient or periodic data features can be detected and reconstructed by stretching or contracting a single wavelet to generate the matching building blocks. Consequently, wavelet analysis provides many flexible and effective ways to post-process images that surpass classical techniques – making it very attractive for data analysis, and modeling. The continuous WT is defined as

$$\Phi(a,b) = |a|^{-1/2} \int_{-W}^{W} x(t)\Psi\left[\frac{t-b}{a}\right]\mathrm{d}t \qquad [15]$$

where a and b are scaling and translation factors and $\Psi(t)$ is the mother wavelet. The WT may be viewed as a multiresolution analysis with shifted and scaled versions of the mother wavelet. Corresponding WT coefficients $c_{m,n}$ are

$$c_{m,n} = |a_0|^{-m/2} \int x(t)\Psi([a_0^{-m}t - nb_0])\mathrm{d}t \qquad [16]$$

The reconstruction of the signal is achieved using the admissibility condition, $\int \Psi(t)\mathrm{d}t = 0$, as follows:

$$x(t) = c \int\int_{a>0} \left[\Phi(a,b)\frac{\Psi a, b(t)}{a}\right]\mathrm{d}a\,\mathrm{d}b \qquad [17]$$

where c is a constant. For compact dyadic wavelets, binary scaling and dyadic translation of the mother wavelet form the basis functions. A dyadic translation is a shift by the amount $n/2^m$ that is an integer multiple of the binary scale factor and of the width of the wavelet as well. The discrete WT (DWT) is the natural choice for digital implementation of WT. The DWT basis and 'sub-band coding' process for discretization of a and b are identified. The iterative bandpass filter that finally leads to the wavelet is given as

$$\Psi m, n(x) = 2^{m/2}\Psi(2^{-m}x - n) \qquad [18]$$

The above eqn [18] forms the basis for 'sub-band' implementation for multiresolution analysis (MRA) of wavelet processing.

Image Post-Processing Examples

Some of the important application areas for electronic image post-processing involve the following:

(i) Biomedical image analysis and object detection;
(ii) Image compression for transmission and distribution;
(iii) Satellite image processing and noise removal;
(iv) IR/SAR/detection and clutter removal; and
(v) Image classification and machine vision.

In this article, we provide examples of some of these image-post-processing applications.

Example I: Spatial Domain Processing: Image Post-Processing in Biomedical Image

The mega voltage X-ray images are the X-ray images taken using high voltage X-radiations. These images are often characterized by low resolution, low contrast, and blur. The importance of mega voltage X-ray images arises in the context of radiation therapy for cancer treatment wherein the mega voltage X-radiation is used as a therapeutic agent. Figure 5 shows such mega voltage X-ray images, also known as an electronic portable digital (EPID) image with a very low level of detail. Figure 5a shows poor dynamic range. In order to improve the contrast of this image, without affecting the structure (i.e., geometry) of the information contained therein, we can apply the histogram equalization operation discussed in eqn [10]. Figure 5b presents the result of the histogram image enhancement post-processing process. The low level of detail in the bony anatomy is easily visible in Figure 5b.

Example II: Frequency Domain Processing: Image Post-Processing in Biomedical Tissue Detection

In medical imaging, texture is a fundamental characteristic that can be exploited to analyze tissues and pathologies in a biomedical image. The image texture is often characterized by the random nature of the objects such as tissues and body structures, noise, imaging modality, imaging limitations, and a variety of measurement parameters affecting the image acquisition process. Extensive research suggests that the fractal analysis may be combined with MRA techniques to post-process the texture content of an image in general and tumor detection in particular. In addition, the stochastic fractal Brownian motion (fBm) is well suited to describe texture and tumor characteristics since fBm offers an elegant integration of fractal and multiresolution analysis.

The fBm is a part of the set of $1/f$ processes, corresponding to a generalization of the ordinary Brownian motion $B_{\mathrm{H}}(s)$. It is a nonstationary zero-mean Gaussian random function, defined as

$$B_{\mathrm{H}}(t) - B_{\mathrm{H}}(s) = \frac{1}{\Gamma(H+0.5)} \times \left\{ \int_{-\infty}^{0} [(t-s)^{H-0.5} - s^{H-0.5}] \mathrm{d}B(s) + \int_{0}^{\infty} (t-s)^{H-0.5} \mathrm{d}B(s) \right\}, \quad B_{\mathrm{H}}(0) = 0 \qquad [19]$$

where the Hurst coefficient H, restricted to $0 < H < 1$, is the parameter that characterizes fBm; t and s correspond to different observation times of the process B_{H}, and Γ to the Euler's Gamma function. From the frequency domain perspective, it is known that some of the most frequently seen structures in fractal geometry, generally known as $1/f$ processes, show a power spectrum satisfying the power law relationship:

$$S(\omega) \propto \frac{k}{|\omega|^{\gamma}} \qquad [20]$$

where ω corresponds to the spatial frequency, and $\gamma = 2H + 1$. The observations of stationarity and self-similarity of fBm suggest that the use of time-frequency signal decomposition techniques, such as MRA, are well suited for the analysis of fractal signals. Thus, the fBm analysis framework, along with eqn [13], may be successfully exploited to estimate H, and hence, FD as follows:

$$\mathrm{FD} = D_{\mathrm{E}} + 1 - H \qquad [21]$$

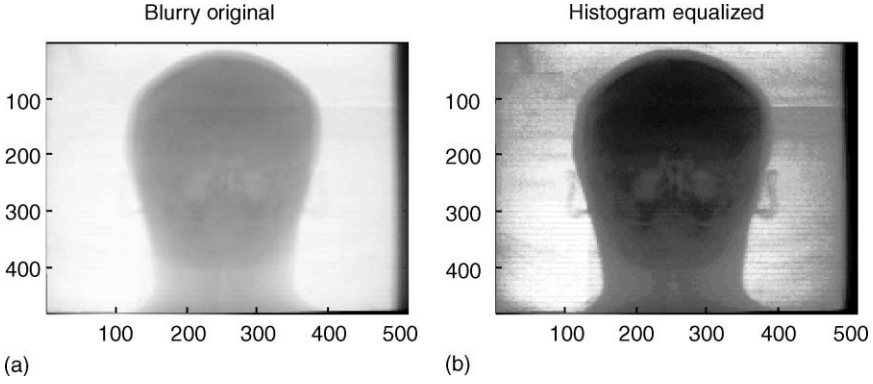

Figure 5 (a) Original EPID image; and (b) Histogram enhanced image.

where D_E is the Euclidean dimension that contains the fBm (i.e., the position of each point of the process is described with the vector $x = (x_1, \ldots, x_E)$).

We exploit the wavelet MRA combined with complementary signal processing techniques such as time-frequency descriptions and parameter estimation of stochastic signals in fBm framework for tumor detection in CT images. We demonstrate an example of image post-processing for tumor segmentation. We test our models to estimate FD in brain MR images as shown in Figures 6a and b, respectively. The images are scanned pixel-by-pixel with a sliding window that defines the subimage for analysis. Pre-processing, such as median filtering, is used to remove noise from the original images.

The results for the spectral analyses of CT image are shown in Figure 7. The results suggest that the FD values do not depend on the mother wavelet used. The window size that offers the best results is the 16×16 pixels, while better discrimination between low and high H values is obtained using biorthogonal wavelet. To improve tumor detection performance of the spectral technique, we apply post-processing filters on the results in Figures 8a and b, respectively. In Figure 8, for an example, we show the filtered fractal analysis results corresponding to a 16×16 pixels window with Daubechies 4. It is possible to obtain an even better description of the location and shape of the tumor after applying a two-dimensional post-processing filter to the matrices derived from the variance estimation algorithms with biorthogonal 1.5 wavelet and an 8×8 pixels window, respectively. The results are shown in Figure 9 and are similar for both averaging and Gaussian filters as well.

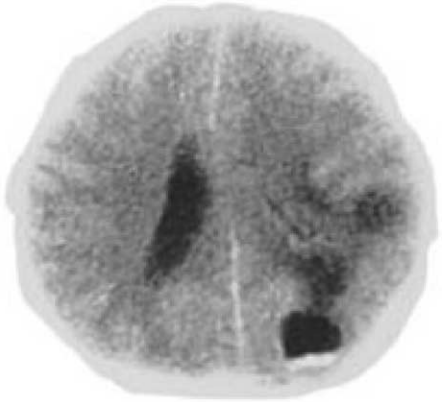

Figure 6 Biomedical images used to test the proposed algorithms.

Example III: Time-Frequency Domain Filtering: Image Post-Processing in Noise Reduction (De-Noising)

This section discusses an example of image post-processing in image noise removal (or de-noising) using a scale-frequency technique such as wavelets. The wavelet transform has been proved to be very successful in reducing noise (de-noising) in an image. We recently propose a new family of wavelets namely Joint Harmonic Wavelet Transform (JHWT) that offers better speckle noise reduction for image post-processing. Unlike wavelets generated by discrete dilation functions, as shown in eqn [18], whose shape cannot be expressed in functional form, JHWT has a simple structure, which can be written, in the

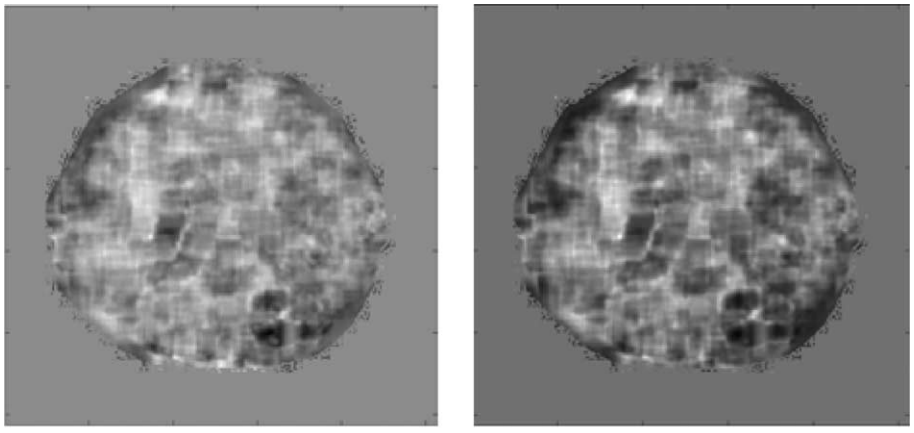

Figure 7 MR-Fractal analysis using spectral method (a) and (b) correspond to a 16×16 analyzing window for Daubechies 4 and biorthogonal 1.5 wavelets, respectively.

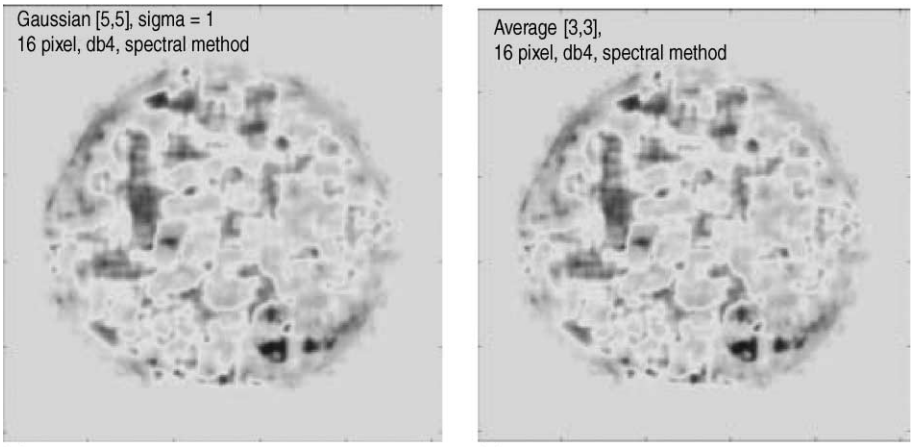

Figure 8 Post-processing results using: (a) 5 × 5 Gaussian filtering with $\sigma = 1$ and (b) 3 × 3 averaging filter.

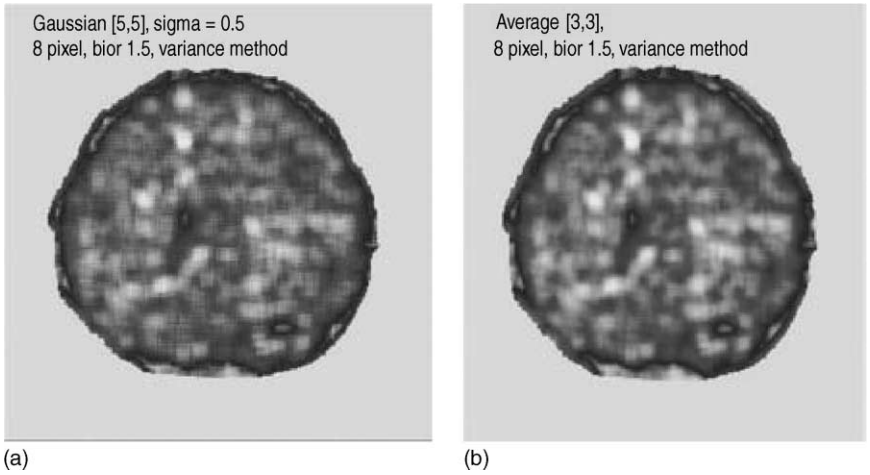

Figure 9 Post-processing on the fractal analysis results of **Figure 8** for (a) 5 × 5 Gaussian filtering with $\sigma = 1$, and (b) 3 × 3 averaging filtering.

frequency domain:

$$W(\omega) = \int_{-\infty}^{\infty} w(x)\exp(-\mathrm{i}\omega x)\mathrm{d}x,$$
$$= \begin{cases} 1 & \text{for } 2\pi \le \omega < 4\pi \\ 0 & \text{elsewhere} \end{cases} \quad [22]$$

Now, at level j, we let $g(x) = w(2^j x)$ and shift it by $k/2^j$ to obtain the harmonic wavelet as:

$$g(x - k/2^j) = \{\exp\{\mathrm{i}4\pi(2^j x - k)\} - \exp\{\mathrm{i}2\pi(2^j x - k)\}\}/\mathrm{i}2\pi(2^j x - k) \quad [23]$$

where integers j and k define the scale and translation of the wavelet $w(x)$, respectively on the x-axis. Now consider a real function $f(t)$ is represented by the sequence f_r of length $(n-1)$, where $r = 0$ to $2^n - 1$. To obtain JHWT coefficients, we take FFT of f_r such that,

$$|F_{2^j+s}|^2 = (1/n^2)\sum_{k=0}^{n-1} |a_{2^j+k}|^2 \exp(-\mathrm{i}4\pi sk/n), \quad [24]$$
where $r = 0$ to $n-1$ and $s = 0$ to $n-1$

where j denotes the level of the wavelet, k is the translation, m and n are adjacent levels of wavelets with $n = 2^j$, and $s = m - n$. The JHWT in eqn [24] offers all the properties and advantages of standard discrete wavelet transform. Putting $n = 2^j$ and $m = s + n$, eqn [24] yields all the JHWT coefficients from

Figure 10 (a) Noisy image; (b) de-noised image with JHWT-filtering; and (c) de-noised image with WP-filtering.

the Fourier coefficients as

$$\sum_{j=0}^{N-1}|F_{2^j+4}|^2=|a_0|^2+\sum_{j=0}^{n-2}(1/2^j)\times\sum_{k=0}^{2^j-1}\left(|a_{2^j+k}|^2+|a_{N-2^j-k}|^2\right)+(a_{N/2})^2=(1/N)\sum_{r=0}^{N-1}f_r^2 \quad [25]$$

Unlike conventional correlation techniques, the perfect octave band limited characteristics of JHWT eliminate the necessity of any multiplication. We show an example of image de-noising in Figure 10 using JHWT.

Image Post-processing, Transmission, and Distribution

One of the areas wherein image post-processing plays a vital role is in image transmission. A significant problem for any digital library is the network bandwidth required to transmit large digital images. The bandwidth consumption depends on the number of images used by a single user, and with the number of users requesting the services of the library. The popularity of database browsers such as Gopher and Mosaic has serious implications for image transmission and distribution. There has been active research in innovative new compression schemes and transmission protocols that reduce bandwidth requirements for many users along with software servers and visualization. Further, compression of digital image and video data plays an important role in reducing the transmission and distribution cost for visual communication.

One of the requirements for effective image transmission and distribution is reduced data size for faster speed. Image compression schemes are often used for image data reduction. Most of the successful image compression schemes exploit subdividing the image into blocks for increased compression. However, this subdivision of image renders a blocky effect on the compressed image. There has been intense research in removing the blocky effect on the compressed image. To achieve high bit rate reduction while maintaining the best possible perceptual quality, post-processing techniques provide one attractive solution. There has been a significant amount of work done in post-processing of compressed image/video. Some of them are developed from the image enhancement point of view while others are from image restoration. In the case of image restoration, the post-processing is considered as a reconstruction problem. Image enhancement methods are performed based on the local contents of the decoded image as discussed above.

The image post-processing algorithms are, generally, very effective in removing blocking artifacts. A straightforward approach to remove blocking artifacts is to apply lowpass filtering to the region, where artifacts occur. Consequently, the filter must be adapted to the block boundaries, i.e., the image partition. Further, if high frequency details such as edges and texture are to be preserved, then lowpass filter coefficients should be selected appropriately in regions where such details occur. Therefore, adaptive image post-processing such as spatial filtering methods may be applied to deal with this problem. In low-bit-rate image and video compression and distribution systems, high frequency transformed coefficients are often lost due to aggressive quantization or uneven error protection schemes. However, with the block-based encoding and transmission methods, the amount of high frequency texture loss is uneven between adjacent blocks. Thus, it is possible to exploit this texture-level correlation between adjacent image blocks to reconstruct the lost texture.

A relevant problem of robust transmission and distribution of compressed electronic images involves unreliable networks. The pre- and post-processing of the image data may play a vital role in addressing this problem. With the rapid growth of mobile wireless

communication systems, wireless multimedia has recently undergone enormous development. However, to design an efficient multimedia communication system over wireless channels, there still exist many challenges due to severe wireless channel conditions, special characteristics of the compressed multimedia data, and resource limitation, such as power supply. Since multimedia data, such as an image, contain redundancy, to efficiently utilize limited resources, source compression may be necessary. Further, as mentioned above, the ease of image creation, processing, transmission, and distribution has also magnified the associated counterfeiting problems. We discuss the relevant issues of image distribution in the following sections.

Techniques in Image Distribution

The spectacular development of imaging sensors, communication, and internet infrastructure has also made the counterfeiting tools easily accessible and more affordable. In addition, the threats and vulnerabilities of the internet have also increased manyfold. All of these together pose a formidable challenge to the secure distribution and post-processing of images.

Requirements of Secure Digital Image Distribution

In light of the above-mentioned vulnerabilities of image distribution channels and processes, below are a few requirements of secure image distribution:

- *Data Integrity and Authentication*: Digital image is easy to tamper with. Powerful publicly available image processing software packages such as Adobe Photoshop or PaintShop Pro make digital forgeries a reality. Integrity of the image content and authentication of the source and destination of the image distribution are, therefore, of utmost importance.
- *Digital Forensic Analysis*: Consider a litigation involving a medical image that is used for diagnosis and treatment of a disease, as shown in the post-processing example in Figures 7 or 8 above. Integrity of the image again is vital for the proper forensic analysis.
- *Copyright Protection*: Digital copyright protection has become an essential issue to keep the healthy growth of the internet and to protect the rights of on-line content providers. This is something that a textual notice alone cannot do, because it can so easily be forged. An adversary can steal an image, use an image processing program to replace the existing copyright notice with a different notice and then claim to own the copyright himself. This requirement has resulted in a generalized digital rights management initiative that involves copyright protection technologies, policies, and legal issues.
- *Transaction Tracking/Fingerprinting*: In the continuous (re)distribution of digital images through internet and other digital media (CD, camera, etc.), it is important to track the distribution points to track possible illegal distribution of images.

Next, we will discuss how the digital watermarking technology can help enforce these security requirements.

Example of secure image distribution: digital watermarking

Digital watermarking is the process of embedding a digital code (watermark) into a digital content like image, audio, or video. The embedded information, sometimes called a watermark, is dependent on the security requirements mentioned above. For example, if it is copyright application, the embedded information could be the copyright notice. Figure 11 shows a block diagram of the digital watermarking process.

Consider that we want to embed a message M in an image, f_o, also known as the original image. For the sake of brevity, we drop the indices representing the pixel coordinates. The message is first encoded using source coding and optionally with the help of error correction and detection coding, represented in Figure 11 as $e(M)$ such that

$$W_m = e(M) \quad [26]$$

The encoded message W_m is then combined with the key-based reference pattern W_k, in addition to the scaling factor α, to result in W_a which is the signal that is actually added to the original image, given as

$$W_a = \alpha(f_o)[W_M \otimes W_K] \quad [27]$$

Note that the scaling coefficient α may be a constant or image dependent or derived from a model of image perceptual quality. When the scaling factor α is dependent on the original image, we can have informed embedding which may result in more perceptually adaptive watermarking. The operation involving W_m and W_k is the modulation part, which is dependent on the actual watermarking algorithm used. As an example, in a typical spread-spectrum based watermarking, this operation is usually an exclusive NOR (XNOR) operation. The final operation is an additive or multiplicative embedding of W_a with the original image. We show a simple additive watermarking process as

$$f_w = f_o + W_a \quad [28]$$

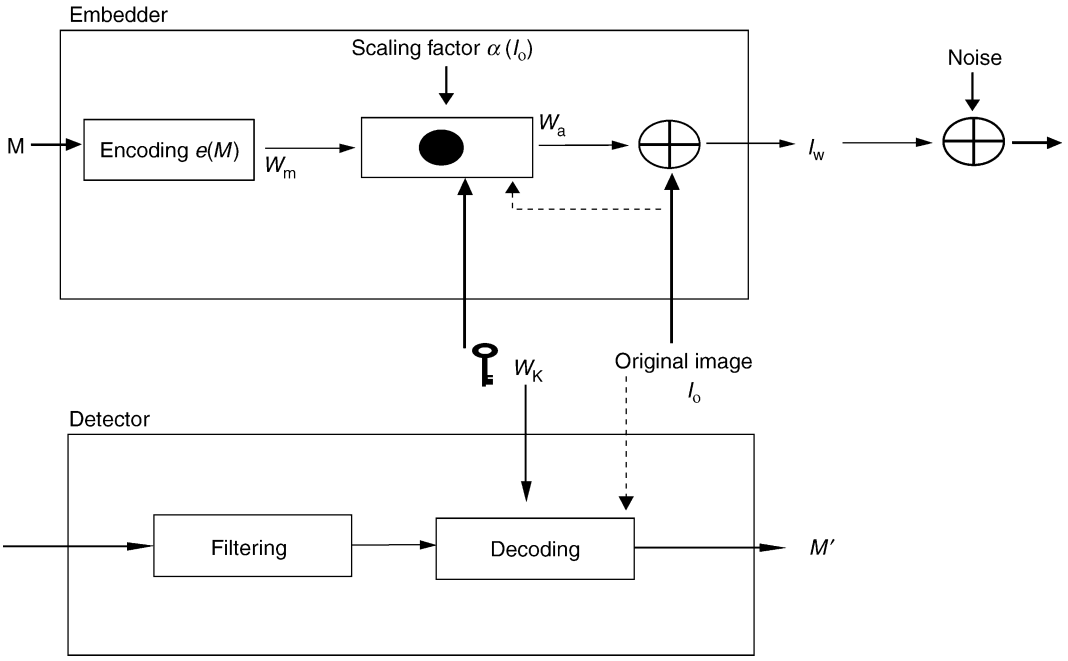

Figure 11 A simple watermarking process: embedder and detector.

Figure 12 (a) Original image, (b) watermarked image, and (c) the difference image.

The result of this process is the watermarked image f_w which may actually need some clipping and clamping operations to have the image pixel values in the desired range.

The detector, as shown in Figure 11, does the inverse operations of the embedder. If the original image is known, as in the case of nonblind watermarking, it is first subtracted from the watermarked image. Blind watermarking detector, on the other hand, uses some filtering with a goal to estimate and subtract the original image component. The result of filtering is then passed to the decoder, which collects the message bits with the help of the shared key, and finally gets back the decoded message M'.

Figure 12 shows the original image, watermarked image, and the difference image using a spread-spectrum based watermarking algorithm, respectively. The enhanced difference image represents a noise-like image, wherein the scaling coefficient α is clearly dependent on the original image. As evident from Figure 12b, the hidden message is imperceptible as well as the change in the original image. The imperceptibility is one of the primary criteria of digital watermarking.

There are other criteria such as unobtrusiveness, capacity, robustness, security, and detectability. Thus, digital watermarking is a multidimensional problem, which attempts to make a trade-off among a number of different criteria. The inserted

watermark should not be obtrusive to the intended use of the original image. Because the watermarking process does not increase the size of the original image, it may be desirable to add as much information as possible. However, generally speaking, the more information one adds, the more severe will be the impact on the perceptual quality of the image. From the detection point of view, watermark should be robust enough to tolerate a range of image post-processing and degradation. In addition, the embedded watermark should also be secure enough so that it may not be removed from the watermarked image. Finally, detectability of the embedded watermark is an important criterion that places some constraints on the embedding algorithm.

In order to fully appreciate the use of watermarking for image distribution, it is instructive to look at different classes of watermark, which is delineated in Figure 13.

For an example, depending on the robustness criterion of watermarking, they can be classified into three categories such as robust, fragile, and semi-fragile. Note that while the robustness of watermark is important, it is not always equally desirable in all applications. Let us take the authentication as an example. If you, as the owner of a digital image, embed some authentication information into the image using watermarking, you might want to see the authentication fail, when some one steals your image. This is an example of nonrobust watermark, where the fragility of the embedded watermark is required to detect any forging done on the digital image.

Now, consider how watermark provides the security requirements for secure image distribution. In particular, we look into the authentication of watermark. Figure 14 shows the use of watermark for image authentication, which has some similarities with the cryptographic authentication using digital signature. However, there are potential benefits to using watermarks in content authentication and verification. Unlike cryptography, watermarking offers both in-storage and in-transit authentication. Watermarking is also faster compared to encryption, which is very important in internet-based image distribution. By comparing a watermark against a known reference, it may be possible to infer not just that an alteration occurred but what, when and where changes have occurred. As shown in Figure 14, first we identify some features from the image and then we compute the digital signature, which is then embedded into the image. The detector takes a test image, computes the signature and extracts the embedded

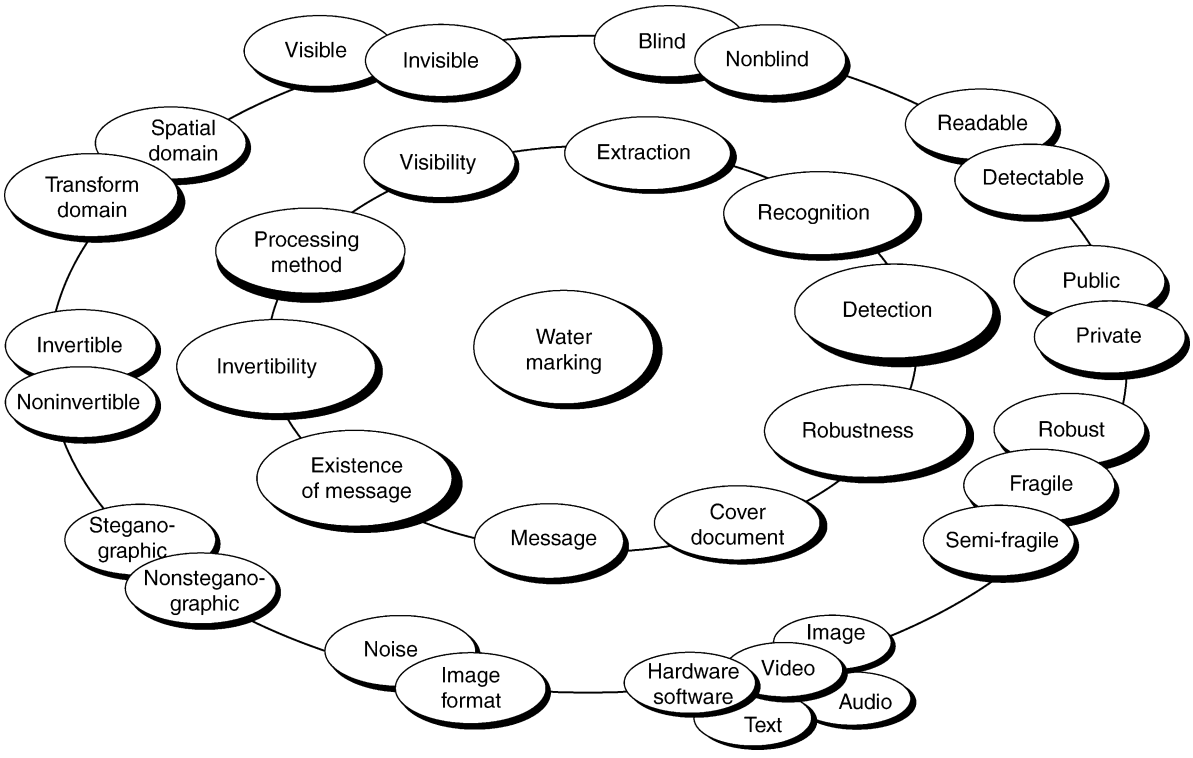

Figure 13 Watermark classifications.

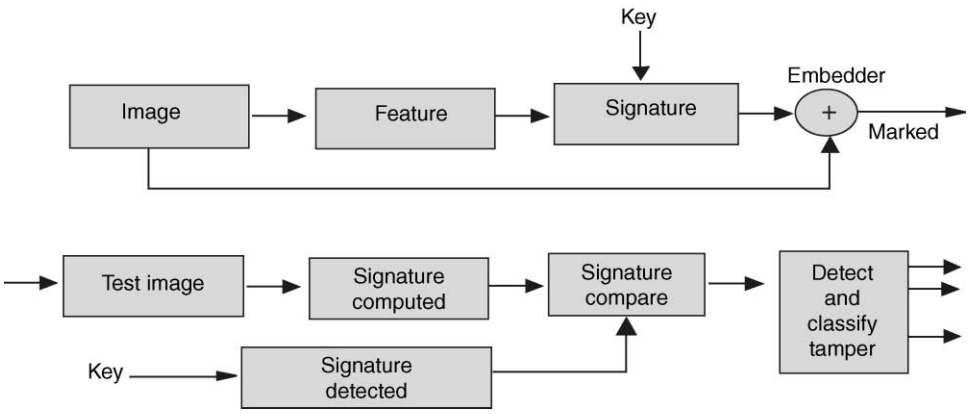

Figure 14 Image authentication using watermark.

signature, and then compares the two. If they match, the image is authenticated. If they do not match, then the image may have gone through some forging/tampering effects and the algorithm may optionally detect the tamper area as well.

One of the limitations of the watermarking approach in secure image distribution is that the technology is not yet widely deployed, and nor is the protocol satisfactorily standardized. Other major limitation is that the watermarking process cannot be made sufficiently robust to arbitrary types of different attacks. In reality, therefore, the hybrid combination of cryptography and watermarking is expected to improve the secure distribution of images across the unreliable internet.

Concluding Remarks

In this chapter, we discussed the principles of image post-processing and distribution. We showed a few representative examples for post-processing and distribution. We also explained the relevant issues in image distribution and present digital watermarking as one of the solutions for secure image distribution.

Introduction

For more than 50 years silicon has been the semiconductor on which the enormous progress of microelectronics is based. Since silicon is also an excellent detector for electromagnetic radiation, in particular in the visible spectrum between 400 and 700 nm, the advances in semiconductor technology have directly influenced the progress of solid-state image sensing. Once the relentlessly shrinking dimensions of transistors have reached a critical minimum limit, it has become economically feasible to co-integrate analog and digital circuitry with each light-sensitive pixel. This capability is at the heart of the technological revolution called smart pixel arrays.

The first section relates how the shrinkage of minimum feature size on silicon chips paralleled the reduction of solid-state pixel geometry, as a function of time. This development ceased once the pixel size reached the optical diffraction limit, which marked the birth of the field of smart pixel arrays. In the second section, the basic functionality and the most important physical limitations of conventional pixels and photosensors are given. The third section deals with opto-electronic functionality that is preferred today, of smart pixel arrays; in particular, the capability of spatio-temporal demodulation is very much in demand. In the fourth section, some of the most useful modular building blocks for smart pixel arrays are presented, together with a few key applications. An outlook on photonic systems-on-chip (SoC) is given in the fifth section, with a discussion of single-chip machine vision systems (so-called seeing chips), organic semiconductors for even higher levels of integration of photonic microsystems, and smart pixel arrays that are sensitive to physical parameters other than electromagnetic radiation.

Silicon Technology for Image Sensing

Long before it was realized that silicon would be the material on which modern semiconductor industry and the information technology revolution is based, in 1940 Russell Ohl discovered that silicon is an excellent detector of electromagnetic radiation. In particular, silicon is an excellent detector for light in the visible and near infrared part of the spectrum, for wavelengths between 400 and 1,000 nm. This is very fortunate because it allows designers of image sensors to profit directly from the amazing progress of silicon technology. Since the 1970s, the minimum feature size on silicon chips showed a reliable exponential reduction of about 10% per year, as illustrated in Figure 1. This is a direct consequence of the observation by Intel's Gordon Moore, sometimes called 'Moore's law', that the number of transistors per integrated circuit doubles about every two years. The evolution of minimum feature size is paralleled by the evolution of minimum pixel size of solid-state image sensor, as illustrated in Figure 2. Once the pixel size reached a record low value of 2.4 μm in the year 1996, no further reduction in pixel size seemed desirable, because the optical diffraction limit was essentially reached.

The combination of technological availability of smaller and smaller electronic components and pixel size that demanded no further reduction, inspired researchers to provide each pixel with an increasing amount of electronic functionality, all of which is available simultaneously for massively parallel information processing. This represents the heart of the smart pixel array revolution; pixels that not only sense the incident electromagnetic radiation but that are capable of pre-processing the acquired information in a relevant fashion.

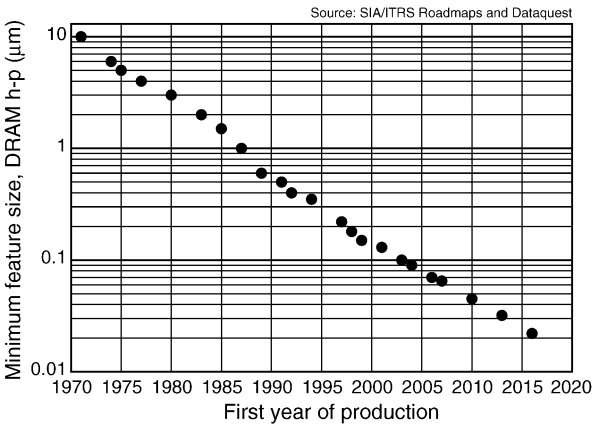

Figure 1 Evolution of minimum feature size (DRAM half-pitch) in state-of-the-art silicon technology, showing an exponential reduction for the past 30 years, which is expected to continue for at least another decade.

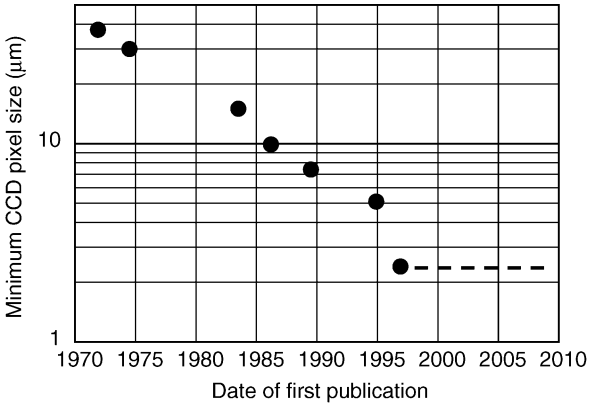

Figure 2 Evolution of minimum pixel pitch in CCD image sensors, tracking the exponential reduction of minimum feature size shown in **Figure 1**, until a lower limit was reached in 1997, imposed by optical diffraction. Since then, no smaller pixel pitches have been described in the literature; this is indicated graphically with the hatched 'diffraction limit' line.

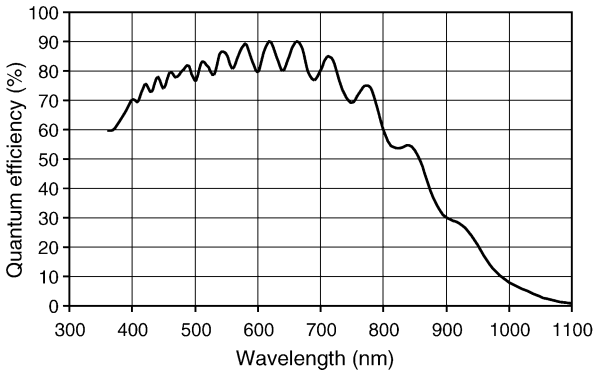

Figure 3 External quantum efficiency of a photosensor realized with an industry standard CMOS process, showing quantum efficiencies above 50% in the whole visible spectral region.

Basic Functionality and Physical Limitations of Conventional Solid-State Photosensors

The prime task of a pixel is the detection of incident electromagnetic radiation. The detection process consists of six basic steps:

1. The incident photon impinges on the surface of the image sensor, and it has to reach the bulk of the semiconductor.
2. In the bulk of the semiconductor the photon has to interact with the semiconductor, converting its energy into a number of electron–hole pairs.
3. The photogenerated charge carriers must be transported to the sensor surface.
4. At the surface, the photogenerated charge needs to be collected and accumulated in the storage part of the pixel.
5. The accumulated photocharge must be transferred to the input of an electronic circuit capable of detecting this charge.
6. The charge detection circuit converts photocharge into a corresponding voltage, exhibiting a monotonous (but not necessarily linear) transfer function.

Since the interaction length of electromagnetic radiation in silicon is in the tens of micrometers for incident photon energies between 1 eV and 10 keV (corresponding to a wavelength range of about 0.1 to 1,000 nm), silicon is an excellent detector for this large spectral range. This is illustrated for the visible and near infrared spectral range in **Figure 3**, showing the absolute external quantum efficiency of a pixel realized with an industry standard silicon process. In the visible spectral range, absolute external quantum efficiencies close to 100% can be reached, even with standard silicon processes for the microelectronics industry that were not optimized for photosensing applications.

Photocharge transport to the surface of the semiconductor is mainly provided by diffusion, i.e. random thermal motion of the charge carriers that exhibit a velocity of about 10^5 m/s in silicon at room temperature. The mean distance L traveled by a diffusing charge carrier during time t is given by

$$L = \sqrt{Dt} \qquad [1]$$

with the diffusivity D, which has a value of around 40 cm^2/s for electrons in low-doped silicon at room temperature.

Once the photocharge carriers are close to the surface of the semiconductor, they are transported by drift in an electric field E, exhibiting a linear dependence of the transport distance L with time t:

$$L = \mu E t \qquad [2]$$

with the mobility μ which has a value of around 1300 cm^2/Vs for electrons in low-doped silicon at room temperature.

There are two basic principles for creating the electric field with which the photocharge carriers are transported to their storage site within the pixel. A photodiode consists of a semiconductor junction between a p-doped and an n-doped region, as illustrated in **Figure 4**. Such a photodiode also represents a capacitance on which photocharge can be accumulated and stored. Photodiodes are used as photosensors in one

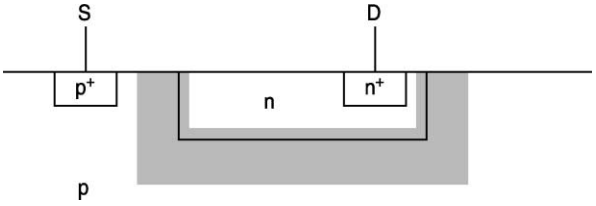

Figure 4 Cross-section of a photodiode, consisting of an n-doped region in a p-doped substrate. The substrate is contacted using a heavily p-doped diffusion S, and the n-region is contacted using a heavily n-doped diffusion D. The space–charge region is illustrated as hatched area at the pn-junction.

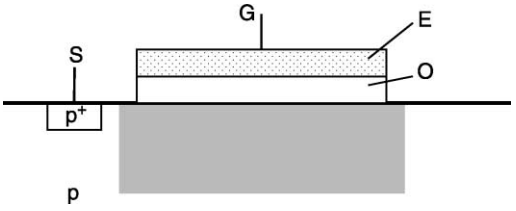

Figure 5 Cross-section of an MOS capacitance, the basic element of a CCD image sensor. On top of a p-substrate a thin transparent insulator O and a transparent electrode E are fabricated. The substrate is contacted with a heavily p-doped diffusion S, and the electrode E is contacted with the gate contact G. The hatched area illustrates the space–charge region under the electrode.

popular type of image sensor, so-called APS (active pixel sensor) or CMOS (complementary metal oxide semiconductor) imagers.

An alternative to a photodiode is an MOS (metal oxide semiconductor) capacitor, consisting of a transparent electrode that covers an insulating layer on top of semiconducting material, as illustrated in Figure 5. An MOS capacitor is the basic element of a charge coupled device (CCD), the other widespread type of image sensor.

The charge transfer between photodiodes and photodetector circuits is based on electrical conduction, occurring essentially with the speed of light. In CCDs, the charge transfer is effectuated with clocks, and excellent charge transfer efficiencies can be observed at clock frequencies of several tens of MHz.

The major limitation in semiconductor photosensors is the last element in the line, i.e. the electronic charge detection circuit. In Figure 6, a so-called source follower is illustrated, which is by far the most frequently used photocharge detection circuit. Its performance is limited by the thermal (Johnson) noise in the channel of the first field effect transistor (FET). This corresponds to a statistical uncertainty with which an amount of photocharge can be measured at the gate of the FET. The input referred charge noise

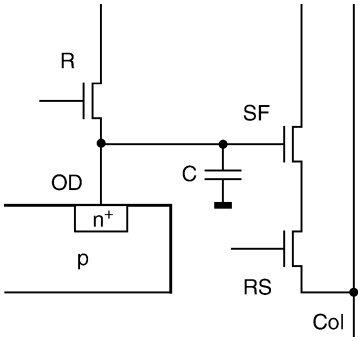

Figure 6 Schematic diagram of a photosensor's output diffusion OD connected to a reset transistor R and a source follower transistor SF, the most widely used charge detection circuit for image sensors and smart pixel arrays. The photocharge is stored on the effective capacitance C at the gate of transistor SF, which is read out using a row select transistor RS, connecting the source follower to the readout column Col.

variance s_Q is given approximately by

$$s_Q \cong C^2 \frac{4kTB}{g} \qquad [3]$$

where C is the effective capacitance seen by the gate of the FET, k is Boltzmann's constant, T is the absolute temperature, B is the effective bandwidth at the FET's channel, and g is the transconductance of the FET.

Desired Optoelectronic Functionality in Smart Pixel Arrays

From the previous section it becomes clear that even conventional pixel and photosensors can be improved in several desirable respects:

- The spectral response can be improved in the ultraviolet (50–400 nm), or it can be expanded significantly into the X-ray region (below 0.1 nm) and into the infrared region (above 1,000 nm).
- The speed of the photosensors can be increased by replacing diffusion based photocharge transfer mechanisms with the directed, more efficient drift in electric fields. This is true for the vertical as well as for the lateral charge transport direction.
- The sensitivity of the electronic charge detection process can be improved in two ways. It can be achieved by decreasing the effective detection capacitance C at the input of the charge detection circuit, as can easily be seen from eqn [3]. An alternative is to make use of a physical charge amplification process (i.e. avalanche multiplication in a high electric field), that has low intrinsic noise.

- A derivative improvement that is desired is the increase of the dynamic range D/R of the complete detection process, as defined, for example, by

$$D/R = 10^{10} \log \frac{Q_{\max}^2}{s_Q} \qquad [4]$$

where $Q_{\max}$ denotes the maximum (or saturation) charge and s_Q is the total charge noise variance of the electronic detection circuit.

In addition to the above described improvements of conventional pixel functionality, a huge demand exists for the capability to measure the parameters of modulated electromagnetic signals, i.e. to demodulate such signals. This demand is related to the large number of very powerful electronic and opto-electronic measurement principles, capable of improving the sensitivity of the measurement process significantly by employing modulated signals, either in the temporal or in the spatial domain. For this reason, smart pixel arrays are sought that offer this combination of photodetection and demodulation.

Modular Building Blocks for Smart Pixel Arrays

Towards the end of the last century, a large body of literature has been created, addressing various approaches for the realization of one of the above described desired opto-electronic functionalities. The result is a powerful 'toolbox' of modular building blocks for custom smart pixel arrays, with which optimized solutions for optical measurement problems and practical applications can be constructed.

High-Sensitivity Charge Detection

From the noise formula (eqn [3]) two possibilities for the improvement of the sensitivity of image sensors can be deduced: A first approach is the reduction of the capacitance value. An excellent example for this is the invention of the 'double gate' FET, in which the charge to be measured is not placed on a gate electrode at the surface but resides in the semiconductor bulk. In this way the effective capacitance of the pixel can be reduced by at least one order of magnitude compared to conventional pixels. The resulting capacitance of less than 1 fF leads to a readout noise of about one electron at room temperature and for a readout bandwidth of several MHz. Unfortunately the small capacitance allows the storage of only around ten thousand electrons. For such small charge packets, quantum noise is still relevant, leading to significantly degraded image quality, even when the images are taken under favorable lighting conditions.

A second approach to high-sensitivity photosensing exploits the dependence of the charge detection variance on the measurement bandwidth, as indicated in eqn [3]. One method for exploiting this consists of reading out the image sensor at a significantly reduced bandwidth of a few 10 kHz. At the same time, the image sensor is cooled to temperatures of around −100 °C. This becomes necessary because readout at such slow speeds increases the time, to read one complete image, to many minutes, requiring a substantial reduction of the dark current. Instead of working at low readout bandwidths, it is also possible to read out the same information repeatedly and non-destructively at high speed, and to average many measurements of the same amount of photocharge. Both methods have been shown to lead to readout noise levels of about one electron; on the other hand, both approaches require very long times for the acquisition of complete images.

This problem can be resolved by exploiting the massive parallelism that smart pixel arrays offer: low-bandwidth techniques can be employed without losing effective readout speed. Pixels and columns are read out with low-bandwidth amplifiers that are all active simultaneously, and only the final off-chip readout amplifier needs to operate at a large bandwidth. In practice, this approach has been used successfully in single-chip digital cameras with Megapixel resolution, exhibiting a readout noise of only a very few electrons.

A completely different approach is based on the use of a physical amplification mechanism with low intrinsic noise, before detecting the amplified charge packets with a conventional electronic circuit; the avalanche multiplication effect in high electric fields is very well suited to this approach. Each pixel is supplied with its own combination of stabilized avalanche multiplier and conventional charge detection circuit. This approach has been used for the realization of a fully integrated 2D array of single photon detectors that can be fabricated with industry standard CMOS processes. Similar performance is obtained with the Impactron™ series of high-sensitivity CCD image sensors offered by Texas Instruments Inc., making use of a single multistage avalanche multiplier at the output of the image sensor. For both high-sensitivity smart pixel arrays, single-photoelectron performance is reported at room temperature and at readout frequencies of several MHz, as required for video applications.

Photosensing with Improved Dynamic Range

Conventional solid-state image sensors and cameras usually have a very limited dynamic range, as defined in eqn [4]. Typical values are between 40 and 80 dB, rarely exceeding four orders of magnitude. In natural scenes, however, much higher D/R values can be encountered. To cope with this, the human eye is capable of spanning a dynamic range of more than 150 dB. This realization has spurred the invention of several methods with which the D/R of smart pixel arrays can be increased.

One approach consists of acquiring several images of the same scene with different exposure times, with the subsequent combination into one high-dynamic-range composite picture. D/R values exceeding 120 dB have been obtained with such multi-exposure methods. Fast-moving objects, however, will have relocated from one exposure to the next, resulting in false, blurred representations of these objects in the composite picture.

This can be overcome using nonlinear response characteristics similar to the ones found in natural vision. Impinging light produces a photocurrent that is highly linear with the incident light intensity. Because the voltage across the photodiode is logarithmically dependent on the photocurrent, a logarithmic voltage-illumination response is obtained, with a D/R exceeding 120 dB. Such logarithmic pixels are well-suited for applications providing high illumination levels but they suffer from excessive noise and slow response speed at low light levels.

This disadvantage led to the development of linear-logarithmic pixels, exhibiting a high-sensitivity linear response at low light levels, and a gradual changeover to logarithmic response once a certain, programmable light level is reached. The design principle is illustrated in Figure 7. An otherwise conventional CMOS/APS pixel is supplied with a device that exhibits logarithmic voltage–current response, such as a diode. As long as the cathode is at a higher voltage than the anode, no current flows across the diode, and the pixel response is linear. Once the photocurrent has lowered the cathode voltage below the anode voltage, the pixel response becomes logarithmic, as described above. The D/R of such a linear-logarithmic pixel reaches unprecedented high values; almost 200 dB have already been obtained in practice. Because of the simplicity and robustness of this principle, such linear-logarithmic smart pixel arrays have found their way into commercial sensor and camera products that are available commercially, as illustrated in Figure 8. A circuit board and a light bulb are imaged in linear mode (Figure 8a), showing highly saturated areas, and in linear-logarithmic mode (Figure 8b), in which even the light bulb's filament can clearly be seen.

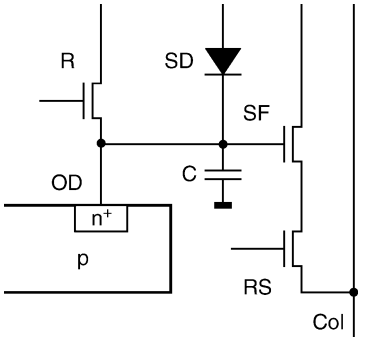

Figure 7 Schematic diagram of a high-dynamic-range pixel, consisting of a conventional APS/CMOS pixel, as illustrated in Figure 6, in combination with a shunt diode SD. The photocurrent lowers the voltage at the gate of transistor SF continuously. Below a certain value of this voltage, the diode starts to become forward biased, leading to a linear-logarithmic illumination response, with a dynamic range that can be as high as 200 dB.

Extension of the Spectral Sensitivity Range

The spectral sensitivity of silicon is essentially restricted to the spectral wavelength range between 0.1 and 1,100 nm. With a suitable choice of materials that cover the silicon sensor's surface, this sensitive wavelength range can be extended. For high-energy radiation, scintillator materials are employed, capable of converting incident high-energy photons into a proportional number of visible photons. Scintillators render smart image sensors particularly sensitive in the UV (300–400 nm), deep UV (below 300 nm), X-ray (0.002–1 nm), and gamma ray (below 0.002 nm) spectral region. Typically, the scintillator materials are fabricated as platelets that are glued on the surface of the produced CMOS/CCD image sensor.

The extension of the sensitive spectral range to the infrared can be achieved with semiconductor materials with smaller energy bandgaps than silicon. Examples include Ge, SiGe, SiC, PtSi, IrSi, InAs, InGaAs, or InGaAsP. Typically, these materials are deposited on the produced CMOS/CCD image sensor in an ultra-high vacuum environment. An alternative is the use of bump-bonding, with which the CMOS/CCD image sensor can be connected to a small-bandgap material chip at each pixel site. With these technologies, silicon-based smart pixel arrays become sensitive to wavelengths of several microns.

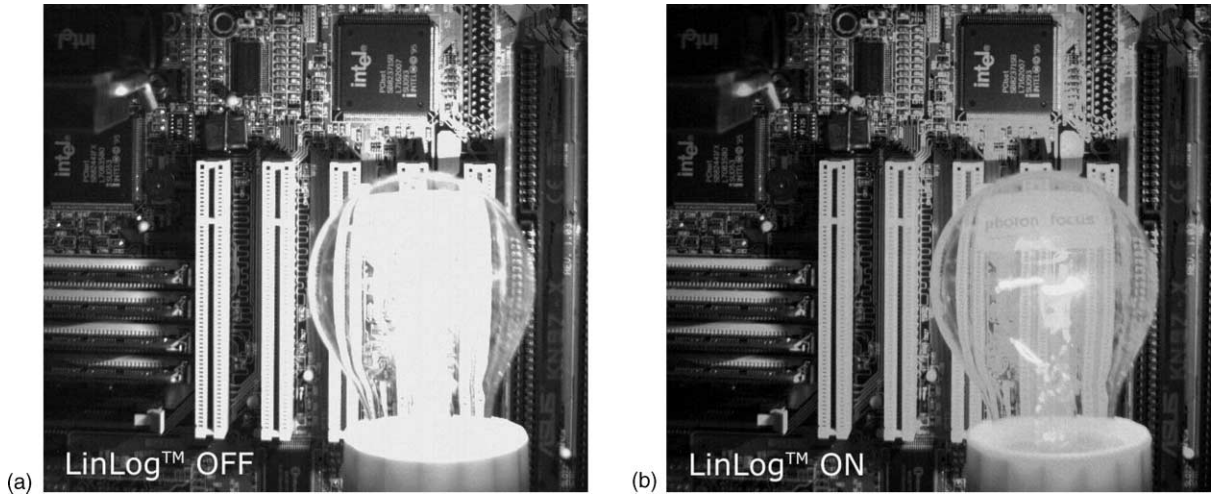

Figure 8 Images of a scene with high dynamic range, taken with an image sensor exhibiting linear illumination response (a) and linear-logarithmic illumination response (b). A similar pixel architecture as illustrated in Figure 7 is employed. (Courtesy of Photonfocus AG, Lachen, Switzerland.)

High-Speed Image Sensing

Increasing the speed of the photosensing process necessitates improvements in two key areas. Photocharges need to be collected and transported faster, and the acquired information must be read out faster.

A comparison of eqns [1] and [2] immediately reveals that the replacement of diffusion by drift transport provides the desired speed improvement. In the vertical direction, the electric field of photodiodes or MOS capacitances reaches more deeply into the semiconductor bulk if lower doping levels of the substrate are used or the bias voltage is increased. Improving the lateral transport speed is more difficult. A highly successful approach in so-called drift-field pixels is illustrated in Figure 9. On top of a thin (a few tens of nanometers) transparent insulator, a highly resistive layer – often of polysilicon – is placed. When a voltage difference is applied at the two ends, a small current flows across the resistive layer, inducing a linear potential variation at the semiconductor surface. A simple calculation shows that very small transit times for photocharges can be obtained in this way. Assuming a (quite large) pixel size of 25 μm and a voltage difference of 5 V, the maximum transit time of photoelectrons that have to move from one end of the pixel to the other, is less than 1 ns. This is more than two orders of magnitude faster than can be achieved with diffusion transport.

Smart pixel arrays provide a simple solution to the problem of speeding up the readout of the acquired picture information; a large degree of parallelism. This is illustrated with the architecture of a split-field high-speed image sensor, shown schematically in Figure 10. The photosensitive area is split into two

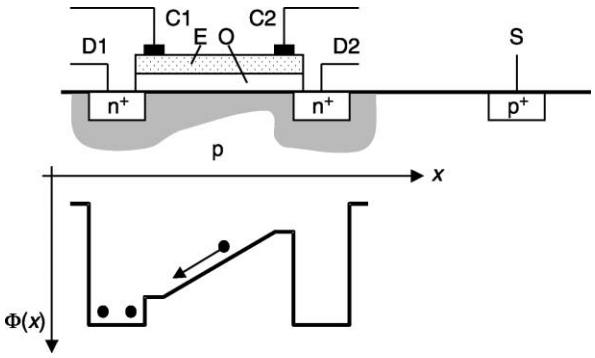

Figure 9 Cross-section of a drift field pixel, exploiting the lateral drift field at the semiconductor–oxide interface. The corresponding sloped potential distribution $\Phi(x)$ is created with a highly resistive transparent electrode E on top of a thin transparent insulator O; this conductor has two contacts C1 and C2 at its ends, to which a voltage difference is applied. Depending on the sign of the slope, the photoelectrons are collected either in diffusion D1 or D2. The hatched area indicates the space-charge region.

parts, so that the column amplifiers of one half have time to settle to their proper voltages, while the columns of the other half are being read out. No time is lost, therefore, when another row of the image is selected for readout. A large number of output amplifiers are provided for highly parallel readout of the image data, each with a typical readout rate of 40–100 MHz. In this way, sustainable pixel rates of several GHz can be achieved in practice.

Static Spatial Demodulation

The spatially varying geometry of the photosensitive part of a pixel can be used for the static spatial

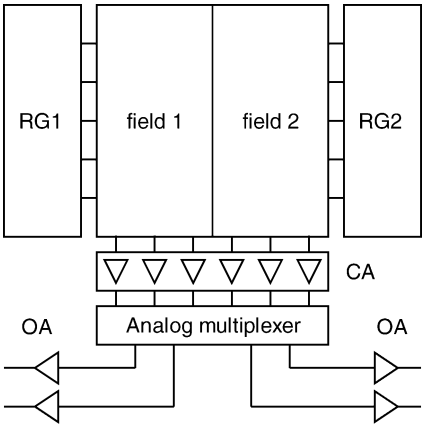

Figure 10 Block diagram of a high-speed image sensor, making use of the large amount of parallelism possible in smart pixel arrays. The light-sensitive area is split into two fields whose rows can be addressed independently with two separate row address generators RG. In this way, one row of one field can be selected and the corresponding column amplifiers CA can reach equilibrium, while the columns of the other field are being read out using several parallel output amplifiers OA.

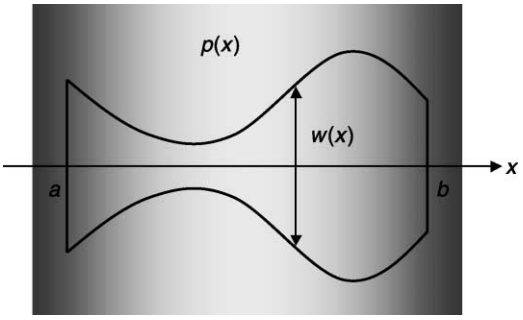

Figure 11 Illustration of a one-dimensional intensity distribution $p(x)$ of light which is incident on a shaped photodiode with position-dependent width $w(x)$, between the two boundaries a and b.

demodulation of an impinging light field. When a one-dimensional intensity distribution $p(x)$ is incident on a photodiode with spatially varying width $w(x)$ between the limits a and b, as illustrated in Figure 11, an output signal r is produced:

$$r = \int_a^b p(x)w(x)\mathrm{d}x \qquad [5]$$

By shaping the photodiode appropriately, any type of parametrized linear transform can be realized, as illustrated by the photomicrograph in Figure 12. In this practical example, four photodiodes are shaped sinusoidally and cosinusoidally, weighted with a slowly varying windowing function. Their signals are used for determining the Fourier coefficients

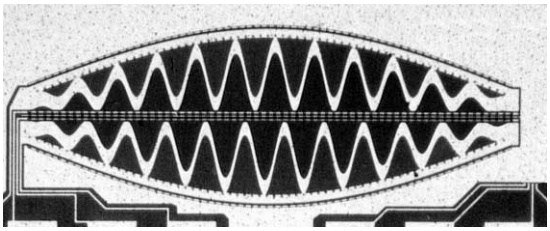

Figure 12 Photomicrograph of two photodiode pairs that are shaped as spatial sine and cosine functions, weighted with a slowly varying windowing function. The four photosignals can be employed to determine the phase and amplitude of a one-dimensional intensity signal that has the same spatial frequency as the sine and cosine. In practice, the accuracy of the phase determination is as high as 0.1% of the spatial wavelength. The width of the photomicrograph corresponds to about 1 mm in reality.

(the sine and cosine transform) of an incident light distribution for a fixed spatial frequency. This is employed, for example, in cost-effective optical encoders, capable of measuring linear displacement with an accuracy below 50 nm.

Dynamic Spatial Convolution

Many image-processing tasks require the convolution of the pixel data $P_{i,j}$ at the position (i, j) in an image with a two-dimensional convolution kernel $w_{k,l}$:

$$R_{k,l} = \sum_{i=-N}^{N} \sum_{j=-N}^{N} P_{i,j} w_{k-i,l-j} \qquad [6]$$

Instead of employing a purely geometrical solution, as described in the previous section, an alternate approach is found when interpreting the convolution eqn [6] in the following way. The resulting image R is obtained by displacing the original image P laterally by an amount (k,l), by multiplying the shifted pixel values with the corresponding weight $w_{k,l}$, and by adding up all these products.

The lateral displacement is realized with a CCD structure, implementing the 2D lateral movement of the acquired image charge packets, the multiplications with the convolution kernel values are realized by using various exposure times for each lateral shift position, proportional to the corresponding weight value, and the summation is just the natural charge accumulation of CCD structures. The problem of negative weights is solved by separately determining the positive and negative parts of the weight function, each stored separately in the pixel, and by calculating the difference of the two values during readout, either on-chip or off-chip. In this way, such convolution image sensors

can be used for the determination of complete, programmable, real-time image convolutions, with arbitrary kernels that are fully under the dynamic control of digital logic or microprocessors. Practical experience with such convolution imagers shows that the convolution results exhibit inaccuracies of less than 1%.

Temporal Demodulation

In many relevant optical measurement techniques, temporally modulated light fields are employed. For this reason, smart pixel arrays are desired, providing synchronous demodulation of these signals. An electromagnetic signal $S(t)$ that is harmonic as a function of time with given frequency ω, having unknown modulation amplitude A, offset B and phase delay φ, is described by

$$S(t) = A \sin(\omega t + \varphi) + B \qquad [7]$$

The three unknowns A, B and φ can be measured if three or more sampling points are sampled synchronously per period in so-called 'lock-in' pixels. An example of a lock-in pixel employing the drift-field transport principle with four accumulation taps, is illustrated in Figure 13. Demodulation frequencies of several tens of MHz have already been demonstrated in practice.

The most important application of such synchronous demodulation pixels is in optical time-of-flight range cameras. Such a camera incorporates a light source, usually an array of infrared or visible LEDs, that is modulated at a few tens of MHz. The modulated light is reflected diffusely by the various objects, and the camera's lens images it onto a lock-in image sensor. Each of its pixels carries out synchronous sampling/accumulation of photocharges. At the end of the exposure time, the accumulated photocharge samples are read out, and the three modulation parameters of the reflected light are determined for each pixel. The phase shift is a direct measure of the local distance. It has been shown that for a wide range of operating conditions, the distance resolution of such optical range cameras is already limited just by the photo shot noise. A typical result of such a depth image is shown in Figure 14.

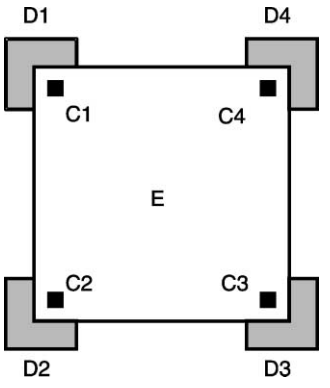

Figure 13 Schematic top view of a lock-in pixel based on the lateral drift-field approach illustrated in Figure 9. A square electrode is fabricated with a highly resistive transparent material on top of a thin insulator. The electrode contacts C1 to C4 are employed to create a 'reeling' potential distribution that rotates with the modulation frequency of the incident light that requires synchronous demodulation, so that the photocharges are collected at diffusions D1 to D4, respectively, at the appropriate time during each period.

Photonic Systems-on-chip

The microelectronics revolution is based on the key notion of integration. More functionality integrated monolithically on the same chip leads to faster, smaller, better performing, and cheaper products. The same is true for smart pixel arrays, for which progress through integration is attained in several respects.

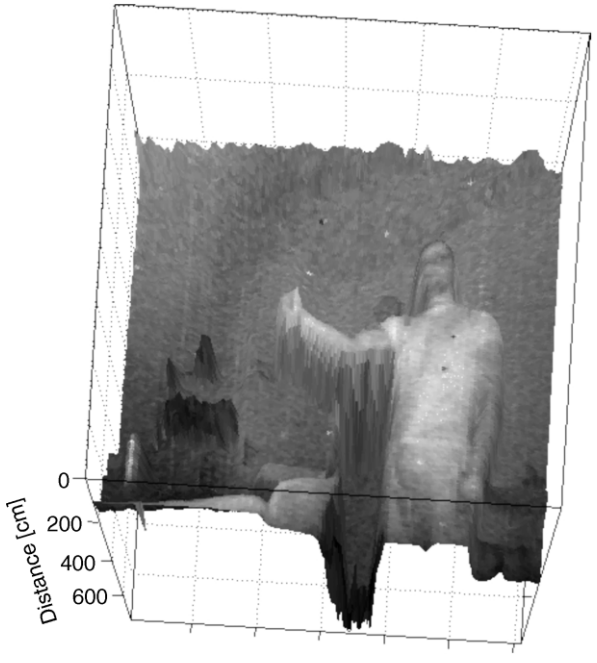

Figure 14 Example of a distance picture (a person) out of a 3D range image sequence, taken with an optical time-of-flight distance camera making use of lock-in pixels. Depending on the available light level, the background illumination and the modulation frequency, such solid-state range cameras can have a resolution of a few mm.

Seeing Chips

Already, in the mid-1980s, researchers were excited about the possibility of integrating local signal processing capabilities in each pixel, implementing some functions of biological vision systems. It was envisioned that an increasing amount of bio-inspired functionality would lead to smart image sensors, exhibiting a primitive sense of vision. The idea of a 'seeing chip', with the capability to interpret a scene, was born.

Unfortunately, even today, our understanding of the enormously successful biological vision systems has not yet reached a mature enough state allowing us to implement signal processing functions that approximate any 'image understanding'. Published algorithms are still incapable of interpreting a scene and 'perceiving' its contents. Obviously, no set of vision algorithms is yet known with which seeing chips could be realized. Although progress is slower than envisioned, single-chip machine vision systems of growing complexity and increasing functionality are being developed.

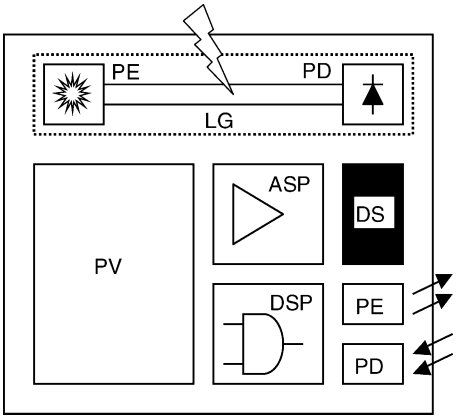

Figure 15 Schematic block diagram of a monolithically integrated photonic microsystem, that is expected to be producable in the near future with organic semiconductors. All optoelectronic devices are fabricated on the same planar surface: photovoltaic power supplies (PV); analog and digital signal processing (ASP and DSP); photodetectors (PD); photoemitters (PE) – used for bidirectional communication or as parts of a photonic detector subsystem – a light guiding structure (LG) that can be sensitized for specific sensing applications, and a display subsystem (DS).

Organic Semiconductors for Monolithic Photonic Microsystems

The realization that organic materials with conjugated double bonds, in particular noncrystalline polymers, are direct bandgap semiconductors, has recently led to a flurry of R&D activities in the domain of organic photonics. Organic light-emitting diodes (OLEDs), color displays, lighting panels, photodiodes, image sensors, photovoltaic cells, RF transponders, and tags, and several other organic photonic devices have not only been demonstrated but many are already commercially available. The special appeal of organic semiconductors stems from their potential for monolithic, low-cost integration of complete, large-area photonic microsystems, even on thin, flexible substrates. In Figure 15, such a monolithic photonic microsystem is illustrated schematically, combining a photovoltaic power supply, a photonic detector subsystem, analog and digital signal processing, as well as bidirectional optical communications with the outside world, possibly including also an on-chip display. The photonic detector subsystem typically consists of a light source, a light guiding structure that is sensitized – for example chemically – and a photodetector/image sensor subsection. In such a monolithic photonic microsystem, the term 'smart pixel array' obtains a much broader meaning, opening up a huge number of practical applications in essentially all domains of our daily and professional lives. This domain of organic semiconductors for integrated photonic microsystems is still largely unexplored, and it is offering exciting opportunities for research and product development.

Smart Pixel Arrays Beyond Electromagnetic Field Imaging

The sensing capabilities of smart pixel arrays are not restricted to electromagnetic radiation; this technology can also be used for the acquisition of other two- or three-dimensional physical fields. As an example, electrostatic imaging can be used for the temporally and spatially resolved acquisition of surface potential distributions in living cells. Electrostatic potential values of several hundred mV can be acquired with a precision of 1 mV and a temporal resolution below 1 millisecond. Other acquisition modalities include magnetostatic field imaging, for example by employing the Hall effect, or imaging of local electrostatic charge or current density distributions.

Summary

The relentless advances of semiconductor technology make it possible to integrate an increasing amount of photosensitive, analog, and digital functionality in the same smart pixel and on the same smart pixel array. Unusual photosensor devices can be fabricated with commercially available

semiconductor processes, implementing innovative designs and layouts, as well as novel electronic circuits, with which the physical limits of photosensing and photocharge processing may be reached. Novel opto-electronic microsystems can be developed, based on application-specific smart pixel arrays, either by realizing known optical measurement techniques more efficiently or by implementing new techniques, whose realization requires the availability of nonconventional image sensing functionality.

Already, smart pixel arrays are opening up a large number of new opportunities in photonics research and product development. The continuously increasing levels of integration lead to new forms of system-on-chip solutions for a wide range of practical applications. Smart pixel arrays can perform at the basic limits imposed by physics, and they have become indispensable tools in almost any type of research laboratory and any field of science and engineering.

List of Units and Nomenclature

Bandwidth	B	s^{-1}
Boltzmann's constant	k	J/K
Capacitance	C	F
Charge	Q	C
Charge carrier mobility	μ	$m^2/(V\,s)$
Charge noise variance	s_Q	C^2
Diffusivity	D	m^2/s
Distance	L	m
Dynamic range	D/R	dB
Field effect transistor transconductance	g	A/V
Integrated power measured with shaped photodiode	r	W
Intensity of electromagnetic wave	S, A, B	W/m^2
One-dimensional light intensity distribution	$p(x)$	W/m^2
One-dimensional width distribution	$w(x)$	m
Phase delay	φ	–
Pixel value at position (i,j) in an image	$P_{i,j}; R_{i,j}$	–
Temperature	T	K
Temporal frequency	ω	s^{-1}
Time	t	s
Two-dimensional convolution kernel	$w_{k,l}$	–

Diffraction Gratings

J Turunen and T Vallius, University of Joensuu, Joensuu, Finland

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

The classic textbook example of a diffraction grating is a periodic arrangement of parallel opaque wires: if a plane wave is incident upon such a structure, it is divided into a multitude of plane waves propagating in well-defined directions. In particular, the dramatic wavelength-dependence of these directions has attracted great interest ever since the potential of diffraction gratings in spectroscopy was realized in the late 1700s. Today spectroscopy is only one, though important, application of diffraction gratings. Gratings of many different forms belong to the basic building blocks in modern wave-optics-based design of optical elements and systems.

Grating Equations

Some examples of the wide variety of possible grating structures are illustrated in Figure 1, which shows the profiles of some commonly encountered diffraction gratings that are invariant in the y direction. These are known as linear gratings. Each grating may be of reflection type (the refractive index n_{III} is complex) or of transmission type (n_{III} is real). In all cases n_1 and n_2 can both be real or one of them can be complex. Here we assume that the incident field is a plane wave with wave vector $\boldsymbol{k}$ in the x–z plane; more general illumination waves can be represented as superpositions of plane waves.

Figure 1a illustrates a binary grating: in the modulated region $0 < z < H$ the refractive index alternates between n_1 and n_2, changing from one value to another at certain transition points within the period d. The structure in Figure 1b represents a sinusoidal surface-relief grating as an example of smooth grating profiles. Finally, Figure 1c shows a triangular grating profile.

The periodicity of a grating, illuminated by a plane wave, usually leads to the appearance of a set of reflected and transmitted plane waves (diffraction orders of the grating) that propagate in directions determined by the grating period d, the illumination wavelength λ, and the refractive indices n_{I} and n_{III} (see Figure 2a). These directions are obtained from the transmission grating equation:

$$n_{\mathrm{III}} \sin\theta_m = n_{\mathrm{I}} \sin\theta + m\lambda/d \qquad [1]$$

where m is the index of the diffraction order and θ_m is its propagation angle. For reflected orders (superscript r) one simply replaces n_{III} by n_{I} in eqn [1].

Obviously only a limited number of orders satisfy the condition $|\theta_m| < \pi/2$ and thereby represent conventional propagating plane waves. Higher, so-called evanescent orders are inhomogeneous waves that propagate along the grating surface and decay exponentially in the z direction. However, they cannot be ignored in grating analysis, as we shall see.

In the case of a biperiodic grating with a period $d_x \times d_y$ the propagation direction of the incident beam is defined by two angles θ and ϕ illustrated in Figure 2b. The grating equations now read as:

$$n_{\mathrm{III}} \sin\theta_{mn} \cos\phi_{mn} = n_{\mathrm{I}} \sin\theta \cos\phi + m\,\lambda/d_x \qquad [2]$$

$$n_{\mathrm{III}} \sin\theta_{mn} \sin\phi_{mn} = n_{\mathrm{I}} \sin\theta \sin\phi + n\lambda/d_y, \qquad [3]$$

where θ_{mn} and ϕ_{mn} define the propagation directions of the diffraction order with indices m and n. For reflected orders n_{III} is again replaced by n_{I}. These expressions apply also to the special case of linear gratings (limit $d_y \to \infty$) illuminated by a plane

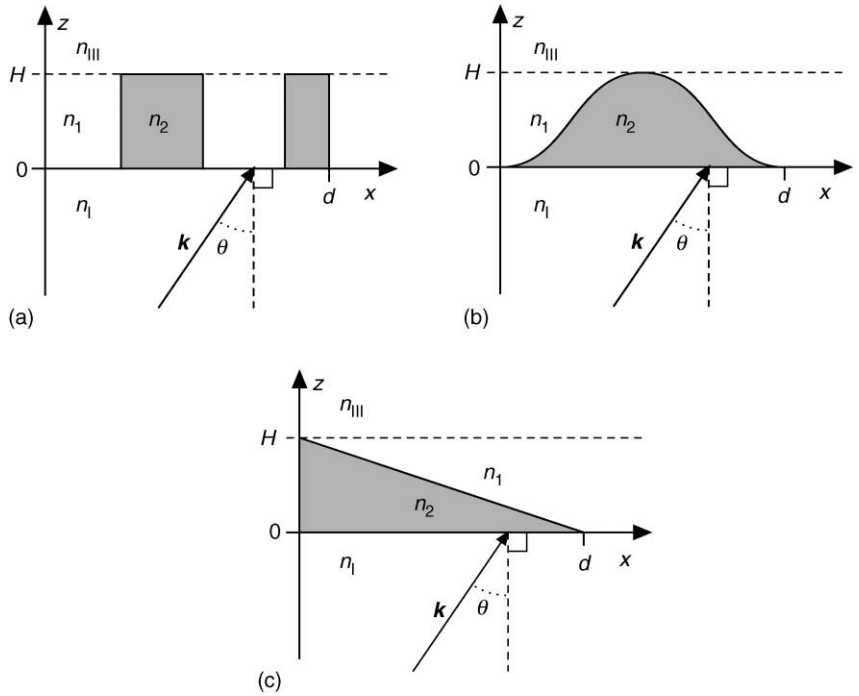

Figure 1 Examples of linear gratings. (a) Binary grating; (b) sinusoidal grating; (c) triangular grating. Here d is the grating period, H is the thickness of the modulated region, θ is the angle of incidence, and n denotes refractive index.

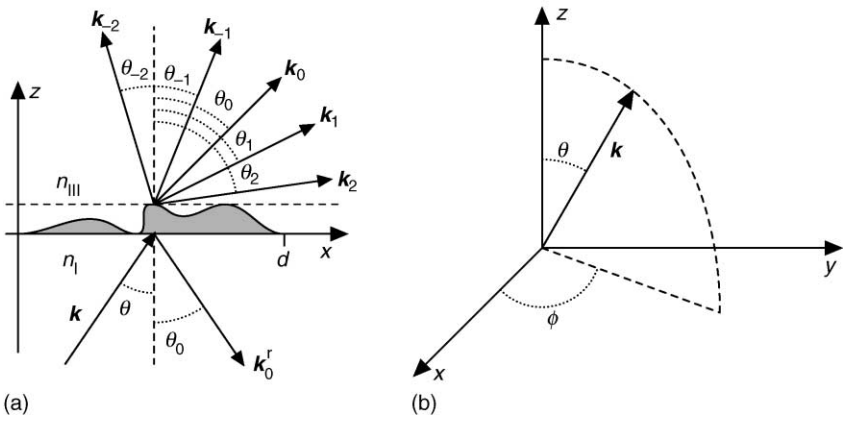

Figure 2 Diffraction by gratings. (a) Linear grating; (b) definitions of direction angles in the case of a biperiodic grating.

wave not propagating in the x–z plane (conical incidence).

Some two-dimensionally periodic gratings are illustrated in Figure 3. The structure illustrated in Figure 3a is an extension of a binary grating to the biperiodic geometry: here a single two-dimensional feature is placed within the grating period but, of course, more features with different outlines could be included as well. Moreover, each period could contain a continuous 'mountain-range' or consist of a 'New-York'-style pixel structure. Figure 3b illustrates a structure consisting of an array of rectangular-shaped holes pierced in a flat screen, while Figure 3c defines an array of isolated particles on a flat substrate. If the grid or the particles are metallic, surrounded by dielectrics from all sides, one speaks of inductive and capacitive structures, respectively: in the former case relatively free-flowing currents are induced in the metallic grid structure, but in the latter case the isolated metal particles become polarized (and therefore capacitive) when illuminated by an electromagnetic field.

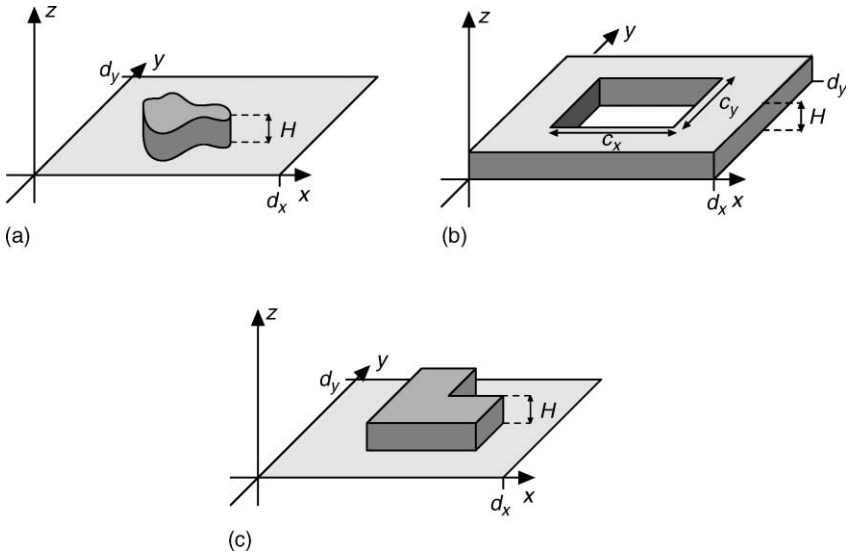

Figure 3 Examples of biperiodic gratings. (a) General binary grating; (b) inductive structure; (c) capacitive structure.

Grating Theory

Gratings equations provide exact knowledge of the propagation directions of the diffraction orders, but they give no information about the distribution of light among different orders. To obtain such information, one must in general solve Maxwell's equations exactly (rigorous diffraction theory), but within certain limits simpler methods are available. In all cases, however, the transmitted and reflected fields are represented as superpositions of plane waves that propagate in the directions allowed by the grating equations (these are known as Rayleigh expansions).

The most popular method for rigorous grating analysis is the Fourier Modal Method (FMM), though many alternative analysis methods exist. To understand the principle of FMM, consider first binary gratings. The field inside the modulated region $0 < z < H$ is represented as a superposition of waveguide modes, determined by imagining that the modulated region would extend from $x = -\infty$ to $x = \infty$. With given transition points the electric permittivity, its inverse, and the electric field inside the grating, can be represented in the form of Fourier series and one ends up with a matrix eigenvalue problem with finite dimensions when the matrices are truncated. A numerical solution of this problem provides a set of orthogonal modes that can propagate in the structure with certain propagation constants. The relative weights of the modes are then determined by applying the electromagnetic boundary conditions at the planes $z = 0$ and $z = H$ to match the modal expansions inside the grating with the plane-wave (Rayleigh) expansions of the fields in the homogeneous materials on both sides of the grating. This matching procedure, which is numerically implemented by solving a set of simultaneous linear equations, yields the complex amplitudes of the electric and magnetic field components associated with the reflected and transmitted diffraction orders of the grating.

Of main interest are the diffraction efficiencies, η_m (or η_{mn} for biperiodic gratings) of the orders, which tell the distribution of energy between different propagating orders. In electromagnetic theory the diffraction efficiency is defined as the z-component of the time-averaged Poynting vector associated with the particular order, divided by that of the incident plane wave.

Gratings with z-dependent surface profiles can be handled similarly if they are 'sliced' into a sufficient number of layers, in each of which the grating is modeled as a binary structure. The electromagnetic boundary conditions are applied at each slice boundary and the approach models the real continuous structure with arbitrary degree of accuracy when the number of the slices is increased; in practice it is usually sufficient to use approximately 20–30 slices for sufficiently accurate modeling of any continuous grating profile by FMM.

The main problem with rigorous techniques such as FMM is bad scaling. If, in the case of 1D modulated (or y-invariant) gratings, the period is increased by a factor of two, the computation time required to solve the eigenvalue problem is increased by a factor of around eight. Thus we have a d^3 type

scaling law. The situation is much worse for bi-periodic gratings, for which the exponent is around six. Thus no foreseeable developments in computer technology will solve the problem, and approximate analysis methods have to be sought. A multitude of such methods are under active development, but in this context we discuss the simplest example only.

If $d \gg \lambda$ and the grating profile does not contain wavelength-scale features, one can describe the effects of a grating on the incident field merely by considering it as a complex-amplitude-modulating object, which imposes a position-dependent phase shift and amplitude transmission (or reflection) coefficient on the incident field. This model is known as the thin-element approximation (TEA).

At normal incidence the plane-wave expansion of any scalar field component U immediately behind the grating (at $z = H$) takes the form:

$$U(x, y, H) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} T_{mn} \times \exp[\mathrm{i}2\pi(mx/d_x + ny/d_y)] \quad [4]$$

where

$$T_{mn} = \frac{1}{d_x d_y} \int_0^{d_x} \int_0^{d_y} U(x, y, H) \times \exp[-\mathrm{i}2\pi(mx/d_x + ny/d_y)]\mathrm{d}x\,\mathrm{d}y \quad [5]$$

are the complex amplitudes of the transmitted diffraction orders. In TEA the field at $z = H$ may be connected to the field at $z = 0$ (a unit-amplitude plane wave is assumed here) by optical path integration along a straight line though the modulated region of the grating:

$$U(x, y, H) = \int_0^H \exp\left[\mathrm{i}\frac{2\pi}{\lambda}\hat{n}(x, y, z)\right]\mathrm{d}z \quad [6]$$

where $\hat{n}(x, y, z) = n(x, y, z) + \mathrm{i}\kappa(x, y, z)$ is the complex refractive-index distribution in the region $0 < z < H$. With TEA the diffraction efficiencies can be calculated from a simple formula:

$$\eta_{mn} = |T_{mn}|^2 \quad [7]$$

which, however, ignores Fresnel reflections.

Equations [5]–[7] allow one to obtain closed-form expressions for the diffraction efficiencies η_{mn} in many grating geometries. For example, a y-invariant triangular profile with $H = \lambda/|n_\mathrm{I} - n_\mathrm{III}|$ gives $\eta_{-1} = 100\%$ if $n_1 = n_\mathrm{III}$, $n_2 = n_\mathrm{I}$, and $\theta = 0$. For a Q-level stair-step-quantized version of this grating we obtain:

$$\eta_m = \sin c^2(1/Q) \quad [8]$$

where $\sin cx = \sin(\pi x)/(\pi x)$. It should be noted, however, that these results are valid only for gratings with $d \gg \lambda$, even if they are corrected by Fresnel transmission losses at the interface between the two media.

Fabrication of Gratings

Gratings can be manufactured in a number of different ways, perhaps the simplest being to plot an equidistant array of straight black and white lines and to reduce the scale of the pattern photographically. This method can be readily adapted to the generation of more complex grating structures and diffractive elements, but it is not suitable for the production of high-quality gratings required in, for example, spectroscopy.

Ruling engines represent the traditional way of making gratings with periods of the order of the wavelength of light, especially for spectroscopic applications. These are machines equipped with a triangularly shaped diamond ruling edge and an interferometrically controlled two-dimensional mechanical translation stage that moves the substrate with respect to the ruling edge. Triangular-profile gratings of high quality can be produced with such machines, but the fabrication process is slow and the cost of the manufactured gratings is therefore high. In addition, even with real-time interferometric control of the ruling-edge position, it is impossible to avoid small local errors in the grating geometry. Such errors are particularly harmful if they are periodic since, according to the grating equation, these errors will generate spurious spectral lines known as ghosts. Such lines generated by the grating 'super-period' are weak but they may be confused with real spectral lines in the source spectrum. If the ruling errors are random, they result in 'pedestal-type' background noise. While such errors do not introduce ghosts, they nevertheless reduce the visibility of weak original spectral lines.

The introduction of lasers in the early 1960s made it possible to form stable and high-contrast interference patterns over a sufficient time-scale to allow the exposure of photographic films and other photosensitive materials such as polymeric photoresists. This interferometric technique offers a direct method for the fabrication of large diffraction gratings without appreciable periodic errors. With this technique it is possible to make highly regular

gratings for spectroscopy, but it does not permit easy generation of arbitrarily shaped grating structures. The two intersecting plane waves can also be generated with a linear grating using diffraction orders $m = +1$ and $m = -1$, suppressing the zero order by appropriate design of the grating profile and choosing the period in such a way that all higher transmitted orders are evanescent. This so-called phase mask technique is suitable, for example, for the exposure of Bragg gratings in fibers.

To generate arbitrary gratings one usually employs lithographic techniques. Some of the possible processes are illustrated in Figure 4. The exposure can be performed with scanning photon, electron, or ion beams, etc. The process starts with substrate preparation, i.e., coating it with a beam-sensitive layer known as resist, and in the case of electron beam exposure with a thin conductive layer to prevent charging. Following the exposure the resist is developed chemically, and in this process either the exposed or nonexposed parts of the resist are dissolved (depending on whether the resist is of positive or negative type), leading to a surface-relief profile. Several alternative fabrication steps may follow the development, depending on the desired grating type. If a high-contrast resist is used, a slightly 'undercut' profile as illustrated in Figure 4c is obtained. This can be coated with a metal layer and the resist can be 'lifted off' chemically. Thus a binary metallic grating is formed. To produce a binary dielectric profile one bombards the substrate with ions either purely mechanically (ion beam milling) or with chemical assistance (reactive ion etching), and finally the residual metal is dissolved.

Alternatively, the particle beam dose can be varied with position to obtain an analog profile in the resist after development. This resist profile can be transformed into the substrate by proportional etching, which leads to an analog dielectric surface-relief structure (see Figure 4f). This profile can be made

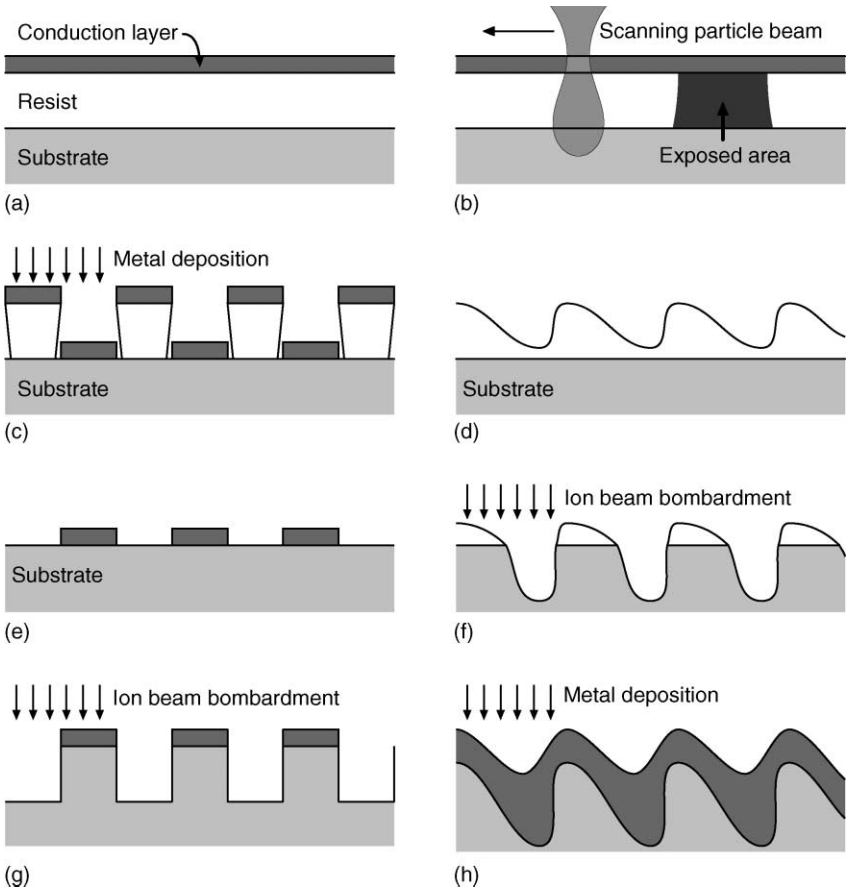

Figure 4 Lithographic processes for grating fabrication. (a) Substrate after preparation for electron beam exposure; (b) exposure by a scanning electron beam; (c) slightly undercut profile in hight-contrast resist after development, under metal film evaporation; (d) analog resist profile after variable-dose exposure and resist development; (e) finished binary metallic grating after resist lift-off; (f) transfer of the analog surface-relief profile into the substrate by proportional etching; (g) etching of a binary profile into the substrate with a metal mask; (h) growth of a metal film on an analog surface profile.

reflective by depositing a thin metal film on top of it. If large-scale fabrication of identical gratings is the goal, a thick ($\sim 100\ \mu m$) metal layer (for example nickel) can be grown on the surface by electroplating. After separation from the substrate, the electroplated metal film, which is a negative of the original profile, can be used as a stamp in replicating the original profile in plastics using methods such as hot embossing, ultraviolet radiation curing, and injection molding. In particular, the latter method provides the key to high-volume and low-cost production of various types of diffraction gratings and other grating-based diffractive structures in the industrial scale.

Some Grating Applications

We now proceed to describe a collection of representative grating applications. More exhaustive coverage of grating applications can be found in the Further Reading section at the end of this article.

Spectroscopic Gratings

The purpose of a spectroscopic grating is to divide the incident light into a spectrum, i.e., to direct different frequency components of the incident beam into different directions given by the grating (eqn [1]). When the grating period is reduced, the angular dispersion $\partial\theta_m/\partial\lambda$, and therefore the resolution of the spectrograph, increases.

In the numerical examples presented in Figure 5 we assume a reflection grating in a Littrow mount, i.e., $\theta_m^r = -\theta$. This mount is common in spectroscopy; it obviously requires that the grating is rotated when the spectrum is scanned. We see from eqn [1] that in the Littrow mount:

$$\sin\theta = \frac{m\lambda}{2d} \qquad [9]$$

By inserting this result back into eqn [1] and differentiating we obtain a quantitative measure for dispersion in the Littrow mount:

$$\frac{\partial\theta_m}{\partial\lambda} = -\frac{m}{2d\cos\theta} \qquad [10]$$

We consider TE polarization (electric field is linearly polarized in the y-direction) and order $m = -1$, optimize H to give maximum efficiency at $\lambda_0 = 550$ nm, and plot the diffraction efficiency η_{-1} over the visible wavelength range for two values of the grating period, $d = \lambda_0$ and $d = 2\lambda_0$. Rigorous diffraction theory is used with $n_I = n_2 = 1$, and the metal is assumed to be aluminum (n_1 and n_{III} are complex-valued).

In Figure 5a binary gratings with one groove (width $d/2$) per period is considered. Parametric optimization gives $H = 422$ nm if $d = 1\lambda$, and $H = 168$ nm if $d = 2\lambda$. Figure 5b illustrates the results for sinusoidal gratings with $H = 345$ nm if $d = 1\lambda$, and

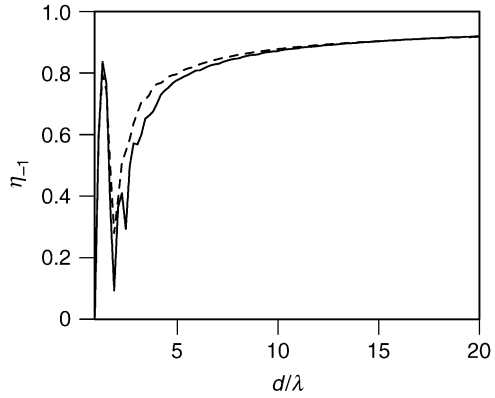

Figure 7 Diffraction efficiency versus wavelength for triangular transmission gratings illuminated at normal incidence. Solid lines: TE polarization. Dashed lines: TM polarization.

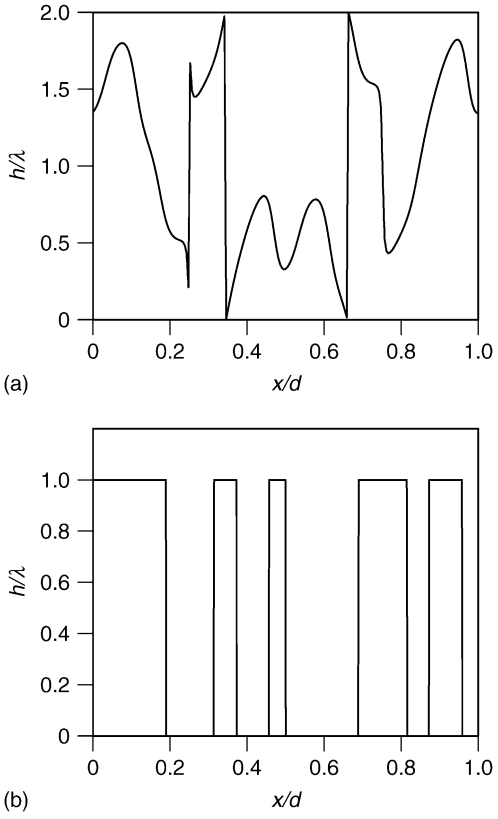

Figure 8 Surface-relief profiles of (a) continuous and (b) binary $1 \rightarrow 8$ beamsplitter gratings.

$H = 520$ nm if $d = 2\lambda$. Finally, triangular gratings with $H = 431$ nm if $d = 1\lambda$, and $H = 316$ nm if $d = 2\lambda$, are considered. The triangular grating profile is seen to be the best choice in general.

Diffractive Lenses

Diffractive lenses are gratings with locally varying period and groove orientation. Figure 6 illustrates the central part of a diffractive microlens fabricated by lithographic methods. It is seen to consist of concentric zones with radially decreasing width.

The phase transmission function of an ideal diffractive focusing lens can be obtained by a simple optical path calculation, and is given by

$$\phi(r) = \frac{2\pi}{\lambda_0}(f - \sqrt{f^2 + r^2}) \approx -\frac{\pi}{\lambda_0 f} r^2 \qquad [11]$$

where f is the focal length, r is the radial distance from the optical axis, and the approximate expression is valid in the paraxial region $r \ll f$. Here λ_0 is the design wavelength, which determines the modulation depth of the locally blazed grating profile:

$$H = \frac{\lambda_0}{n(\lambda_0) - 1} \qquad [12]$$

and $n(\lambda_0)$ is the refractive index of the dielectric material at $\lambda = \lambda_0$.

The zone boundaries r_n are defined by the condition $\phi(r_n) = -2\pi m$, and therefore we obtain from eqn [11]:

$$r_n = \sqrt{2nf\lambda_0 + (n\lambda_0)^2} \approx \sqrt{2nf\lambda_0} \qquad [13]$$

Obviously, when the numerical aperture of the lens is large, the zone width in the outer regions of the lens is reduced to values of the order of λ. Figure 7 illustrates the local diffraction efficiency in different part of a diffractive lens: we use the order $m = -1$ of a locally triangular diffraction grating of the

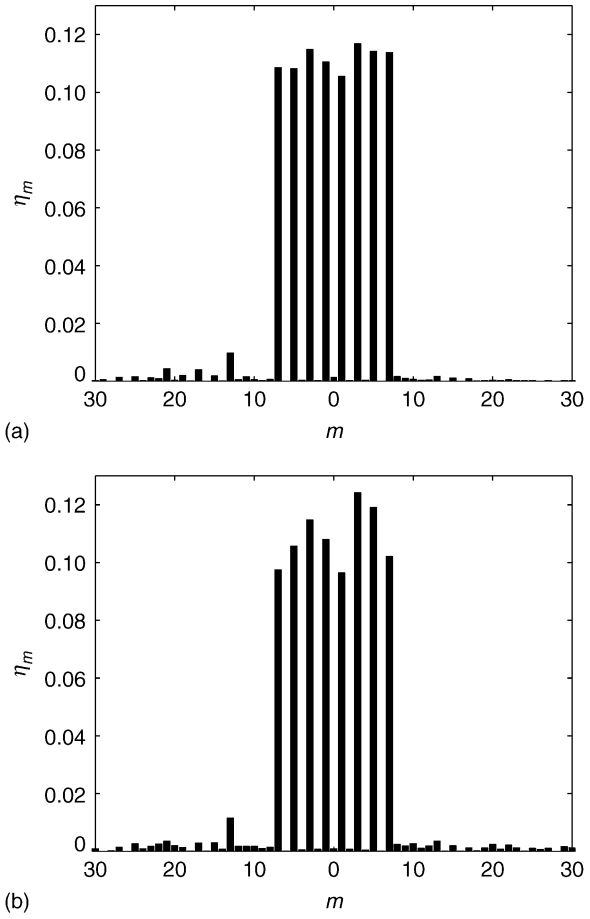

Figure 9 Diffraction pattern produced by a continuous-profile beamsplitter grating when (a) $d = 200\lambda$ and (b) $d = 50\lambda$.

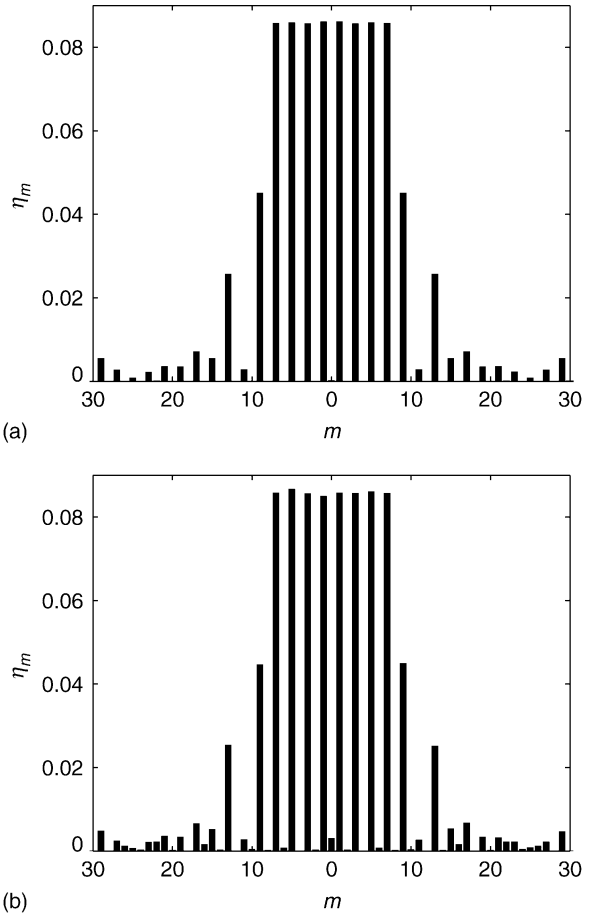

Figure 10 Diffraction pattern produced by a binary beamsplitter grating grating when (a) $d = 200\lambda$ and (b) $d = 50\lambda$.

type shown in Figure 1c with $\theta = 0$, assuming that $n_{\mathrm{I}} = n_2 = 1.5$ (fused silica) and $n_1 = n_{\mathrm{III}} = 1$. The efficiency η_{-1} is calculated as a function of λ using rigorous diffraction theory for both TE and TM polarization (the electric vector points in the groove direction in the TE case and is perpendicular to it in the TM case). It is seen that the local efficiency of the lens becomes poor in regions where the local grating period is small, and thus diffractive lenses operate best in the paraxial region (it is, however, possible to obtain improved non-paraxial performance by optimizing the local grating profile).

A factor that limits the use of diffractive lenses with polychromatic light is their large chromatic aberration: in the paraxial limit the focal length depends on the wavelength according to the formula:

$$f(\lambda) = \frac{\lambda_0}{\lambda} f \qquad [14]$$

However, since the dispersion of a grating has an opposite sign compared to the diffraction of a prism, a weak positive diffractive lens can be combined with a relatively strong positive refractive lens to form a single-element achromatic lens. Such a hybrid lens is substantially thinner and lighter than a conventional all-refractive achromatic lens made of crown and flint glasses.

Beam Splitter Gratings

Multiple beamsplitters, also known as array illuminators, are gratings with sophisticated periodic structure that are capable of transforming an incident plane wave into a set of diffraction orders with a specified distribution of diffraction efficiencies. Most often one wishes to obtain a one- or two-dimensional array of diffracted plane waves with equal efficiency. This goal can be achieved by appropriate design of the grating profile, which may be of binary, multilevel, or continuous form.

Figure 8 illustrates binary and continuous grating profiles capable of dividing one incident plane wave into eight diffracted plane waves (central odd-numbered orders of the grating) with equal efficiency in view of TEA. Figure 9 shows the distribution of energy among the different diffraction orders in and around the array produced by the continuous profile, evaluated by rigorous theory for two different grating periods, while Figure 10 gives corresponding results for the binary grating.

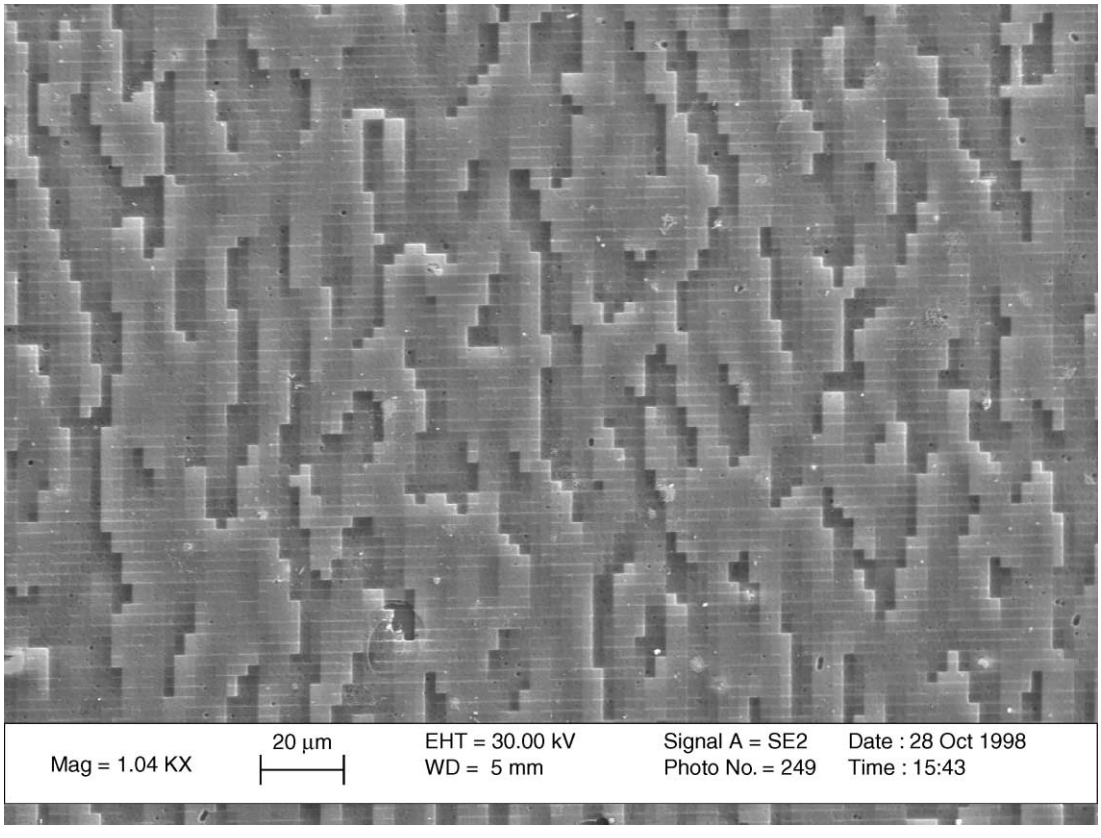

Figure 11 Scanning electron micrograph of a sophisticated beamsplitter grating.

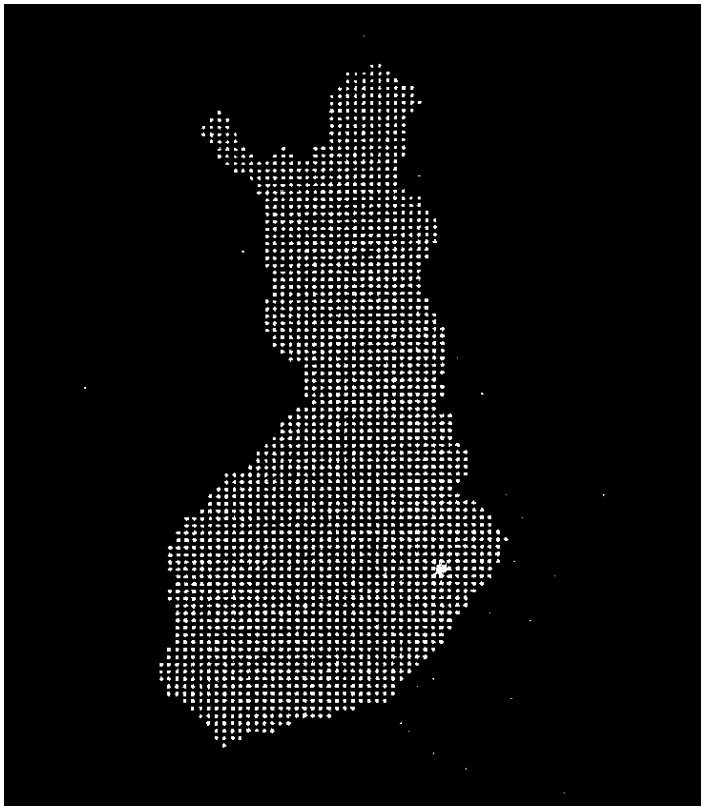

Figure 12 The far-field diffraction pattern produced by the grating in Figure 11.

The fraction of incident energy that ends up in the desired eight orders is 72% for the binary grating and 96% for the continuous grating according to TEA, making the latter more attractive from a theoretical viewpoint. However, the continuous profile is more difficult to fabricate accurately than the binary one, especially for small values of the ratio d/λ. Moreover, the array uniformity produced by the continuous profile degrades faster than that of the binary profile when the period is reduced.

An example of the structure of a biperiodic grating that is capable of forming a large, shaped array of diffraction orders with equal efficiency is presented in Figure 11. Figure 12 shows the far-field diffraction pattern produced by this element: the shape of Finland with the location of the town of Joensuu highlighted by placing the zero diffraction order on the appropriate position on the map (the apparent nonuniformity in the array is mostly due to the finite resolution of the CCD detector).

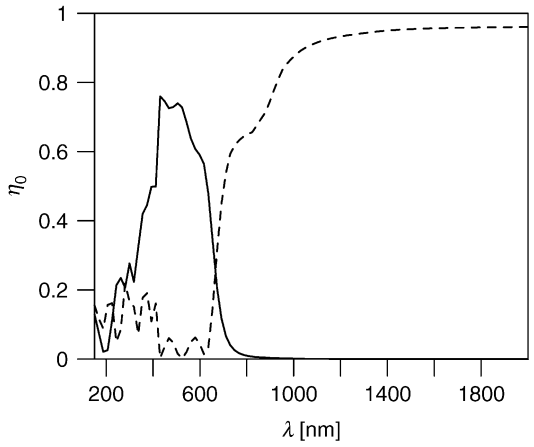

Figure 13 Zero order spectral transmission (solid line) and reflection (dashed line) of an aluminium inductive grid filter with 400 nm period.

Inductive Grid Filters

As a final example we consider a scaled-down version of a device well known from the door of a microwave oven: one can see in through the holes pierced in the metallic screen in the oven door, but the microwaves are trapped inside because their wavelengths are large in comparison with the dimensions of the holes. Another example of these inductive grid filters is found in large radio telescope mirrors for centimeter-scale

wavelengths, which are wide-grid structures rather than smoothly curved metal surfaces.

Figure 13 illustrates the spectral transmission and reflection curves of an inductive grid filter of the type illustrated in Figure 3b. We assume that $d_x = d_y = d = 400$ nm, $c_x = c_y = c = 310$ nm, $H = 500$ nm, and that the grid is a self-supporting structure ($n_{\mathrm{I}} = n_{\mathrm{III}} = 1$) made of aluminum. Only the zero reflected and transmitted orders propagate when $\lambda > d$, but other orders (with rather low efficiency) appear for smaller wavelengths. We see that the filter reflects infrared radiation effectively, but transmits a substantial part of radiation at visible and shorter wavelength regions.

List of Units and Nomenclature

Complex field amplitude	U
Diffraction angles [rad]	θ, ϕ
Diffraction efficiency	η
Focal length [m]	f, f_0
Grating period [m]	d
Grating thickness [m]	H
Number of quantization levels	Q
Phase function [rad]	$\phi(r)$
Refractive index	n
Wavelength [m]	λ, λ_0
Wave vector [m^{-1}]	$\mathbf{k}$

Introduction

Geometrical optics does a reasonable job of describing the propagation of light in free space unless that light encounters an obstacle. Geometrical optics predicts that the obstacle would cast a sharp shadow. On one side of the shadow's edge would be a bright uniform light distribution, due to the incident light, and on the other side there would be darkness. Close examination of an actual shadow edge reveals, however, dark fringes in the bright region and bright fringes in the dark region. This departure from the predictions of geometrical optics was given the name diffraction by Grimaldi.

There is no substantive difference between diffraction and interference. The separation between the two subjects is historical in origin and is retained for pedagogical reasons. Since diffraction and interference are actually the same physical process, we expect the observation of diffraction to be a strong function of the coherence of the illumination. With incoherent sources, geometrical optics is usually all that is needed to predict the performance of an optical system and diffraction can be ignored except at dimensions on the scale of a wavelength. With light sources having a large degree of spatial coherence, it is impossible to neglect diffraction in any analysis.

Even though diffraction produced by most common light sources and objects is a small effect, it is possible to observe diffraction without special equipment. By viewing a light source through a slit formed by two fingers that are nearly touching, fringes can be observed. Diffraction is used by photographers and television cameramen to provide artistic highlights in an image containing small light sources. They accomplish this by placing a screen in front of the camera lens. Light from point sources in the field of view is diffracted by the screen and produces 'stars' in the image. A third place where diffraction effects are easily observed is when a mercury or sodium streetlight, a few hundred meters away, is viewed through a sheer curtain.

Fresnel originally developed an approximate scalar theory based on Huygens' principle which states that:

> Each point on a wavefront can be treated as a source of a spherical wavelet called a secondary wavelet or a Huygens' wavelet. The envelope of these wavelets, at some later time, is constructed by finding the tangent to the wavelets. The envelope is assumed to be the new position of the wavefront.

Rather than simply using the wavelets to construct an envelope, Fresnel's scalar theory assumes that the Huygens' wavelets interfere to produce a new wavefront (*see* **Diffraction:** Fresnel Diffraction).

A rigorous diffraction theory is based on Maxwell's equations and uses the boundary conditions associated with the obstacle to calculate a field scattered by the obstacle. The origins of this scattered field are currents induced in the obstacle by the incident field. The scattered field is allowed to interfere with the incident field to produce a resultant diffracted field. The application of the rigorous theory is very difficult and for most problems an approximate scalar theory developed by Kirchhoff and Sommerfeld is used.

Kirchhoff Theory of Diffraction

Kirchhoff's theory was based on the elastic theory of light but can be reformulated into a vector theory. Here we will limit our discussion to the scalar formulation. Given an incident wave, φ, we wish to calculate the optical wave at point P_0, in Figure 1, located at $\mathbf{r}_0$, in terms of the wave's value on a surface, S, that we construct about the observation point.

To obtain a solution to the wave equation at the point, P_0, we select as a Green's function the one proposed by Kirchhoff (Box 1), a unit amplitude spherical wave, expanding about the point at $\mathbf{r}_0$, denoted by Ψ, and then apply Green's theorem (see Box 2). We will run into boundary condition problems as we proceed with the derivation of the solution. Sommerfeld removed the problems by assuming a slightly more complex Green's function (see Box 1). We will limit our discussion to the Kirchhoff Green's function.

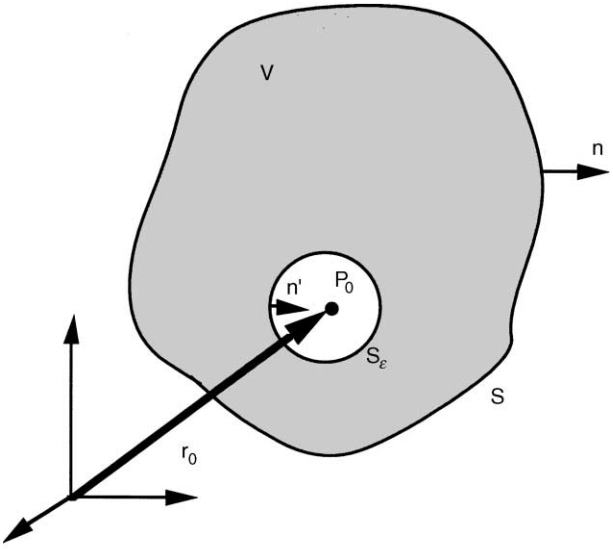

Figure 1 Region of integration for solution of Kirchhoff's diffraction integral. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Green's theorem requires that there be no sources (singularities) inside the surface S but our Green's function [1] is based on a source at r_0. We eliminate the source by constructing a small spherical surface S_ε, of radius ε, about $\mathbf{r}_0$, excluding the singularity at $\mathbf{r}_0$ from the volume of interest, shown in gray in Figure 1. The surface integration that must be performed in Green's theorem is over the surface $S' = S + S_\varepsilon$.

Within the volume enclosed by S′, the Green's function, Ψ, and the incident wave, φ, satisfy the scalar Helmholtz equation so that the volume integral can be written as

$$\iiint_V (\Psi\nabla^2\varphi - \varphi\nabla^2\Psi)\mathrm{d}\nu = -\iiint_V (\Psi\varphi k^2 - \varphi\Psi k^2)\mathrm{d}\nu \qquad [7]$$

The right side of [7] is identically equal to zero. This fact allows us to use [6] to produce a simplified statement of Green's theorem:

$$\iint_{S'} \left(\Psi\frac{\partial\varphi}{\partial n} - \varphi\frac{\partial\Psi}{\partial n}\right)\mathrm{d}s = 0 \qquad [8]$$

Box 1

Green's Function

1. **Kirchhoff Green's function**: Assume that the wave, Ψ, is due to a single point source at $\mathbf{r}_0$. At an observation point, $\mathbf{r}_1$, the Green's function is given by

$$\Psi(\mathbf{r}_1) = \frac{e^{-i\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}, \qquad [1]$$

   where $r_{01} = |\mathbf{r}_{01}| = |\mathbf{r}_1 - \mathbf{r}_0|$ is the distance from the source of the Green's function, at $\mathbf{r}_0$, to the observation position, at $\mathbf{r}_1$.
2. **Sommerfeld Green's function**: Assume that there are two point sources, one at P_0 and one at P_0' (see Figure 2 where the source, P_0', is positioned to be the mirror image of the source at P_0 on the opposite side of the screen, thus

$$r_{01} = r_{01}' \qquad \cos(\hat{\mathbf{n}}, \mathbf{r}_{01}) = -\cos(\hat{\mathbf{n}}, \mathbf{r}_{01}') \qquad [2]$$

   A Green's function that could be used is

$$\Psi' = \frac{e^{-i\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}} - \frac{e^{-i\mathbf{k}\cdot\mathbf{r}_{01}'}}{r_{01}'} \qquad [3a]$$

   or

$$\Psi' = \frac{e^{-i\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}} + \frac{e^{-i\mathbf{k}\cdot\mathbf{r}_{01}'}}{r_{01}'} \qquad [3b]$$

Box 2

Green's Theorem

To calculate the complex amplitude, $\tilde{E}(\mathbf{r})$, of a wave at an observation point defined by the vector $\mathbf{r}$, we need to use a mathematical relation known as Green's Theorem. Green's theorem states that, if φ and Ψ are two scalar functions that are well behaved, then

$$\iint_S (\varphi \nabla\Psi\cdot\hat{\mathbf{n}} - \Psi\nabla\varphi\cdot\hat{\mathbf{n}})\mathrm{d}s = \iiint_V (\varphi\nabla^2\Psi - \Psi\nabla^2\varphi)\mathrm{d}\nu \qquad [4]$$

The vector identities

$$\nabla\Psi\cdot\hat{\mathbf{n}} = \frac{\partial\Psi}{\partial n} \qquad \nabla\varphi\cdot\hat{\mathbf{n}} = \frac{\partial\varphi}{\partial n} \qquad [5]$$

allow Green's theorem to be written as

$$\iint_S \left[\varphi\frac{\partial\Psi}{\partial n} - \Psi\frac{\partial\varphi}{\partial n}\right]\mathrm{d}s = \iiint_V [\varphi\nabla^2\Psi - \Psi\nabla^2\varphi]\mathrm{d}\nu \qquad [6]$$

This equation is the prime foundation of scalar diffraction theory but only the proper choice of Ψ, φ and the surface, S, allows direct application to the diffraction problem.

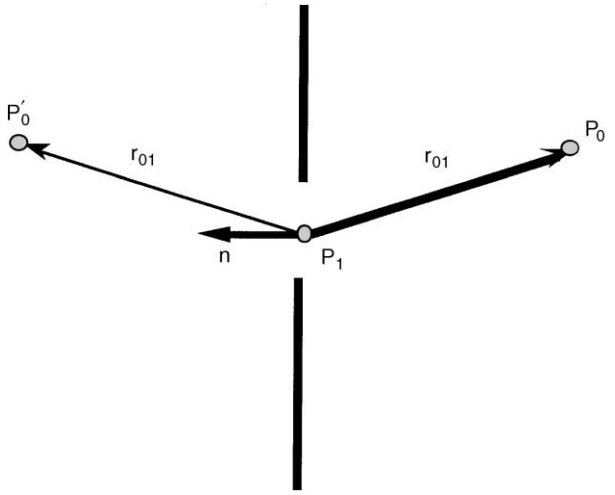

Figure 2 Geometry for the Sommerfeld Green's function. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Because the integral over the combined surfaces, S and S_ε, is equal to zero, the integral over the surface S must equal the negative of the integral over the surface, S_ε:

$$-\iint_{S_\varepsilon}\left(\Psi\frac{\partial\varphi}{\partial n}-\varphi\frac{\partial\Psi}{\partial n}\right)\mathrm{d}s=\iint_{S}\left(\Psi\frac{\partial\varphi}{\partial n}-\varphi\frac{\partial\Psi}{\partial n}\right)\mathrm{d}s \quad [9]$$

To perform the surface integrals, we must evaluate the Green's function on the surface, S′. We therefore select $\mathbf{r}_1$, the vector defining the observation point, to be on either of the two surfaces that make up S′. The derivative, $\partial\Psi/\partial n$, to be evaluated is

$$\frac{\partial\Psi}{\partial n}=\frac{\partial\Psi}{\partial r}\frac{\partial r}{\partial n}$$
$$=\left(-\mathrm{i}k\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}-\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}^2}\right)\cos(\mathrm{n},\mathbf{r}_{01}) \quad [10]$$

where $\cos(\hat{\mathbf{n}},\mathbf{r}_{01})$ is the cosine of the angle between the outward normal $\hat{\mathbf{n}}$ and the vector $\mathbf{r}_{01}$, the vector between points P_0 and P_1. (Note from Figure 1 that the outward normal on S_ε is inward, toward P_0, while the normal on S is outward, away from P_0.)

For example if $\mathbf{r}_1$ were on S_ε, then

$$\cos(\mathbf{n},\mathbf{r}_{01})=-1, \quad [11]$$

$$\frac{\partial\Psi(\mathbf{r}_1)}{\partial n}=\left[\frac{1}{\varepsilon}+\mathrm{i}k\right]\frac{\mathrm{e}^{-\mathrm{i}k\varepsilon}}{\varepsilon}, \quad [12]$$

where ε is the radius of the small sphere we constructed around the point at P_0.

We now use [10] to rewrite the two integrals in [9]. The integral over the surface S_ε is

$$\iint_{S_\varepsilon}\left(\Psi\frac{\partial\varphi}{\partial n}-\varphi\frac{\partial\Psi}{\partial n}\right)\mathrm{d}s$$
$$=\iint_{S_\varepsilon}\left[\frac{\partial\varphi}{\partial n}\frac{\mathrm{e}^{-\mathrm{i}k\varepsilon}}{\varepsilon}-\varphi\frac{\mathrm{e}^{-\mathrm{i}k\varepsilon}}{\varepsilon}\left(\frac{1}{\varepsilon}+\mathrm{i}k\right)\right]$$
$$\times\varepsilon^2\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \quad [13]$$

while the integral over the surface S is

$$\iint_{S}\left[\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}\frac{\partial\varphi}{\partial n}-\varphi\frac{\partial}{\partial n}\left(\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}\right)\right]r^2\sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi \quad [14]$$

The omitted volume contained within the surface S_ε is allowed to shrink to zero by taking the limit as $\varepsilon\to 0$. Equation [14] will not be affected by taking the limit. The first and last terms of the right side of [13] go to zero as $\varepsilon\to 0$ because they contain $\varepsilon\mathrm{e}^{-\mathrm{i}k\varepsilon}$. The second term in [13] contains $\mathrm{e}^{-\mathrm{i}k\varepsilon}$ which goes to 1 as $\varepsilon\to 0$. Therefore, in the limit as $\varepsilon\to 0$, [9] becomes

$$\varphi(\mathbf{r}_0)=\frac{1}{4\pi}\iint_{S}\left[\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}\frac{\partial\varphi}{\partial n}-\varphi\frac{\partial}{\partial n}\left(\frac{\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{r}_{01}}}{r_{01}}\right)\right]\mathrm{d}s \quad [15]$$

which is sometimes called the integral theorem of Kirchhoff. By carefully selecting the surface of integration in [15], we can calculate the diffraction field observed at P_0 produced by an aperture in an infinite opaque screen.

Assume that a source at P_2 in Figure 3 produces a spherical wave that is incident on an infinite, opaque screen from the left. To find the field at P_0 in Figure 3, we apply [15] to the surface $S_1+S_2+\Sigma$, where S_1 is a plane surface adjacent to the screen, Σ is that portion of S_1 in the aperture and S_2 is a large spherical surface, of radius R, centered on P_0, see Figure 3. The first question to address is how to calculate the contribution from S_2 or better yet how do we show we can ignore contributions from S_2. As R increases, Ψ and φ will decrease as $1/R$. However, the area of integration increases as R^2 so the $1/R$ fall-off is not a sufficient reason for neglecting the contribution of the integration over S_2.

On the surface S_2, the Green's function and its derivative are

$$\Psi=\frac{\mathrm{e}^{-\mathrm{i}kR}}{R} \quad [16]$$

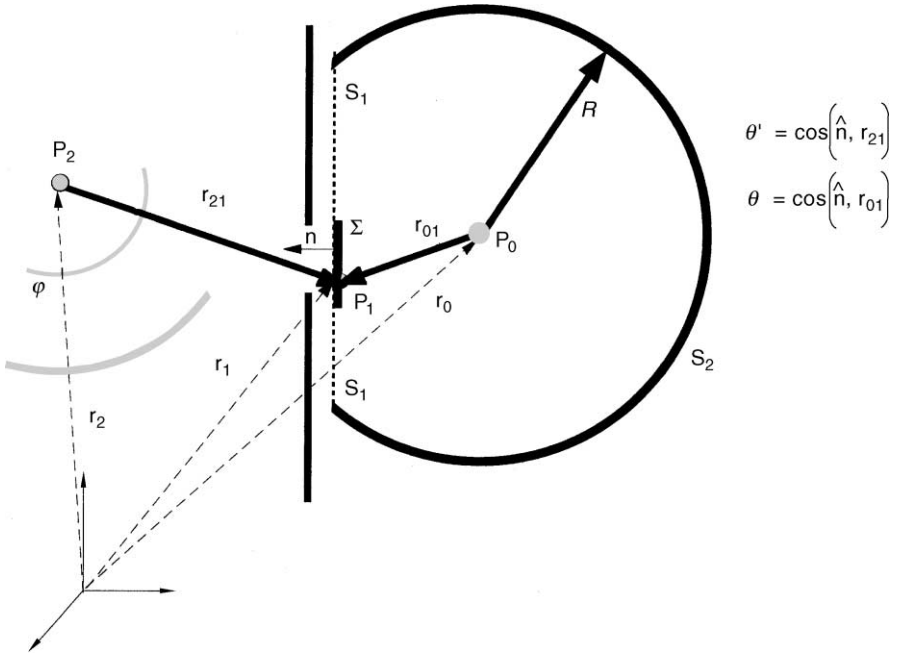

Figure 3 Integration surface for diffraction calculation. P_2 is the source and P_0 is the point where the field is to be calculated. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

$$\frac{\partial \Psi}{\partial n} = \left(-ik - \frac{1}{R} \right) \frac{e^{-ikR}}{R} \approx -ik\Psi \qquad [17]$$

where the approximate equality is for large R. Thus, the integral over S_2 for large R is

$$\int\int_{S_2} \left[\Psi \frac{\partial \varphi}{\partial n} + \varphi(ik\Psi) \right] ds$$

$$= \int\int_{S_2} \Psi \left(\frac{\partial \varphi}{\partial n} + ik\varphi \right) R^2 \sin\theta \, d\theta \, d\phi \qquad [18]$$

The quantity $R\Psi = e^{-ik \cdot R}$ is finite as $R \to \infty$ so for the integral to vanish, we must have

$$\lim_{R \to \infty} R \left(\frac{\partial \varphi}{\partial n} + ik\varphi \right) = 0 \qquad [19]$$

This requirement is called the Sommerfeld radiation condition and is satisfied if $\varphi \to 0$ as fast as $1/R$ (for example, a spherical wave). Since the illumination of the screen will be a spherical wave, or at least a linear combination of spherical waves, we should expect the integral over S_2 to make no contribution (it is exactly zero).

Another way to insure that surface S_2 makes no contribution is to assume that the light turns on at time t_0. At a later time, t, when we desire to know the field at P_0, the radius of S_2 is $R > c\ (t - t_0)$ which physically means that the light has not had time to reach S_2. In this situation, there can be no contribution from S_2. This is not a perfect solution because when the wave is of finite duration it can no longer be considered monochromatic.

We should expect the major contribution in the integral over S_1 to come from the portion of the surface in the aperture, Σ. We make the following assumptions about the incident wave, φ (these assumptions are known as St. Venaut's hypothesis or Kirchhoff's boundary conditions)

1. We assume that, in the aperture, φ and $\partial\varphi/\partial n$ have the values they would have if the screen were not in place.
2. On the portion of S_1 not in the aperture, φ and $\partial\varphi/\partial n$ are identically zero.

The Kirchhoff boundary conditions allow the screen to be neglected, reducing the problem to an integration only over the aperture. It is surprising that the assumptions about the contribution of the surface S_2 and the screen yield very accurate results (as long as polarization is not important, the aperture is large with respect to the wavelength, and we don't get too close to the aperture).

Mathematically the Kirchhoff boundary conditions are incorrect. The two Kirchhoff boundary conditions imply that the field is zero everywhere behind the screen, except in the aperture, which makes Ψ and $\partial\Psi/\partial n$ discontinuous on the boundary of the aperture. Another problem with the boundary conditions is

that Ψ and $\partial\Psi/\partial n$ are known only if the problem has already been solved.

The Sommerfeld Green's functions will remove the inconsistencies of the Kirchhoff theory. If we use the Green's function [3a] then Ψ vanishes in the aperture while $\partial\Psi/\partial n$ can assume the value required by Kirchhoff's boundary conditions. If we use the Green's functions [3b] then the converse holds, i.e. $\partial\Psi/\partial n$ is zero in the aperture. This improved Green's function makes the problem harder with little gain in accuracy so we will retain the Kirchhoff formalism.

As a result of the above discussion, the surface integral [15] is only performed over the surface, Σ, in the aperture. The evaluation of the Green's function on this surface can be simplified by noting that normally $r_{01} \gg \lambda$, i.e., $k \gg 1/r_{01}$, thus on Σ,

$$\begin{aligned}\frac{\partial\Psi}{\partial n} &= \cos(\mathbf{n}, \mathbf{r}_{01})\left(-ik - \frac{1}{r_{01}}\right)\frac{e^{-ik\cdot r_{01}}}{r_{01}} \\ &\approx -ik\cos(\hat{\mathbf{n}}, \mathbf{r}_{01})\frac{e^{-ik\cdot r_{01}}}{r_{01}}\end{aligned} \quad [20]$$

Substituting this approximate evaluation of the derivative into [15] yields

$$\varphi(\mathbf{r}_0) = \frac{1}{4\pi}\iint_{\Sigma}\frac{e^{-ik\cdot r_{01}}}{r_{01}}\left[\frac{\partial\varphi}{\partial n} + ik\varphi\cos(\hat{\mathbf{n}}, \mathbf{r}_{01})\right]ds \quad [21]$$

The source of the incident wave is a point source located at P_2, with a position vector, $\mathbf{r}_2$, measured with respect to the coordinate system and a distance $|\mathbf{r}_{21}|$ away from P_1, a point in the aperture (see Figure 3). The incident wave is therefore a spherical wave of the form

$$\varphi(\mathbf{r}_{21}) = A\frac{e^{-ik\cdot r_{21}}}{r_{21}} \quad [22]$$

which fills the aperture. Here also we will assume that $r_{21} \gg \lambda$ so that the derivative of the incident wave assumes the same form as [20]. Then [21] can be written

$$\varphi(\mathbf{r}_0) = \frac{iA}{\lambda}\iint_{\Sigma}\frac{e^{-ik\cdot(r_{21}+r_{01})}}{r_{21}r_{01}} \times\left[\frac{\cos(\hat{\mathbf{n}}, \mathbf{r}_{01}) - \cos(\hat{\mathbf{n}}, \mathbf{r}_{21})}{2}\right]ds \quad [23]$$

This relationship is called the Fresnel–Kirchhoff diffraction formula. It is symmetric with respect to r_{01} and r_{21}, making the problem identical when the source and measurement point are interchanged.

A physical understanding of [23] can be obtained if it is rewritten as

$$\varphi(\mathbf{r}_0) = \iint_{\Sigma}\Phi(\mathbf{r}_{21})\frac{e^{-ik\cdot r_{01}}}{r_{01}}ds \quad [24]$$

The field at P_0 is due to the sum of an infinite number of secondary Huygens sources in the aperture Σ. The secondary sources are point sources radiating spherical waves of the form

$$\Phi(\mathbf{r}_{21})\frac{e^{-ik\cdot r_{01}}}{r_{01}} \quad [25]$$

with amplitude $\Phi(r_{21})$, defined by

$$\Phi(\mathbf{r}_{21}) = \frac{i}{\lambda}\left[A\frac{e^{-ik\cdot r_{21}}}{r_{21}}\right]\left[\frac{\cos(\hat{\mathbf{n}}, \mathbf{r}_{01}) - \cos(\hat{\mathbf{n}}, \mathbf{r}_{21})}{2}\right] \quad [26]$$

The imaginary constant, i, causes the wavelets from each of these secondary sources to be phase shifted with respect to the incident wave. The obliquity factor, in the amplitude [26]

$$\tfrac{1}{2}[\cos(\hat{\mathbf{n}}, \mathbf{r}_{01}) - \cos(\hat{\mathbf{n}}, \mathbf{r}_{21})] \quad [27]$$

causes the secondary sources to have a forward directed radiation pattern.

If we had used the Sommerfeld Green's function, the only modification to our result would be a change in the obliquity factor to $\cos(\mathbf{n},\mathbf{r}_{01})$. In our discussions below we will assume that the angles are all small, allowing the obliquity factor to be replaced by 1 so that in the remaining discussion the choice of Green's function has no impact.

We will assume the source of light is at infinity, $z_1 = \infty$ in Figure 3, so that the aperture is illuminated by a plane wave, traveling parallel to the z-axis. With this assumption

$$\theta' = \cos(\mathrm{n}, \mathbf{r}_{21}) \approx -1 \quad [28]$$

We will also make the paraxial approximation which assumes that the viewing position is close to the z-axis, leading to

$$\theta = \cos(\mathbf{n}, \mathbf{r}_{01}) \approx 1 \quad [29]$$

With these assumptions eqn [24] becomes identical to the Huygens–Fresnel integral discussed in the section on Fresnel diffraction:

$$\tilde{E}(\mathbf{r}_0) = \frac{i}{\lambda}\int\int_{\Sigma}\frac{\tilde{E}_i(\mathbf{r})}{R}e^{-ik\cdot R}\,ds \quad [30]$$

The modern interpretation of the Fresnel–Kirchhoff (or now in the small-angle approximation, the Fresnel–Huygens) integral is to view it as a convolution integral. By considering free space to be a linear system, the result of propagation can be calculated by convolving the incident (input) wave with the impulse response of free space (our Green's function),

$$\frac{i}{\lambda}\frac{e^{-ik\cdot R}}{R} \qquad [31]$$

The job of calculating diffraction has only begun with the derivation of the Fresnel–Kirchhoff integral. In general, an analytic expression for the integral cannot be found because of the difficulty of performing the integration over R. There are two approximations that will allow us to obtain analytic expressions of the Fresnel–Kirchhoff integral. In both approximations, all dimensions are assumed to be large with respect to the wavelength. In one approximation, the viewing position is assumed to be far from the obstruction; the resulting diffraction is called Fraunhofer diffraction and will be discussed here. The second approximation, which leads to Fresnel diffraction, assumes that the observation point is nearer the obstruction, to be quantified below. This approximation, which is the more difficult mathematically, is discussed in the article on **Diffraction:** Fresnel Diffraction.

Fraunhofer Approximation

In Fraunhofer diffraction, we require that the source of light and the observation point, P_0, be far from the aperture so that the incident and diffracted wave can be approximated by plane waves. A consequence of this requirement is that the entire waveform passing through the aperture contributes to the observed diffraction.

The geometry to be used in this derivation is shown in Figure 4. The wave incident normal to the aperture, Σ, is a plane wave and the objective of the calculation is to find the departure of the transmitted wave from its geometrical optical path. The calculation will provide the light distribution, transmitted by the aperture, as a function of the angle the light is deflected from the incident direction. We assume that diffraction makes only a small perturbation on the predictions of geometrical optics. The deflection angles encountered in this derivation are, therefore, small, as assumed above, and we will be able to use the paraxial approximation.

The distance from a point P, in the aperture, to the observation point P_0, of Figure 4, is

$$R^2 = (x-\xi)^2 + (y-\eta)^2 + Z^2 \qquad [32]$$

From Figure 4 we see R_0 is the distance from the center of the screen to the observation point, P_0,

$$R_0^2 = \xi^2 + \eta^2 + Z^2 \qquad [33]$$

The difference between these two vectors is

$$\begin{aligned} R_0^2 - R^2 &= (R_0 - R)(R_0 + R) \\ &= \xi^2 + \eta^2 + Z^2 - Z^2 - (x^2 - 2x\xi + \xi^2) \\ &\quad - (y^2 - 2y\eta + \eta^2) \\ &= 2(x\xi + y\eta) - (x^2 + y^2) \end{aligned} \qquad [34]$$

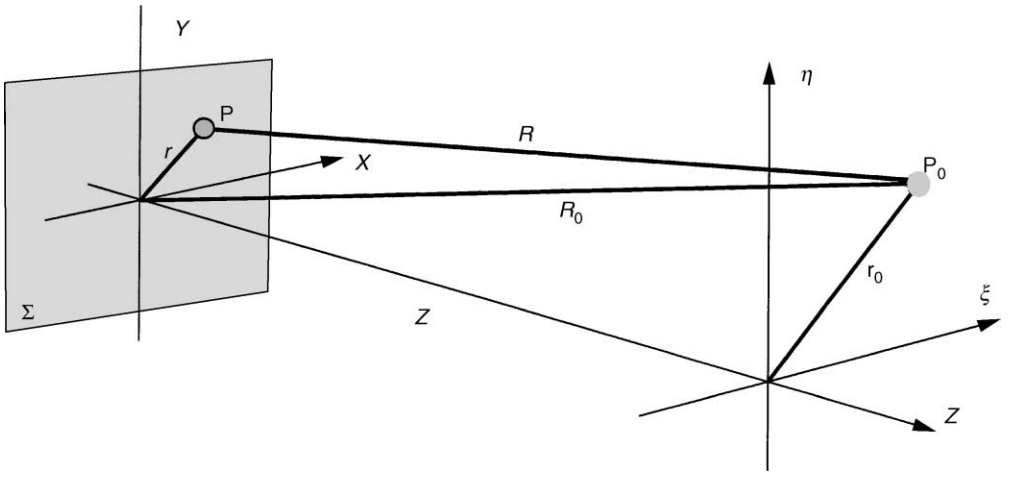

Figure 4 Geometry for Fraunhofer diffraction. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

The equation for the position of point P in the aperture can be written in terms of [34]:

$$r = R_0 - R = \frac{R_0^2 - R^2}{R_0 + R},$$
$$= [2(x\xi + y\eta) - (x^2 + y^2)]\frac{1}{R_0 + R} \qquad [35]$$

The reciprocal of $(R_0 + R)$ can be written as

$$\frac{1}{R_0 + R} = \frac{1}{2R_0 + R - R_0} = \frac{1}{2R_0}\left(1 + \frac{R - R_0}{2R_0}\right)^{-1} \qquad [36]$$

Now using [36]

$$R_0 - R = \left[\frac{x\xi + y\eta}{R_0} - \frac{x^2 + y^2}{2R_0}\right]\left[1 - \frac{R_0 - R}{2R_0}\right]^{-1}$$
$$= \left[\frac{x\xi + y\eta}{R_0} - \frac{x^2 + y^2}{2R_0}\right]\left[1 - \frac{r}{2R_0}\right]^{-1} \qquad [37]$$

If the diffraction integral [30] is to have a finite (nonzero) value, then

$$k|R_0 - R| \ll kR_0 \qquad [38]$$

This requirement insures that all the Huygens's wavelets, produced over the aperture from the center out to the position r, will have similar phases and will interfere to produce a nonzero amplitude at P_0. This requirement results in

$$\frac{1}{1 - \dfrac{r}{2R_0}} \approx 1 \qquad [39]$$

From this equation we are tempted to state that the aperture dimension must be small relative to the observation distance. However, for the exponent to provide a finite contribution in the integral, it is kr that is small, not the aperture dimension, r.

Using the approximation for $(R_0 - R)$, we obtain the diffraction integral

$$\tilde{E}_P = \frac{i\alpha\, e^{-i\mathbf{k}\cdot\mathbf{R}_0}}{\lambda R_0}\iint_{\Sigma} f(x, y) e^{+ik\left(\frac{x\xi + y\eta}{R_0} - \frac{x^2 + y^2}{2R_0}\right)}\, dx\, dy \qquad [40]$$

The change in the amplitude of the wave due to the change in R, as we move across the aperture, is neglected, allowing R in the denominator of the Huygens–Fresnel integral to be replaced by R_0 and moved outside of the integral. We have introduced the complex transmission function, $f(x, y)$, of the aperture to allow a very general aperture to be treated. If the aperture function described the variation in absorption of the aperture as a function of position, as would be produced by a photographic negative, then $f(x, y)$ would be a real function. If the aperture function described the variation in transmission of a biological sample, it might be entirely imaginary.

The argument of the exponent in [40] is

$$ik\left(\frac{x\xi + y\eta}{R_0} - \frac{x^2 + y^2}{2R_0}\right)$$
$$= i2\pi\left(\frac{x\xi + y\eta}{\lambda R_0} - \frac{x^2 + y^2}{2\lambda R_0}\right) \qquad [41]$$

If the observation point, P_0, is far from the screen, we can neglect the second term and treat the phase variation across the aperture as a linear function of position. This is equivalent to assuming that the diffracted wave is a collection of plane waves. Mathematically, the second term in [41] can be neglected if

$$\frac{x^2 + y^2}{2\lambda R_0} \ll 1 \qquad [42]$$

This is called the far-field approximation and the theory yields Fraunhofer diffraction. If the quadratic term of [41] is on the order of 2π then the fraction is

$$\frac{x^2 + y^2}{2\lambda R_0} \approx \Theta(1) \qquad [43]$$

and we must retain the quadratic term and the theory yields Fresnel diffraction.

We define spatial frequencies in the x and y direction by

$$\omega_x = \frac{2\pi}{\lambda}\sin\theta_x = -\frac{2\pi\xi}{\lambda R_0}$$
$$\omega_y = \frac{2\pi}{\lambda}\sin\theta_y = -\frac{2\pi\eta}{\lambda R_0} \qquad [44]$$

We define the spatial frequencies with a negative sign to allow equations involving spatial frequencies to have the same form as those involving temporal frequencies. The negative sign is required because ωt and $\mathbf{k}\cdot\mathbf{r}$ appear in the phase of the wave with opposite signs and we want the Fourier transform in space and in time to have the same form.

With the variables defined in [44], the integral becomes

$$\tilde{E}_P(\omega_x, \omega_y) = \frac{i\alpha\, e^{-i\mathbf{k}\cdot\mathbf{R}_0}}{\lambda R_0}\iint_{\Sigma} f(x, y) e^{-i(\omega_x x + \omega_y y)}\, dx\, dy \qquad [45]$$

The result of our derivation is that the Fraunhofer diffraction field, $\tilde{E}_P$, can be calculated by performing the two-dimensional Fourier transform of the aperture's transmission function.

Definition of Fourier Transform

In this discussion the function $F(\omega)$ is defined as the *Fourier transform* of $f(t)$:

$$\mathcal{F}\{f(t)\} \equiv F(\omega) \equiv \int_{-\infty}^{\infty} f(\tau)\mathrm{e}^{-\mathrm{i}\omega\tau}\,\mathrm{d}\tau \qquad [46]$$

The transformation from a temporal to a frequency representation given by [46] does not destroy information; thus, the inverse transform can also be defined

$$\mathcal{F}^{-1}\{F(\omega)\} = f(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} F(\omega)\mathrm{e}^{\mathrm{i}\omega t}\,\mathrm{d}\omega \qquad [47]$$

By assuming that the illumination of an aperture is a plane wave and that the observation position is in the far field, the diffraction of an aperture is found to be given by the Fourier transform of the function describing the amplitude transmission of the aperture. The amplitude transmission of the aperture, $f(x, y)$, may thus be interpreted as the superposition of mutually coherent plane waves.

Diffraction by a Rectangular Aperture

We will now use Fourier transform theory to calculate the Fraunhofer diffraction pattern from a rectangular slit and point out the reciprocal relationship between the size of the diffraction pattern and the size of the aperture.

Consider a rectangular aperture with a transmission function given by

$$f(x, y) = \begin{cases} 1 & |x| \le x_0, |y| \le y_0 \\ 0 & \text{all other } x \text{ and } y \end{cases} \qquad [48]$$

Because the aperture is two-dimensional, we need to apply a two-dimensional Fourier transform but it is not difficult because the amplitude transmission function is separable, in x and y. The diffraction amplitude distribution from the rectangular slit is simply one-dimensional transforms carried out individually for the x and y dimensions:

$$\tilde{E}_P = \frac{\mathrm{i}\alpha}{\lambda R_0}\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{R}_0}\int_{-x_0}^{x_0} f(x)\mathrm{e}^{-\mathrm{i}\omega_x x}\,\mathrm{d}x\int_{-y_0}^{y_0} f(y)\mathrm{e}^{-\mathrm{i}\omega_y y}\,\mathrm{d}y \qquad [49]$$

Since both $f(x)$ and $f(y)$ are defined as symmetric functions, we need only calculate the cosine transforms to obtain the diffracted field:

To calculate the Fourier transform defined by [46] we can rewrite the transform as

$$F(\omega) = \int_{-\infty}^{\infty} f(\tau)\cos\,\omega\tau\,\mathrm{d}\tau - \mathrm{i}\int_{-\infty}^{\infty} f(\tau)\sin\,\omega\tau\,\mathrm{d}\tau \qquad [50]$$

If $f(\tau)$ is a real, even function then the Fourier transform can be obtained by simply calculating the cosine transform:

$$\int_{-\infty}^{\infty} f(\tau)\cos\,\omega\tau\,\mathrm{d}\tau \qquad [51]$$

$$\tilde{E}_P = \mathrm{i}\frac{4x_0y_0\alpha}{\lambda R_0}\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{R}_0}\frac{\sin\,\omega_x x_0}{\omega_x x_0}\frac{\sin\,\omega_y y_0}{\omega_y y_0} \qquad [52]$$

The intensity distribution of the Fraunhofer diffraction produced by the rectangular aperture is

$$I_P = I_0\frac{\sin^2\omega_x x_0}{(\omega_x x_0)^2}\frac{\sin^2\omega_y y_0}{(\omega_y y_0)^2} \qquad [53]$$

The maximum intensities in the x and y directions occur at

$$\omega_x x_0 = \omega_y y_0 = 0 \qquad [54]$$

The area of this rectangular aperture is defined as $A = 4x_0y_0$, resulting in an expression for the maximum intensity of

$$I_0 = \left[\frac{\mathrm{i}4x_0y_0\alpha\,\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{R}_0}}{\lambda R_0}\right]^2 = \frac{A^2\alpha^2}{\lambda^2 R_0^2} \qquad [55]$$

The minima of [53] occur when $\omega_x x_0 = n\pi$ or when $\omega_y y_0 = m\pi$. The location of the zeros can be specified as a dimension in the observation plane or, using the paraxial approximation, in terms of the angle defined by [44]

$$\begin{aligned} \sin\,\theta_x \approx \theta_x \approx \frac{\xi}{R_0} = \frac{n\lambda}{2x_0} \\ \sin\,\theta_y \approx \theta_y \approx \frac{\eta}{R_0} = \frac{m\lambda}{2y_0} \end{aligned} \qquad [56]$$

The dimensions of the diffraction pattern are characterized by the location of the first zero, i.e., when $n = m = 1$, and are given by the observation plane coordinates, ξ and η. The dimensions of the diffraction pattern are inversely proportional to the dimensions of the aperture. As the aperture dimension expands, the width of the diffraction pattern decreases until, in the limit of an infinitely wide aperture, the diffraction pattern becomes a delta function.

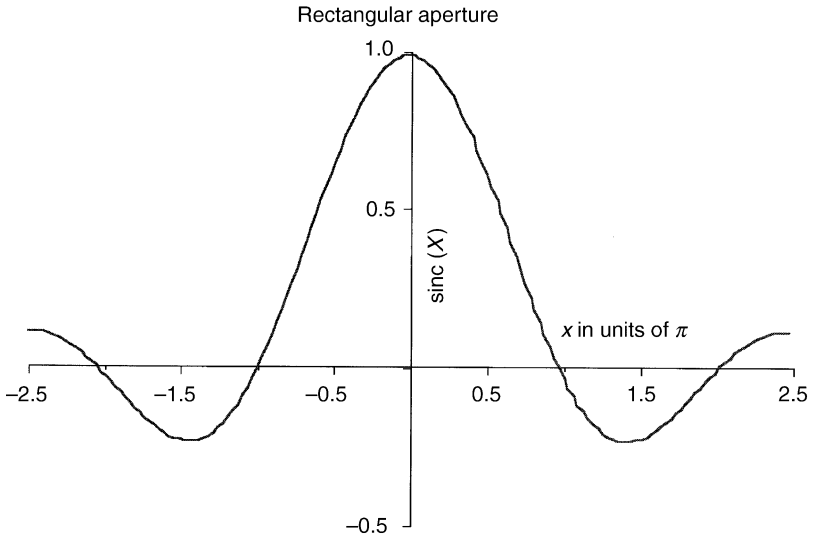

Figure 5 The amplitude of the wave diffracted by a rectangular slit. This sinc function describes the light wave's amplitude that would exist in both the *x* and *y* directions. The coordinate would have to be scaled by the dimension of the slit. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Figure 5 is a theoretical plot of the amplitude of the diffraction wave from a rectangular slit.

Diffraction from a Circular Aperture

To obtain the diffraction pattern from a circular aperture we first convert from the rectangular coordinate system we have used to a cylindrical coordinate system. The new cylindrical geometry is shown in Figure 6. At the aperture plane

$$\begin{aligned} x = s{\cdot}\cos\varphi \qquad & y = s{\cdot}\sin\varphi \\ f(x,y) = f(s,\varphi) \qquad & \mathrm{d}x\,\mathrm{d}y = s\,\mathrm{d}s\,\mathrm{d}\varphi \end{aligned} \quad [57]$$

At the observation plane

$$\xi = \rho{\cdot}\cos\theta \qquad \eta = \rho{\cdot}\sin\theta \quad [58]$$

In the new, cylindrical, coordinate system at the observation plane, the spatial frequencies are written as

$$\begin{aligned} \omega_x &= -\frac{k\xi}{R_0} = -\frac{k\rho}{R_0}\cos\theta \\ \omega_y &= -\frac{k\eta}{R_0} = -\frac{k\rho}{R_0}\sin\theta \end{aligned} \quad [59]$$

From Figure 6 we see that the observation point, P, can be defined in terms of the angle ψ, where

$$\sin\psi = \frac{\rho}{R_0} \quad [60]$$

This allows an angular representation of the size of the diffraction pattern if it is desired.

Using [57] and [59], we may write

$$\begin{aligned} \omega_x x + \omega_y y &= -\frac{ks\rho}{R_0}(\cos\theta\cos\varphi + \sin\theta\sin\varphi), \\ &= -\frac{ks\rho}{R_0}\cos(\theta-\varphi) \end{aligned} \quad [61]$$

The Huygens–Fresnel integral for Fraunhofer diffraction can now be written in terms of cylindrical coordinates:

$$\tilde{E}_P = \frac{\mathrm{i}\alpha}{\lambda R_0}\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{R}_0}\int_0^{\frac{a}{2}}\int_0^{2\pi} f(s,\varphi)\mathrm{e}^{-\mathrm{i}k\frac{s\rho}{R_0}\cos(\theta-\varphi)}\,s\,\mathrm{d}s\,\mathrm{d}\varphi \quad [62]$$

We will use this equation to calculate the diffraction amplitude from a clear aperture of diameter *a*, defined by the equation

$$f(s,\varphi) = \begin{cases} 1 & s \le \frac{a}{2},\ \text{all}\ \varphi \\ 0 & s > \frac{a}{2} \end{cases} \quad [63]$$

The symmetry of this problem is such that

$$f(s,\varphi) = f(s)g(\varphi) = f(s) \quad [64]$$

$$\mathcal{F}\{f(s,\phi)\} = \mathcal{F}\{f(s)\} = F(\rho) \quad [65]$$

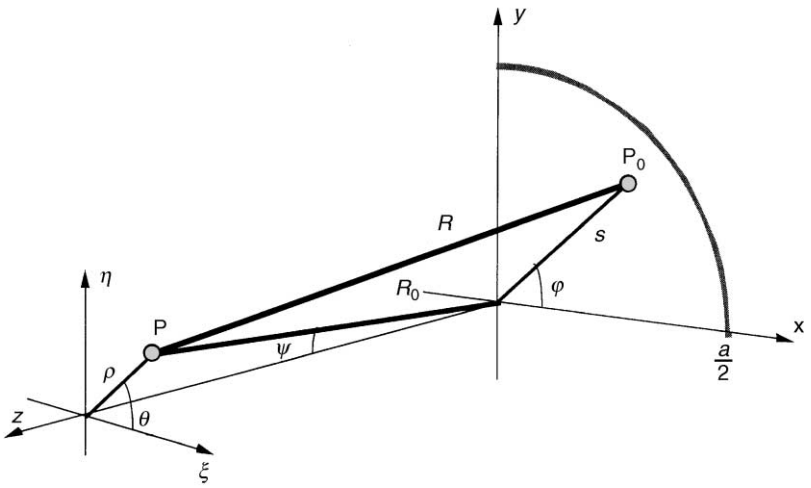

Figure 6 Geometry for calculation of Fraunhofer diffraction from a circular aperture. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

$$F(\rho,\theta)=\int_0^{\infty} f(s)s\,\mathrm{d}s\int_0^{2\pi}\mathrm{e}^{-\mathrm{i}\rho s\cos(\varphi-\theta)}\,\mathrm{d}\varphi \qquad [66]$$

$$F(\rho)=\int_0^{\infty} f(s)\,s\,\mathrm{d}s\int_0^{2\pi}\mathrm{e}^{-\mathrm{i}\rho s\cos\varphi}\,\mathrm{d}\varphi \qquad [67]$$

The second integral in [67] belongs to a class of functions called the Bessel function defined by the integral

$$\mathrm{J}_n(s\rho)=\frac{1}{2\pi}\int_0^{2\pi}\mathrm{e}^{\mathrm{i}[s\rho\sin\varphi-n\varphi]}\mathrm{d}\varphi \qquad [68]$$

In [67] the integral corresponds to the $n=0$, zero-order, Bessel function. Using this definition, we can rewrite [67] as

$$F(\rho)=\int_0^{\infty} f(s)\mathrm{J}_0(s\rho)s\,\mathrm{d}s \qquad [69]$$

This transform is called the Fourier–Bessel transform or the Hankel zero-order transform.

Using these definitions, the transform of the aperture function, $f(s)$, is

$$F(\rho)=\int_0^{\frac{a}{2}}\mathrm{J}_0(s\rho)s\,\mathrm{d}s \qquad [70]$$

We use the identity

$$x\mathrm{J}_1(x)=\int_0^{x}\chi\mathrm{J}_0(\chi)\,\mathrm{d}\chi \qquad [71]$$

to obtain

$$F(\rho)=\frac{a}{2\rho}\mathrm{J}_1\left(\frac{\rho a}{2}\right) \qquad [72]$$

We can now write the amplitude of the diffracted wave as

$$\tilde{E}_P=\frac{\mathrm{i}\alpha}{\lambda}\mathrm{e}^{-\mathrm{i}\mathbf{k}\cdot\mathbf{R}_0}\left[\frac{\pi a}{k\rho}\mathrm{J}_1\left(\frac{ka\rho}{2R_0}\right)\right] \qquad [73]$$

A plot of the function contained within the bracket of [73] is given in Figure 7. If we define

$$u=\frac{ka\rho}{2R_0} \qquad [74]$$

then the spatial distribution of intensity in the diffraction pattern can be written in a form known as the Airy formula,

$$I=I_0\left[\frac{2\mathrm{J}_1(u)}{u}\right]^2 \qquad [75]$$

where we have defined

$$I_0=\left(\frac{\alpha A}{\lambda R_0}\right)^2 \qquad [76]$$

with A representing the area of the aperture, $A=\pi(\frac{a}{2})^2$.

The intensity pattern described by [75] is called the Airy pattern. The intensity at $u=0$ is the same as was obtained for a rectangular aperture of the same area, because, in the limit,

$$\lim_{u\to 0}\left[\frac{2\mathrm{J}_1(u)}{u}\right]=1 \qquad [77]$$

For the Airy pattern, 84% of the total area is contained in the disk between the first zeros of [75]. Those zeros occur at $u=\pm 1.22\pi$, which corresponds

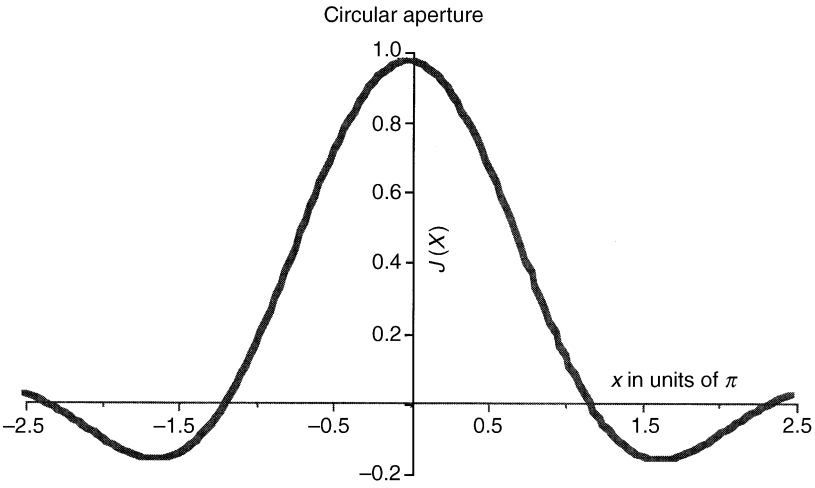

Figure 7 Amplitude of a wave diffracted by a circular aperture. The observed light distribution is constructed by rotating this Bessel function around the optical axis. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

to a radius in the observation plane of

$$\rho = \frac{1.22(\lambda R_0)}{a} \qquad [78]$$

91% of the light intensity is contained within the circle bounded by the second minimum at $u = 2.233\pi$. The intensities in the secondary maxima of the diffraction pattern of a rectangular aperture [53] are much larger than the intensities in the secondary maxima of the Airy pattern of a circular aperture of equal area. The peak intensities, relative to the central maximum, of the first three secondary maxima of a rectangular aperture are 4.7%, 1.6%, and 0.8%, respectively. For a circular aperture, the same quantities are 1.7%, 0.04%, and 0.02%, respectively.

Array Theorem

There is an elegant mathematical technique for handling diffraction from multiple apertures, called the array theorem. The theorem is based on the fact that Fraunhofer diffraction is given by the Fourier transform of the aperture function and utilizes the convolution integral.

The convolution of the functions $a(t)$ and $b(t)$ is defined as

$$g(t) = a(t) \otimes b(t) = \int_{-\infty}^{\infty} a(t)b(\tau - t)\,\mathrm{d}t \qquad [79]$$

The Fourier transform of a convolution of two functions is the product of the Fourier transforms of the individual functions:

$$\mathcal{F}\{a(t) \otimes b(t)\} = \mathcal{F}\left\{\int_{-\infty}^{\infty} a(t)b(\tau - t)\,\mathrm{d}t\right\} = A(\omega)B(\omega) \qquad [80]$$

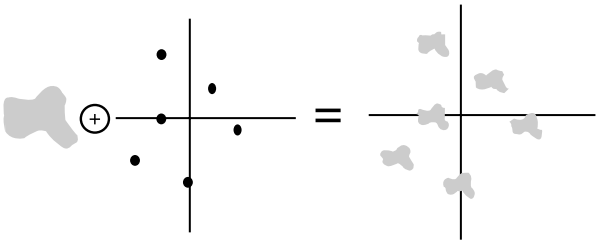

Figure 8 The convolution of an aperture with an array of delta functions will produce an array of identical apertures, each located at the position of one of the delta functions. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

We will demonstrate the array theorem for one dimension, where the functions represent slit apertures. The results can be extended to two dimensions in a straightforward way.

Assume that we have a collection of identical apertures, shown on the right of Figure 8. If one of the apertures is located at the origin of the aperture plane, its transmission function is $\psi(x)$. The transmission function of an aperture located at a point, x_n, can be written in terms of a generalized aperture function, $\psi(x - \alpha)$, by the use of the sifting property of the delta function

$$\psi(x - x_n) = \int \psi(x - \alpha)\delta(\alpha - x_n)\,\mathrm{d}\alpha \qquad [81]$$

The aperture transmission function representing an array of apertures will be the sum of the

distributions of the individual apertures, represented graphically in Figure 8 and mathematically by the summation

$$\Psi(x) = \sum_{n=1}^{N} \psi(x - x_n) \qquad [82]$$

The Fraunhofer diffraction from this array is $\Phi(\omega_x)$, the Fourier transform of $\Psi(x)$,

$$\Phi(\omega_x) = \int_{-\infty}^{\infty} \Psi(x) e^{-i\omega_x x}\, dx \qquad [83]$$

which can be rewritten as

$$\Phi(\omega_x) = \sum_{n=1}^{N} \int_{-\infty}^{\infty} \psi(x - x_n) e^{-i\omega_x x}\, dx \qquad [84]$$

We now make use of the fact that $\psi(x - x_n)$ can be expressed in terms of a convolution integral. The Fourier transform of $\psi(x - x_n)$ is, from the convolution theorem [80], the product of the Fourier transforms of the individual functions that make up the convolution:

$$\begin{aligned}\Phi(\omega_x) &= \sum_{n=1}^{N} \mathcal{F}\{\psi(x - \alpha)\}\mathcal{F}\{\delta(\alpha - x_n)\} \\ &= \mathcal{F}\{\psi(x - \alpha)\} \sum_{n=1}^{N} \mathcal{F}\{\delta(\alpha - x_n)\} \\ &= \mathcal{F}\{\psi(x - \alpha)\}\mathcal{F}\left\{\sum_{n=1}^{N} \delta(\alpha - x_n)\right\} \end{aligned} \qquad [85]$$

The first transform in [85] is the diffraction pattern of the generalized aperture function and the second transform is the diffraction pattern produced by a set of point sources with the same spatial distribution as the array of identical apertures. We will call this second transform the array function.

To summarize, the array theorem states that the diffraction pattern of an array of similar apertures is given by the product of the diffraction pattern from a single aperture and the diffraction (or interference) pattern of an identically distributed array of point sources.

N Rectangular Slits

An array of N identical apertures is called a diffraction grating in optics. The Fraunhofer diffraction patterns produced by such an array have two important properties; a number of very narrow beams are produced by the array and the beam positions are a function of the wavelength of illumination of the apertures and the relative phase of the waves radiated by each of the apertures.

Because of these properties, arrays of diffracting apertures have been used in a number of applications.

- At radio frequencies, arrays of dipole antennas are used to both radiate and receive signals in both radar and radio astronomy systems. One advantage offered by diffracting arrays at radio frequencies is that the beam produced by the array can be electrically steered by adjusting the relative phase of the individual dipoles.
- An optical realization of a two-element array of radiators is Young's two-slit experiment and a realization of a two-element array of receivers is Michelson's stellar interferometer. Two optical implementations of arrays, containing more diffracting elements, are diffraction gratings and holograms. In nature, periodic arrays of diffracting elements are the origin of the colors observed on some invertebrates.
- Many solids are naturally arranged in three-dimensional arrays of atoms or molecules that act as diffraction gratings when illuminated by X-ray wavelengths. The resulting Fraunhofer diffraction patterns are used to analyze the ordered structure of the solids.

The array theorem can be used to calculate the diffraction pattern from N rectangular slits, each of width a and separation d. The aperture function of a single slit is equal to

$$\psi(x, y) = \begin{cases} 1 & |x| \le \frac{a}{2}, |y| \le y_0 \\ 0 & \text{all other } x \text{ and } y \end{cases} \qquad [86]$$

The Fraunhofer diffraction pattern of this aperture has already been calculated and is given by [52]:

$$\mathcal{F}\{\psi(x, y)\} = K \frac{\sin \alpha}{\alpha} \qquad [87]$$

where the constant K and the variable α are

$$\begin{aligned} K &= \frac{i2ay_0\alpha}{\lambda R_0} e^{-i\mathbf{k}\cdot\mathbf{R}_0} \frac{\sin \omega_y y_0}{\omega_y y_0} \\ \alpha &= \frac{ka}{2} \sin \theta_x \end{aligned} \qquad [88]$$

The array function is

$$A(x) = \sum_{n=1}^{N} \delta(x - x_n) \quad \text{where } x_n = (n - 1)d \qquad [89]$$

and its Fourier transform is given by

$$\mathcal{F}\{A(x)\} = \frac{\sin N\beta}{\sin \beta} \qquad [90]$$

$$\beta = \frac{kd}{2}\sin\theta_x$$

The Fraunhofer diffraction pattern's intensity distribution in the x-direction is thus given by

$$I_\theta = I_0 \underbrace{\frac{\sin^2\alpha}{\alpha^2}}_{\text{shape factor}} \underbrace{\frac{\sin^2 N\beta}{\sin^2\beta}}_{\text{grating factor}} \qquad [91]$$

We have combined the variation in intensity in the y-direction into the constant I_0 because we assume that the intensity variation in the x-direction will be measured at a constant value of y.

A physical interpretation of [91] views the first factor as arising from the diffraction associated with a single slit; it is called the shape factor. The second factor arises from the interference between light from different slits; it is called the grating factor. The fine detail in the spatial light distribution of the diffraction pattern is described by the grating factor and arises from the coarse detail in the diffracting object. The coarse, overall light distribution in the diffraction pattern is described by the shape factor and arises from the fine detail in the diffracting object.

Young's Double Slit

The array theorem makes the analysis of Young's two-slit experiment a trivial exercise. This application of the array theorem will demonstrate that the interference between two slits arises naturally from an application of diffraction theory. The result of this analysis will support a previous assertion that interference describes the same physical process as diffraction and the division of the two subjects is an arbitrary one.

The intensity of the diffraction pattern from two slits is obtained from [91] by setting $N = 2$:

$$I_\theta = I_0 \frac{\sin^2\alpha}{\alpha^2}\cos^2\beta \qquad [92]$$

The sinc function describes the energy distribution of the overall diffraction pattern, while the cosine function describes the energy distribution created by interference between the light waves from the two slits. Physically, α is a measure of the phase difference between points in one slit and β is a measure of the phase difference between similar points in the two slits. Zeros in the diffraction intensity occur whenever $\alpha = n\pi$ or whenever $\beta = \frac{1}{2}(2n+1)\pi$. Figure 9 shows the interference maxima, from the grating factor, under the central diffraction peak, described by the shape factor. The number of interference maxima contained under the central maximum is given by

$$\frac{2d}{a} - 1 \qquad [93]$$

In Figure 9 three different slit spacings are shown with the ratio d/a equal to 3, 6, and 9, respectively.

The Diffraction Grating

In this section we will use the array theorem to derive the diffraction intensity distribution of a large number of identical apertures. We will discover that the positions of the principal maxima are a function of the illuminating wavelength. This functional relationship has led to the application of a diffraction grating to wavelength measurements.

The diffraction grating normally used for wavelength measurements is not a large number of diffracting apertures but rather a large number of reflecting grooves cut in a surface such as gold or aluminum. The theory to be derived also applies to these reflection gratings but a modification must be made to the theory. The shape of the grooves in the reflection grating can be used to control the fraction of light diffracted into a principal maximum and we will examine how to take this into account. A grating whose groove shape has been controlled to enhance the energy contained in a particular principal maximum is called a blazed grating. The use of special groove shapes is equivalent to the modification of the phase of individual elements of an antenna array at radio frequencies.

The construction of a diffraction grating for use in an optical device for measuring wavelength was first suggested by David Rittenhouse, an American astronomer, in 1785, but the idea was ignored until Fraunhofer reinvented the concept in 1819. Fraunhofer's first gratings were fine wires spaced by wrapping the wires in the threads of two parallel screws. He later made gratings by cutting (*ruling*) grooves in gold films deposited on the surface of glass. H.A. Rowland made a number of well designed ruling machines, which made possible the production of large-area gratings. Following a suggestion by Lord Rayleigh, Robert Williams Wood (1868–1955) developed the capability to control the shape of the individual grooves.

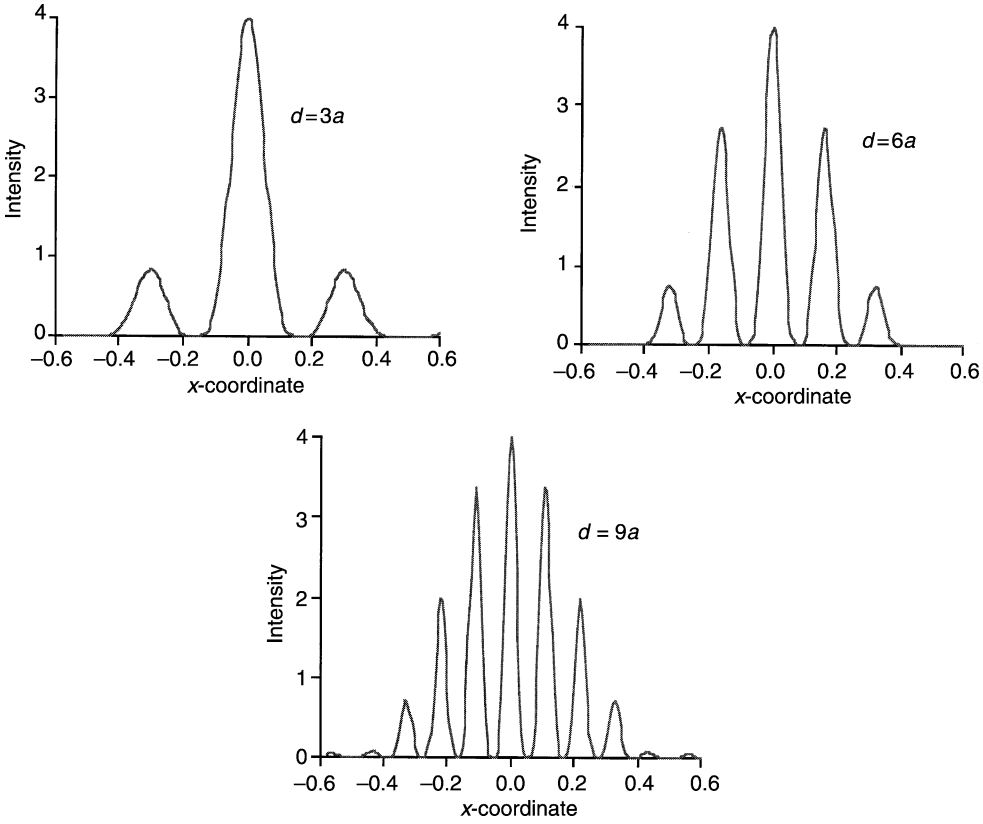

Figure 9 The number of interference fringes beneath the main diffraction peak of a Young's two-slit experiment with rectangular apertures. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

If N is allowed to assume values much larger than 2, the appearance of the interference fringes, predicted by the grating factor, changes from a simple sinusoidal variation to a set of narrow maxima, called principal maxima, surrounded by much smaller, secondary maxima. To calculate the diffraction pattern we must evaluate [91] when N is a large number.

Whenever $N\beta = m\pi$, $m = 0, 1, 2, \ldots$, the numerator of the second factor in [91] will be zero, leading to an intensity that is zero, $I_\theta = 0$. The denominator of the second factor in [91] is zero when $\beta = l\pi$, $l = 0, 1, 2, \ldots$ If both conditions occur at the same time, the ratio of m and N is equal to an integer, $m/N = l$, and instead of zero intensity, we have an indeterminate value for the intensity, $I_\theta = 0/0$. To find the actual value for the intensity, we must apply L'Hospital's rule

$$\lim_{\beta \to l\pi} \frac{\sin N\beta}{\sin \beta} = \lim_{\beta \to l\pi} \frac{N \cos N\beta}{\cos \beta} = N \qquad [94]$$

L'Hospital's rule predicts that whenever

$$\beta = l\pi = \frac{m}{N}\pi \qquad [95]$$

where l is an integer, a principal maximum in the intensity will occur with a value given by

$$I_{\theta P} = N^2 I_0 \frac{\sin^2 \alpha}{\alpha^2} \qquad [96]$$

Secondary maxima, much weaker than the principal maxima, occur when

$$\beta = \left(\frac{2m+1}{2N}\right)\pi \qquad m = 1, 2, \ldots \qquad [97]$$

(When $m = 0$, m/N is an integer, thus the first value that m can have in [97] is $m = 1$.) The intensity of each secondary maximum is given by

$$\begin{aligned} I_{\theta S} &= I_0 \frac{\sin^2 \alpha}{\alpha^2} \frac{\sin^2 N\beta}{\sin^2 \beta} \\ &= I_0 \frac{\sin^2 \alpha}{\alpha^2} \left[\frac{\sin^2\left(\frac{2m+1}{2}\right)\pi}{\sin^2\left(\frac{2m+1}{2N}\right)\pi} \right] \\ &= I_0 \frac{\sin^2 \alpha}{\alpha^2} \left[\frac{1}{\sin\left(\frac{2m+1}{2N}\right)\pi} \right]^2 \end{aligned} \qquad [98]$$

The quantity $(2m+1)/2N$ is a small number for large values of N, allowing the small angle approximation to be made:

$$I_{\theta S} \approx I_0 \frac{\sin^2\alpha}{\alpha^2}\left[\frac{2N}{\pi(2m+1)}\right]^2 \qquad [99]$$

The ratio of the intensity of a secondary maximum and a principal maximum is given by

$$\frac{I_{\theta S}}{I_{\theta P}} = \left[\frac{2}{\pi(2m+1)}\right]^2 \qquad [100]$$

The strongest secondary maximum occurs for $m=1$ and, for large N, has an intensity that is about 4.5% of the intensity of the neighboring principal maximum.

The positions of principal maxima occur at angles specified by the grating formula.

$$\beta = \frac{kd\sin\theta}{2} = l\pi = \frac{m}{N}\pi \qquad [101]$$

The angular position of the principal maxima (the diffracted angle θ_d) is given by the Bragg equation

$$\sin\theta_d = \frac{l\lambda}{d} \qquad [102]$$

where l is called the grating order. This simple relationship between the angle and the wavelength can be used to construct a device to measure wavelength, the grating spectrometer.

The model we have used to obtain this result is based on a periodic array of identical apertures. The transmission function of this array is a periodic square wave. If, for the moment, we treat the grating as infinite in size, we discover that the principal maxima in the diffraction pattern correspond to the terms of the Fourier series describing a square wave.

The zero order, $m=0$, corresponds to the temporal average of the periodic square wave and has an intensity proportional to the spatially averaged transmission of the grating. Because of its equivalence to the temporal average of a time-varying signal, the zero-order principal maximum is often called the dc term.

The first-order principal maximum corresponds to the fundamental spatial frequency of the grating and the higher orders correspond to the harmonics of this frequency.

The dc term provides no information about the wavelength of the illumination. Information about the wavelength of the illuminating light can only be obtained by measuring the angular position of the first or higher order principal maxima.

Grating Spectrometer

The curves shown in Figure 10 display the separation of the principal maxima as a function of $\sin\theta_d$. The angular separation of principal maxima can be converted to a linear dimension by assuming a distance, R, from the graing to the observation plane. In the lower right-hand curve of Figure 10, a distance of 2 meters was assumed. Grating spectrometers are classified by the size in meters of R used in their design. The larger R, the easier it is to resolve wavelength differences. For example, a 1 meter spectrometer is a higher-resolution instrument than a 1/4 meter spectrometer.

The fact that the grating is finite in size causes each of the orders to have an angular width that limits the resolution with which the illuminating wavelength can be measured. To calculate the resolving power of the grating, we first determine the angular width of a principal maximum. This is accomplished by measuring the angular change, of the principal maximum's position, when β changes from $\beta = l\pi = m\pi/N$ to $\beta = (m+1)\pi/N$, i.e., $\Delta\beta = \pi/N$. Using the definition of β

$$\beta = \frac{kd\sin\theta_d}{2} \qquad [103]$$

$$\Delta\beta = \frac{\pi d\cos\theta_d\Delta\theta}{\lambda}$$

and the angular width is

$$\Delta\theta = \frac{\lambda}{Nd\cos\theta_d} \qquad [104]$$

The derivative of the grating formula gives

$$\Delta\lambda = \frac{d}{l}\cos\theta_d\Delta\theta \qquad [105]$$

$$\Delta\theta = \frac{l\Delta\lambda}{d\cos\theta_d}$$

Equating this spread in angle to eqn [104] yields

$$\frac{l\Delta\lambda}{d\cos\theta} = \frac{\lambda}{Nd\cos\theta} \qquad [106]$$

The resolving power of a grating is therefore

$$\frac{\lambda}{\Delta\lambda} = Nl \qquad [107]$$

The improvement of resolving power with N can be seen in Figure 10. A grating 2 inches wide and containing 15 000 grooves per inch would have a resolving power in second order ($l=2$) of 6×10^4. At a wavelength of 600 nm this grating could resolve two waves, differing in wavelength by 0.01 nm.

The diffraction grating is limited by overlapping orders. If two wavelengths, λ and $\lambda+\Delta\lambda$, have successive orders that are coincident, then

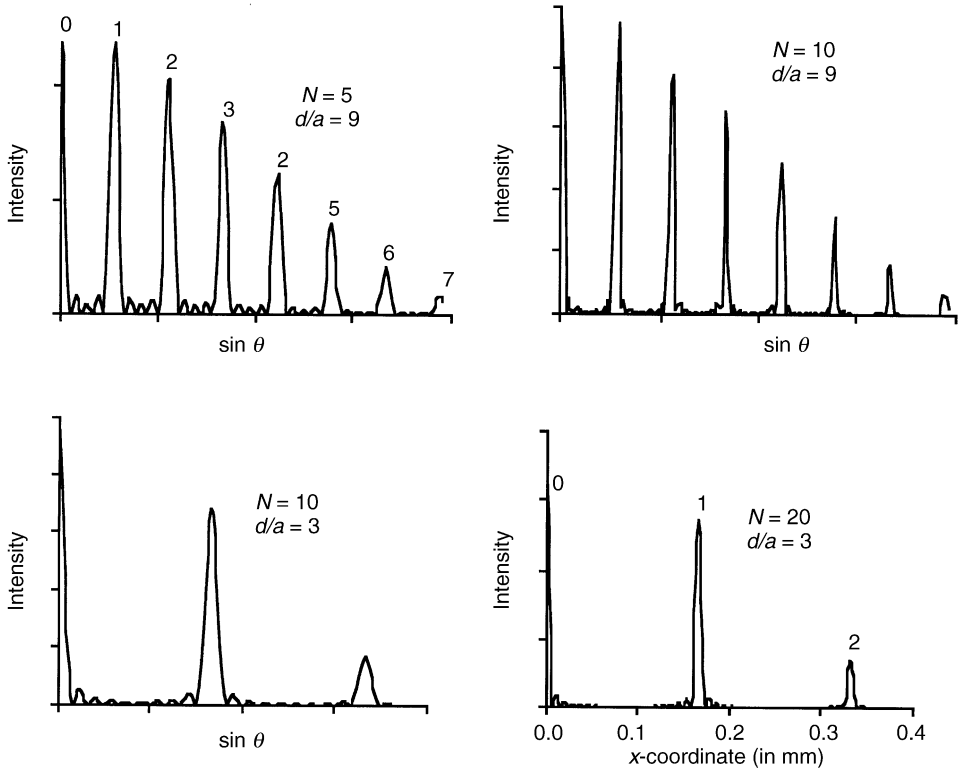

Figure 10 Decrease in the width of the principal maxima of a transmission grating with an increasing number of slits. The various principal maxima are called orders, numbering from zero, at the origin, out to as large as seven in this example. Also shown is the effect of different ratios, d/a, on the number of visible orders. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

from eqn [102]

$$(l+1)\lambda = l(\lambda + \Delta\lambda) \qquad [108]$$

The minimum wavelength difference for which this occurs is defined as the free spectral range of the diffraction grating

$$(\Delta\lambda)_{SR} = \frac{\lambda}{l} \qquad [109]$$

Blazed Gratings

We have been discussing amplitude transmission gratings. Amplitude transmission gratings have little practical use because they waste light. The light loss is from a number of sources.

1. Light is diffracted simultaneously into both positive and negative orders (the positive and negative frequencies of the Fourier transform). The negative diffraction orders contain redundant information and waste light.
2. In an amplitude transmission grating, light is thrown away because of the opaque portions of the slit array.
3. The width of an individual aperture leads to a shape factor for a rectangular aperture of $\text{sinc}^2\alpha = (\sin^2\alpha)/\alpha^2$, which modulates the grating factor and causes the amplitude of the orders to rapidly decrease. This can be observed in **Figure 10**, where the second order is very weak. Because of the loss in intensity at higher orders, only the first few orders ($l = 1, 2$ or 3) are useful. The shape factor also causes a decrease in diffracted light intensity with increasing wavelength for higher-order principal maxima.
4. The location of the maximum in the diffracted light, i.e., the angular position for which the shape factor is a maximum, coincides with the location of the principal maximum due to the zero-order interference. This zero-order maximum is independent of wavelength and is not of much use.

One solution to the problems created by transmission gratings would be the use of a grating that modified only the phase of the transmitted wave. Such gratings would operate using the same physical processes as a microwave phased array antenna, where the location of the shape factor's maximum is controlled by adding a constant phase shift to each antenna element. The construction of an optical

transmission phase grating with a uniform phase variation across the aperture of the grating is very difficult. For this reason, a second approach, based on the use of reflection gratings, is the practical solution to the problems listed above.

By tilting the reflecting surface of each groove of a reflection grating, Figure 11, the position of the shape factor's maximum can be controlled. Problems 1, 3, and 4 are eliminated because the shape factor maximum is moved from the optical axis out to some angle with respect to the axis. The use of reflection gratings also removes Problem 2 because all of the incident light is reflected by the grating.

Robert Wood, in 1910, developed the technique of producing grooves of a desired shape in a reflective grating by shaping the diamond tool used to cut the grooves. Gratings, with grooves shaped to enhance their performance at a particular wavelength, are said to be blazed for that wavelength. The physical properties on which blazed gratings are based can be understood by using Figure 11. The groove faces can be treated as an array of mirror surfaces. The normal to each of the groove faces makes an angle θ_B with the normal to the grating surface. We can measure the angle of incidence and the angle of diffraction with respect to the grating normal or with respect to the groove normal, as shown in Figure 11. From Figure 11, we can write a relationship between the angles

$$\theta_i = \varphi_i - \theta_B \qquad -\theta_d = -\varphi_d + \theta_B \qquad [110]$$

(The sign convention used defines positive angles as those measured in a counterclockwise rotation from the normal to the surface. Therefore, θ_B is a negative angle.) The blaze angle provides an extra degree of freedom that will allow independent adjustment of the angular location of the principal maxima of the grating factor and the zero-order, single-aperture, diffraction maximum. To see how this is accomplished, we must determine, first, the effect of off-axis illumination of a diffraction grating.

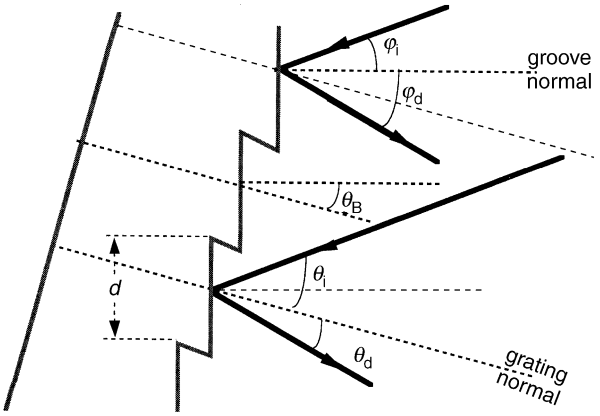

Figure 11 Geometry for a blazed reflection grating. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Off-axis illumination is easy to incorporate into the equation for the diffraction intensity from an array. To include the effect of an off-axis source, the phase of the illuminating wave is modified by changing the incident illumination from a plane wave of amplitude, E, traveling parallel to the optical axis, to a plane wave with the same amplitude, traveling at an angle θ_i to the optical axis: $\tilde{E}\, e^{-ikx \sin \theta_i}$. (Because we are interested only in the effects in a plane normal to the direction of propagation, we ignore the phase associated with propagation along the z-direction, $kz \cos \theta_i$.) The off-axis illumination results in a modification of the parameter for single-aperture diffraction from

$$\alpha = \frac{ka}{2} \sin \theta_d \qquad [111]$$

to

$$\alpha = \frac{ka}{2} (\sin \theta_i + \sin \theta_d) \qquad [112]$$

and for multiple aperture interference from

$$\beta = \frac{kd}{2} \sin \theta_d \qquad [113]$$

to

$$\beta = \frac{kd}{2} (\sin \theta_i + \sin \theta_d) \qquad [114]$$

The zero-order, single-aperture, diffraction peak occurs when $\alpha = 0$. If we measure the angles with respect to the groove face, this occurs when

$$\alpha = \frac{ka}{2} (\sin \varphi_i + \sin \varphi_d) = 0 \qquad [115]$$

The angles are therefore related by

$$\sin \varphi_i = -\sin \varphi_d \qquad [116]$$

$$\varphi_i = -\varphi_d$$

We see that the single-aperture, diffraction maximum (the shape factor's maximum) occurs at the same angle that reflection from the groove faces occurs. We can write this result in terms of the angles measured with respect to the grating normal

$$\theta_i = -(\theta_d + 2\theta_B) \qquad [117]$$

The blaze condition requires the single aperture diffraction maximum to occur at the lth principal

maximum, for wavelength λ_B. At that position

$$l\pi = \frac{2\pi d}{\lambda_B}(\sin\theta_i + \sin\theta_d) \qquad [118]$$

$$l\lambda_B = 2d\sin\tfrac{1}{2}(\theta_i + \theta_d)\cos\tfrac{1}{2}(\theta_i - \theta_d)$$

For the special geometrical configuration called the Littrow condition, where $\theta_i = \theta_d$, we find that [117] leads to the equation

$$l\lambda_B = 2d\sin\theta_B \qquad [119]$$

By adjusting the blaze angle, the single-aperture diffraction peak can be positioned on any order of the interference pattern. Typical blaze angles are between 15° and 30° but gratings are made with larger blaze angles.

Fresnel Diffraction

B D Guenther, Duke University, Durham, NC, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Fresnel was a civil engineer who pursued optics as a hobby, after a long day of road construction. Based on his own very high-quality observations of diffraction, Fresnel used the wave propagation concept developed by Christiaan Huygens (1629–1695) to develop a theoretical explanation of diffraction. We will use a descriptive approach to obtain the Huygens–Fresnel integral by assuming an aperture can be described by N pinholes which act as sources for Huygens' wavelets. The interference between these sources will lead to the Huygens–Fresnel integral for diffraction.

Huygens' principle views wavefronts as the product of wavelets from various luminous points acting together. To apply Huygens' principle to the propagation of light through an aperture of arbitrary shape, we need to develop a mathematical description of the field from an array of Huygens' sources filling the aperture. We will begin by obtaining the field from a pinhole that is illuminated by a plane wave,

$$\tilde{\mathbf{E}}_i(\mathbf{r}, t) = \tilde{\mathbf{E}}_i(\mathbf{r})e^{i\omega t}$$

Following the lead of Fresnel, we will use theory of interference to combine the fields from two pinholes and then generalize to N pinholes. Finally by letting the areas of each pinhole approach an infinitesimal value, we will construct an arbitrary aperture of infinitesimal pinholes. The result will be the Huygens–Fresnel integral.

We know that the wave obtained after propagation through an aperture must be a solution of the wave equation,

$$\nabla^2\tilde{\mathbf{E}} = \mu\varepsilon\frac{\partial^2\tilde{\mathbf{E}}}{\partial t^2}$$

We will be interested only in the spatial variation of the wave so we need only look for solutions of the Helmholtz equation

$$(\nabla^2 + k^2)\tilde{\mathbf{E}} = 0$$

The problem is further simplified by replacing this vector equation with a scalar equation,

$$(\nabla^2 + k^2)\tilde{E}(x, y, z) = 0$$

This replacement is proper for those cases where $\mathbf{n}E(x,y,z)$ [where $\mathbf{n}$ is a unit vector] is a solution of the vector Helmholtz equation. In general, we cannot substitute $\mathbf{n}E$ for the electric field $\mathbf{E}$ because of Maxwell's equation

$$\nabla\cdot\mathbf{E} = 0$$

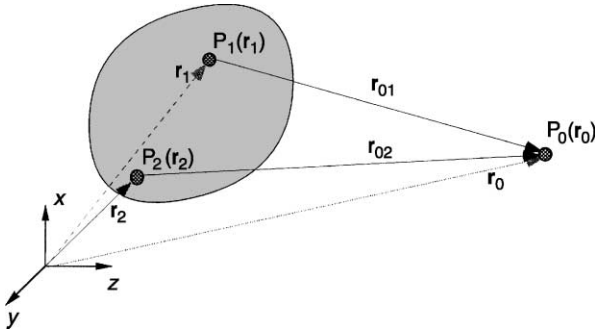

Figure 1 Geometry for application of Huygens' principle to two pinholes. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

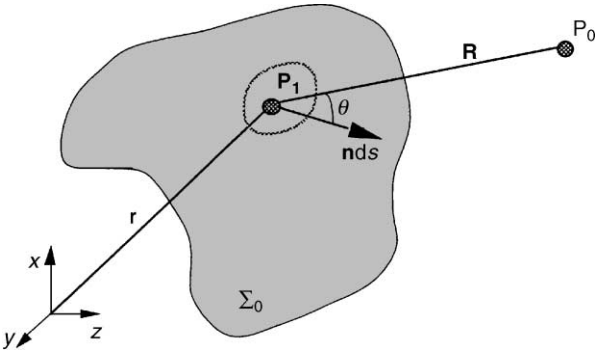

Figure 2 The geometry for calculating the field at P_0 using [9]. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Rather than working with the magnitude of the electric field, we should use the scalar amplitude of the vector potential. We will neglect this complication and assume the scalar, E, is a single component of the vector field, **E**. A complete solution would involve a scalar solution for each component of **E**.

The pinhole is illuminated by a plane wave, and the wave that leaves the pinhole will be a spherical wave which is written in complex notation as

$$\tilde{E}(\mathbf{r})e^{i\omega t} = A\frac{e^{-i\delta}e^{-ik\cdot r}}{r}e^{i\omega t}$$

The complex amplitude

$$\tilde{E}(\mathbf{r}) = A\frac{e^{-i\delta}e^{-ik\cdot r}}{r} \qquad [1]$$

is a solution of the Helmholtz equation. The field at P_0, in Figure 1, from two pinholes: one at P_1, located a distance $\mathbf{r}_{01} = |\mathbf{r}_0 - \mathbf{r}_1|$ from P_0, and one at P_2, located a distance $\mathbf{r}_{02} = |\mathbf{r}_0 - \mathbf{r}_2|$ from P_0, is a generalization of Young's interference. The complex amplitude is

$$\tilde{E}(\mathbf{r}_0) = \frac{A_1}{r_{01}}e^{-ik\cdot r_{01}} + \frac{A_2}{r_{02}}e^{-ik\cdot r_{02}} \qquad [2]$$

We have incorporated the phase δ_1 and δ_2 into the constants A_1 and A_2 to simplify the equations.

The light emitted from the pinholes is due to a wave, E_i, incident onto the screen from the left. The units of E_i are per unit area so to obtain the amount of light passing through the pinholes, we must multiply E_i by the areas of the pinholes. If $\Delta\sigma_1$ and $\Delta\sigma_2$ are the areas of the two pinholes, respectively, then

$$A_1 \propto \tilde{E}_i(\mathbf{r}_1)\Delta\sigma_1 \qquad A_2 \propto \tilde{E}_i(\mathbf{r}_2)\Delta\sigma_2$$

$$\tilde{E}(\mathbf{r}_0) = C_1\frac{\tilde{E}_i(\mathbf{r}_1)}{r_{01}}e^{-ik\cdot r_{01}}\Delta\sigma_1 + C_2\frac{\tilde{E}_i(\mathbf{r}_2)}{r_{02}}e^{-ik\cdot r_{02}}\Delta\sigma_2 \qquad [3]$$

where C_i is the constant of proportionality. The constant will depend on the angle that $\mathbf{r}_{0i}$ makes with the normal to $\Delta\sigma_i$. This geometrical dependence arises from the fact that the apparent area of the pinhole decreases as the observation angle approaches 90°.

We can generalize [3] to N pinholes

$$\tilde{E}(\mathbf{r}_0) = \sum_{j=1}^{N} C_j\frac{\tilde{E}_i(\mathbf{r}_j)}{r_{0j}}e^{-ik\cdot r_{0j}}\Delta\sigma_j \qquad [4]$$

The pinhole's diameter is assumed to be small compared to the distances to the viewing position but large compared to a wavelength. In the limit as $\Delta\sigma_j$ goes to zero, the pinhole becomes a Huygens source. By letting N become large, we can fill the aperture with these infinitesimal Huygens' sources and convert the summation to an integral.

It is in this way that we obtain the complex amplitude, at the point P_0, see Figure 2, from a wave exiting an aperture, Σ_0, by integrating over the area of the aperture. We replace $\mathbf{r}_{0j}$, in [4], by **R**, the position of P_1, the infinitesimal Huygens' source of area, ds, measured with respect to the observation point, P_0. We also replace $\mathbf{r}_j$ by **r**, the position of the infinitesimal area, ds, with respect to the origin of the coordinate system. The discrete summation [4] becomes the integral

$$\tilde{E}(\mathbf{r}_0) = \int\int_A C(\mathbf{r})\frac{\tilde{E}_i(\mathbf{r})}{R}e^{-ik\cdot\mathbf{R}}ds \qquad [5]$$

This is the Fresnel integral. The variable $C(\mathbf{r})$ depends upon θ, the angle between **n**, the unit vector normal to the aperture, and **R**, shown in Figure 2. We now need to determine how to treat $C(\mathbf{r})$.

The Obliquity Factor

When using Huygens' principle, a problem arises with the spherical wavelet produced by each

Huygens' source. Part of the spherical wavelet propagates backward and results in an envelope propagating toward the light source, but such a wave is not observed in nature. Huygens neglected this problem. Fresnel required the existence of an obliquity factor to cancel the backward wavelet but was unable to derive its functional form. When Kirchhoff placed the theory of diffraction on a firm mathematical foundation, the obliquity factor was generated quite naturally in the derivation. In this intuitive derivation of the Huygens–Fresnel integral, we will present an argument for treating the obliquity factor as a constant at optical wavelengths. We will then derive the constant value it must be assigned.

The obliquity factor, $C(\mathbf{r})$, in [5], causes the amplitude per unit area of the transmitted light to decrease as the viewing angle increases. This is a result of a decrease in the effective aperture area with viewing angle. When Kirchhoff applied Green's theorem to the scalar diffraction problem, he found the obliquity factor to have an angular dependence given by

$$\frac{\cos(\hat{\mathbf{n}}, \mathbf{R}) - \cos(\hat{\mathbf{n}}, \mathbf{r}_s)}{2} \qquad [6]$$

which includes the geometrical effect of the incident wave arriving at the aperture, at an angle with respect to the normal to the aperture from a source located at a position $\mathbf{r}_s$, with respect to the aperture. If the source is at infinity, then the incident wave can be treated as a plane wave, incident normal to the aperture, and we may simplify the angular dependence of the obliquity factor to

$$\frac{1 + \cos\theta}{2}$$

where $\theta \rightarrow (\hat{\mathbf{n}}, \mathbf{R})$ is the angle between the normal to the aperture and the vector $\mathbf{R}$. This is the configuration shown in Figure 2. The obliquity factor provides an explanation of why it is possible to ignore the backward-propagating wave that occurs in application of Huygens' principle. For the backward wave, $\theta = \pi$, and the obliquity factor is zero.

The obliquity factor increases the difficulty of working with the Fresnel integral and it is to our benefit to be able to treat it as a constant. We can neglect the angular contribution of the obliquity factor by making an assumption about the resolving power of an optical system operating at visible wavelengths.

Assume we are attempting to resolve two stars that produce plane waves at the aperture of a telescope with an aperture diameter, a. The wavefronts from the two stars make an angle ψ with respect to each other, Figure 3:

$$\tan\psi \approx \psi = \frac{\Delta x}{a}$$

The smallest angle, ψ, that can be measured is determined by the smallest length, Δx, that can be measured. We know we can measure a fraction of wavelength with an interferometer but, without an interferometer, we can measure a length no smaller than λ, leading to the assumption that $\Delta x \geq \lambda$. This reasoning leads to the assumption that the smallest angle we can measure is

$$\psi \geq \frac{\lambda}{a} \qquad [7]$$

The resolution limit established by the above reasoning places a limit on the minimum separation that can be produced at the back focal plane of the telescope. The minimum distance on the focal plane between the images of star 1 and 2 is given by

$$d = f\psi \qquad [8]$$

From [7]

$$d = \frac{\lambda f}{a}$$

The resolution limit of the telescope can also be expressed in terms of the cone angle produced when the incident plane wave is focused on the back focal plane of the lens. From the geometry of Figure 3, the cone angle is given by

$$\tan\theta = \frac{a}{2f}$$

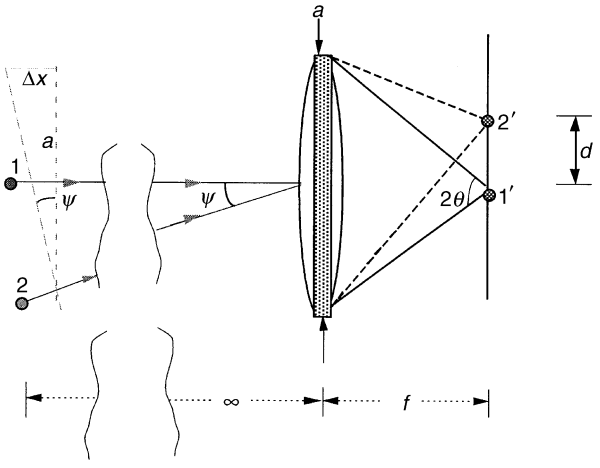

Figure 3 Telescope resolution. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

The separation between the stars 1 and 2 at the back focal plane of the lens in Figure 3 is thus

$$d = \frac{\lambda}{2\tan\theta} \qquad [9]$$

If we assume that the minimum d is 3λ (this is four times the resolution of a typical photographic film at visible wavelengths), then the largest obliquity angle that should be encountered in a visible imaging system is

$$\tan\theta = \frac{\lambda}{2d} = \frac{\lambda}{6\lambda} = \tfrac{1}{6} = 0.167$$

$$\theta = 9.5^\circ \approx 10^\circ$$

yielding a value for $\cos\theta = 0.985$ and $(1 + cos\ \theta)/2 = 0.992$. The obliquity factor has only changed by 0.8% over the angular variation of 0° to 10°. The obliquity factor as a function of angle is shown in Figure 4 for an incident plane wave. The obliquity factor undergoes a 10% change when θ varies from 0° to about 40°; therefore, the obliquity factor can safely be treated as a constant in any optical system that involves angles less than 40°.

While we have shown that it is safe to ignore the variability of C, we still have not assigned a value to the obliquity factor. To find the proper value for C, we will compare the result obtained using [5] with the result predicted by using geometric optics.

We illuminate the aperture Σ_0 in Figure 5 with a plane wave of amplitude α, traveling parallel to the z-axis. Geometrical optics (equivalently the propagation of an infinite plane wave) predicts a field at P_0, on the z-axis, a distance z_0 from the aperture, given by

$$\tilde{E}_{\text{geom}} = \alpha e^{-ikz_0} \qquad [10]$$

The area of the infinitesimal at P_1 (the Huygens' source) is

$$ds = r\,dr\,d\phi$$

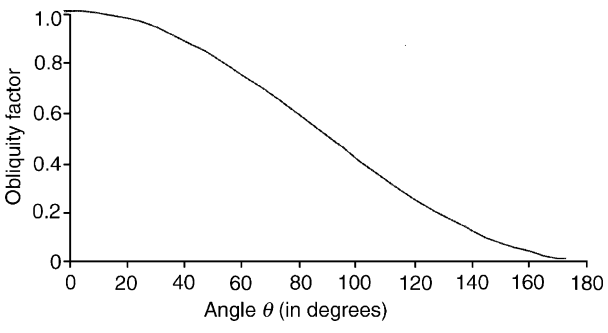

Figure 4 The obliquity factor as a function of the angle defined in eqn [6] for an incident plane wave. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

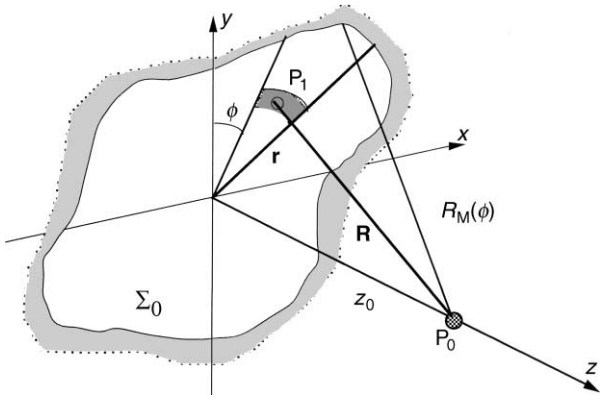

Figure 5 Geometry for evaluating the constant in the Fresnel integral. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Based on our previous argument, the obliquity factor can be treated as a constant, C, that can be removed from under the integral. The incident wave is a plane wave whose value at $z = 0$ is $E(r) = \alpha$. Using these parameters, the Fresnel integral [5] can be written as

$$\tilde{E}(z_0) = C\alpha \int\int \frac{e^{-ik\cdot R}}{R} r\,dr\,d\phi \qquad [11]$$

From the geometry in Figure 5, the distance from the Huygens source to the observation point is

$$z_0^2 + r^2 = R^2$$

where z_0 is a constant equal to the distance from the observation plane to the aperture plane. The variable of integration can be written in terms of R:

$$r\,dr = R\,dR$$

The limits of integration over the aperture extend from $R = z_0$ to the maximum value of R, $R = R_M(\phi)$.

$$\tilde{E}(z_0) = C\alpha \int_0^{2\pi} \int_{z_0}^{R_M(\phi)} e^{-ikR} dR\,d\phi \qquad [12]$$

The integration over R can now be carried out to yield

$$\tilde{E}(z_0) = \underbrace{\frac{C\alpha}{ik} e^{-ikz_0} \int_0^{2\pi} d\phi}_{\text{Geometrical Optics}} - \underbrace{\frac{C\alpha}{ik} \int_0^{2\pi} e^{-ikR_M(\phi)} d\phi}_{\text{Diffraction}} \qquad [13]$$

The first integration in [13] is easy to perform and contains the amplitude at the observation point due to geometric optics. The second term may be interpreted as interference of the waves diffracted by the boundary of the aperture. An equivalent statement is that the second term is the interference of the waves scattered from the aperture's boundary, an interpretation of diffraction that was first suggested by Young.

The aperture is irregular in shape, at least on the scale of a wavelength, thus in general, kR_M will vary over many multiples of 2π as we integrate around the aperture. For this reason, we should be able to ignore the second integral in [13] if we confine our attention to the light distribution on the z-axis. After neglecting the second term, we are left with only the geometrical optics component of [13]:

$$\tilde{E}(z_0) = \frac{2\pi C}{ik}\alpha e^{-ikz_0} \qquad [14]$$

For [14] to agree with the prediction of geometric optics [10] the constant C must be equal to

$$C = \frac{ik}{2\pi} = \frac{i}{\lambda} \qquad [15]$$

The Huygens–Fresnel integral can be written, using the value for C just derived,

$$\tilde{E}(\mathbf{r}_0) = \frac{i}{\lambda}\int\int_{\Sigma}\frac{\tilde{E}_i(\mathbf{r})}{R}e^{-ik\cdot R}\,ds \qquad [16]$$

The job of calculating diffraction has only begun with the derivation of the Huygens–Fresnel integral [16]. Rigorous solutions exist for only a few idealized obstructions. To allow discussion of the general properties of diffraction, it is necessary to use approximate solutions. To determine what type approximations we can make let's look at the light propagation path shown in Figure 6.

For the second term in [13] to contribute to the field at point P_0, in Figure 6, the phase of the exponent that we neglected in [13] must not vary over 2π when the integration is performed over the aperture, i.e.,

$$\Delta = \mathbf{k}\cdot(\mathbf{R}_1 - \mathbf{R}'_1 + \mathbf{R}_2 - \mathbf{R}'_2) < 2\pi$$

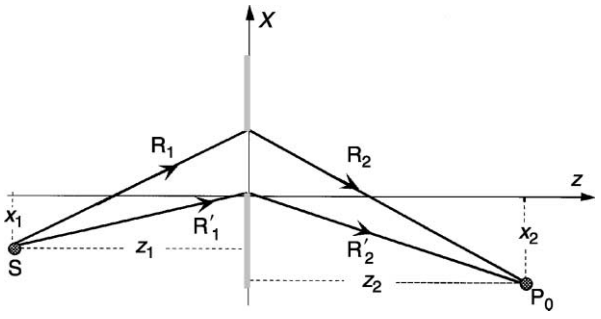

Figure 6 One-dimensional slit used to establish Fresnel approximations. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

From the geometry of Figure 6, the two paths from the source, S, to the observation point, P_0, are

$$R_1 + R_2 = \sqrt{z_1^2 + (x_1 + b)^2} + \sqrt{z_2^2 + (x_2 + b)^2}$$

$$R'_1 + R'_2 = \sqrt{z_1^2 + x_1^2} + \sqrt{z_2^2 + x_2^2}$$

By assuming that the aperture, of width b, is small compared to the distances z_1 and z_2, the difference between these distances, Δ, can be rewritten as a binomial expansion of a square root

$$\sqrt{1+b} = 1 + \frac{b}{2} - \frac{b^2}{8} + \ldots \qquad [17]$$

thus

$$\Delta \approx k\left(\frac{x_1}{z_1} + \frac{x_2}{z_2}\right)b + \frac{k}{2}\left(\frac{1}{z_1} + \frac{1}{z_2}\right)b^2 + \ldots \qquad [18]$$

If we assume that the second term of this expansion is small, i.e.,

$$\frac{k}{2}\left(\frac{1}{z_1} + \frac{1}{z_2}\right)b^2 \ll 2\pi$$

$$\frac{b^2}{2}\frac{1}{z_1} + \frac{1}{z_2} < \lambda$$

we see that the phase of the wavefront in the aperture is assumed to have a quadratic dependence upon aperture coordinates. Diffraction predicted by this assumption is called Fresnel diffraction.

To discover the details of the approximation consider Figure 7. In the geometry of Figure 7, the Fresnel integral [16] becomes

$$\tilde{E}_{P_0} = \frac{i\alpha}{\lambda}\int\int_{\Sigma} f(x,y)\frac{e^{-ik\cdot(R+R')}}{RR'}dx\,dy \qquad [19]$$

As we mentioned in our discussion of [13] the integral that adds diffractive effects to the geometrical optics field is nonzero only when the phase of the integrand is stationary. For Fresnel diffraction, we can insure that the phase is nearly constant if R does not differ appreciably from Z, or R' from Z'. This is equivalent to stating that only the wave in the aperture, around a point in Figure 7 labeled **S**, called the stationary point, will contribute to E_P. The stationary point, **S**, is the point in the aperture plane where the line, connecting the source and observation positions, intersects the plane. Physically, only light propagating over paths nearly equal to the path predicted by geometrical optics (obtained from Fermat's principle) will contribute to E_{P_0}.

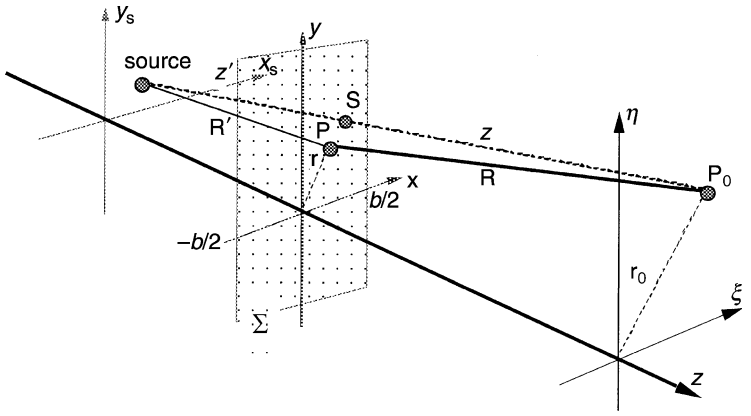

Figure 7 Geometry for Fresnel diffraction. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

The geometry of Figure 7 allows the distances R and R' to be written as

$$R^2 = (x-\xi)^2 + (y-\eta)^2 + Z^2 \qquad [20]$$
$$R'2 = (x_s - x)^2 + (y_s - y)^2 + Z'2$$

To solve these expressions for R and R', we apply the binomial expansion [17] and retain the first two terms:

$$R + R' \approx Z + Z' + \left[\frac{(x-\xi)^2}{2Z} + \frac{(x_s-x)^2}{2Z'}\right] + \left[\frac{(y-\eta)^2}{2Z} + \frac{(y_s-y)^2}{2Z'}\right] \qquad [21]$$

In the denominator of [19], R is replaced by Z and R' by Z'. (By making this replacement, we are implicitly assuming that the amplitudes of the spherical waves are not modified by the differences in propagation distances over the area of integration. This is a reasonable approximation because the two propagation distances are within a few hundred wavelengths of each other). In the exponent, we must use [21], because the phase changes by a large fraction of a wavelength, as we move from point to point in the aperture.

If the wave, incident on the aperture, were a plane wave we can assume $R' = \infty$ and [19] becomes

$$\tilde{E}_{P_0} = \frac{i\alpha}{\lambda}\frac{e^{-ikZ}}{Z}\int\int_{\Sigma} f(x,y)e^{-\frac{ik}{2Z}[(x-\xi)^2+(y-\eta)^2]}dx\,dy \qquad [22]$$

The physical interpretation of [22] states that when a plane wave illuminates the obstruction, the field at point P_0 is a spherical wave, originating at the aperture, a distance Z away from P_0:

$$\frac{e^{-ikZ}}{Z}$$

The amplitude and phase of this spherical wave are modified by the integral containing a quadratic phase dependent on the obstruction's spatial coordinates.

By defining three new parameters,

$$\rho = \frac{ZZ'}{Z+Z'} \quad \text{or} \quad \frac{1}{\rho} = \frac{1}{Z} + \frac{1}{Z'} \qquad [23a]$$
$$x_0 = \frac{Z'\xi + Zx_s}{Z+Z'} \qquad [23b]$$
$$y_0 = \frac{Z'\eta + Zy_s}{Z+Z'} \qquad [23c]$$

the more general expression for Fresnel diffraction of a spherical wave can be placed in the same format as [22]. The newly defined parameters x_0 and y_0 are the coordinates, in the aperture plane, of the stationary point, **S**. The parameters in [23] can be used to express, after some manipulation, the spatial dependence of the phase, in the integrand of [19]

$$R + R' = Z + Z' + \frac{(\xi - x_s)^2 + (\eta - y_s)^2}{2(Z+Z')} + \left[\frac{(x-x_0)^2 + (y-y_0)^2}{2\rho}\right]$$

A further simplification to the Fresnel diffraction integral can be made by obtaining an expression for the distance, D, between the source and the observation point:

$$D = Z + Z' + \frac{(\xi - x_s)^2 + (\eta - y_s)^2}{2(Z+Z')} \qquad [24]$$

We use this definition of D to also write

$$\frac{1}{ZZ'} = \frac{Z+Z'}{ZZ'}\frac{1}{Z+Z'} \approx \frac{1}{\rho D}$$

Using the parameters we have just defined, we may rewrite [19] as

$$\tilde{E}_{P_0} = \frac{i\alpha}{\lambda\rho D} e^{-ikD} \int\int f(x,y) e^{-\frac{ik}{2\rho}[(x-x_0)^2+(y-y_0)^2]} dx\,dy \qquad [25]$$

With the use of the variables defined in [23], the physical significance of the general expression of the Huygens–Fresnel integral can be understood in an equivalent fashion as was [22]. At point P_0, a spherical wave

$$\frac{e^{-ikD}}{D}$$

originating at the source, a distance D away, is observed, if no obstruction are present. Because of the obstruction, the amplitude and phase of the spherical wave are modified by the integral in [25]. This correction to the predictions of geometrical optics is called Fresnel diffraction.

Mathematically, [25] is an application of the method of stationary phase, a technique developed in 1887 by Lord Kelvin to calculate the form of a boat's wake. The integration is nonzero only in the region of the critical point we have labeled **S**. Physically, the light distribution, at the observation point, is due to wavelets from the region around **S**. The phase variations of light, coming from other regions in the aperture, are so rapid that the value of the integral over those spatial coordinates is zero. The calculation of the integral for Fresnel diffraction is complicated because, if the observation point is moved, a new integration around a different stationary point in the aperture must be performed.

Rectangular Apertures

If the aperture function, $f(x,y)$, is separable in the spatial coordinates of the aperture, then we can rewrite [25] as

$$\tilde{E}_{P_0} = \frac{i\alpha}{\lambda\rho D} e^{-ikD} \int_{-\infty}^{\infty} f(x) e^{-ig(x)} dx \int_{-\infty}^{\infty} f(y) e^{-ig(y)} dy$$

$$\tilde{E}_{P_0} = A[C(x) - iS(x)][C(y) - iS(y)]$$

A represents the spherical wave from the source, a distance D away,

$$A = \frac{i\alpha}{2D} e^{-ikD}$$

If we treat the aperture function as a simple constant, C and S are integrals of the form

$$C(x) = \int_{x_1}^{x_2} \cos[g(x)]dx \qquad [26a]$$

$$S(x) = \int_{x_1}^{x_2} \sin[g(x)]dx \qquad [26b]$$

The integrals, $C(x)$ and $S(x)$, have been evaluated numerically and are found in tables of Fresnel integrals. To use the tabulated values for the integrals, [26] must be written in a general form

$$C(w) = \int_0^w \cos\left(\frac{\pi u^2}{2}\right) du \qquad [27]$$

$$S(w) = \int_0^w \sin\left(\frac{\pi u^2}{2}\right) du \qquad [28]$$

The variable u is an aperture coordinate, measured relative to the stationary point, $\mathbf{S}(x_0,y_0)$, in units of

$$\sqrt{\frac{\lambda\rho}{2}}$$

$$u = \sqrt{\frac{2}{\lambda\rho}}(x - x_0) \text{ or } u = \sqrt{\frac{2}{\lambda\rho}}(y - y_0) \qquad [29]$$

The parameter w in [27] and [28] specifies the location of the aperture edge relative to the stationary point **S**. The parameter w is calculated through the use of [29] with x and y replaced by the coordinates of the aperture edge.

The Cornu Spiral

The plot of $S(w)$ versus $C(w)$, shown in Figure 8, is called the Cornu spiral in honor of M. Alfred Cornu (1841–1902) who was the first to use this plot for graphical evaluation of the Fresnel integrals.

To use the Cornu spiral, the limits w_1 and w_2 of the aperture are located along the arc of the spiral. The length of the straight line segment drawn from w_1 to w_2 gives the magnitude of the integral. For example, if there were no aperture present, then, for the x-dimension, $w_1 = -\infty$ and $w_2 = \infty$. The length of the line segment from the point $(-1/2,1/2)$ to $(1/2,1/2)$ would be the value of E_{P_0}, i.e., $\sqrt{2}$. An identical value is obtained for the y-dimension, so that

$$\tilde{E}_{P_0} = 2A = \frac{\alpha e^{-ikD}}{D}$$

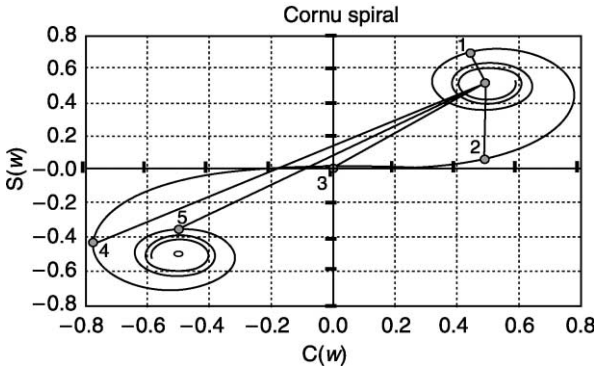

Figure 8 Cornu spiral obtained by plotting the values for $C(w)$ versus $S(w)$ from a table of Fresnel integrals. The numbers indicated along the arc of the spiral are values of w. The points 1–5 correspond to observation points shown in **Figure 9** and are used to calculate the light intensity diffracted by a straight edge. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

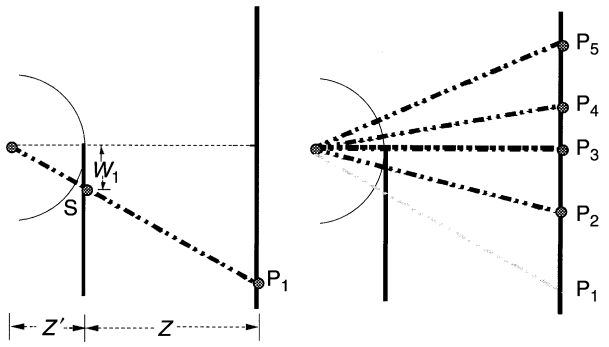

Figure 9 A geometrical construct to determine w_1 for the stationary point S associated with five different observation points. The values of w are then used in **Figure 8** to calculate the intensity of light diffracted around a straight edge. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

This is the spherical wave that is expected when no aperture is present.

As an example of the application of the Fresnel integrals, assume the diffracting aperture is an infinitely long straight edge reducing the problem to one dimension:

$$f(x, y) = \begin{Bmatrix} 1 & x \geq x_1 \\ 0 & x < x_1 \end{Bmatrix}$$

The value of E_{P_0} in the y-dimension is from above $\sqrt{2}$ since $w_1 = -\infty$ and $w_2 = \infty$. In the x-dimension, the value of w at the edge is

$$w_{x_1} = \sqrt{\frac{2}{\lambda\rho}}(x_1 - x_0)$$

We will assume that the straight edge blocks the negative half-plane so that $x_1 = 0$. The straight edge is treated as an infinitely wide slit with one edge located at infinity so that $w_2 = \infty$ in the upper half-plane. When the observation point is moved, the coordinate x_0 of **S** changes and the origin of the aperture's coordinate system moves. New values for the w's must therefore be calculated for each observation point.

Figure 9 shows the assumed geometry. A set of observation points, P_1–P_5, on the observation screen are selected. The origin of the coordinate system in the aperture plane is relocated to a new position (given by the position of **S**) when a new observation point is selected. The value of w_1, the position of the edge with respect to **S**, must be recalculated for each observation point. The distance from the origin to the straight edge, w_1, is positive for P_1 and P_2, zero for P_3, and negative for P_4 and P_5.

Table 1 Fresnel integrals for straight edge

w_1	$C(w_1)$	$S(w_1)$	I_P/I_0	P_j
∞	0.5	0.5	0	
2.0	0.4882	0.3434	0.01

Figure 8 shows the geometrical method used to calculate the intensity values at each of the observation points in Figure 9 using the Cornu spiral. The numbers labeling the straight line segments in Figure 8 are associated with the labels of the observation points in Figure 9.

To obtain an accurate calculation of Fresnel diffraction from a straight edge, a table of Fresnel integrals provides the input to the following equation

$$I_P = I_0\left\{\left[\tfrac{1}{2} - C(w_1)\right]^2 + \left[\tfrac{1}{2} - S(w_1)\right]^2\right\}$$

where $I_0 = 2A^2$. Table 1, shows the values extracted from the table of Fresnel integrals to find the relative intensity at various observation points. The result obtained by using either method for calculating the light distribution in the observation plane, due to the straight edge in Figure 9, is plotted in Figure 10. The relative intensities at the observation points

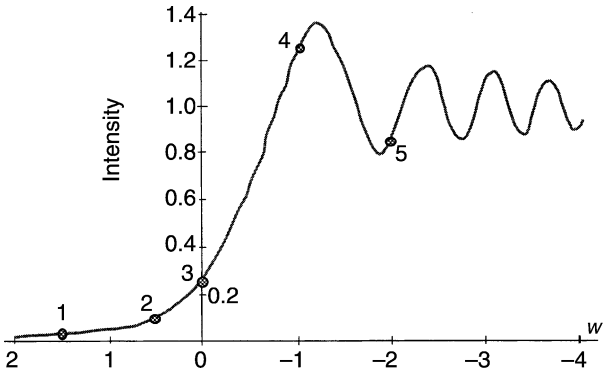

Figure 10 Light diffracted by a straight edge with its edge located at $w = 0$. The points labeled 1–5 were found using the construction in **Figure 9** to obtain w. This was then used in **Figure 8** to find a position on the Cornu spiral. The length of the lines shown in **Figure 8** from the (1/2,1/2) point to the numbered positions led to the intensities shown. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

depicted in **Figure 9** are labeled on the diffraction curve of **Figure 10**.

Fresnel Zones

Fresnel used a geometrical construction of zones to evaluate the Huygens–Fresnel integral. The Fresnel zone is a mathematical construct, serving the role of a Huygens source in the description of wave propagation. Assume that at time t, a spherical wavefront from a source at P_1 has a radius of R'. To determine the field at the observation point, P_0, due to this wavefront, a set of concentric spheres of radii, $Z, Z + (\lambda/2), Z + 2(\lambda/2), \ldots, Z + j(\lambda/2), \ldots$ are constructed, where Z is the distance from the wavefront to the observation point on the line connecting P_1 and P_0 (see **Figure 11**). These spheres divide the wavefront into a number of zones, $\zeta_1, \zeta_2, \ldots, \zeta_j \ldots$, called Fresnel zones, or half-period zones.

We treat each zone as a circular aperture illuminated from the left by a spherical wave of the form

$$\tilde{E}_j(\mathbf{R}') = \frac{A e^{-i\mathbf{k}\cdot\mathbf{R}'}}{R'} = \frac{A e^{-ikR'}}{R'}$$

R' is the radius of the spherical wave. The field at P_0 due to the jth zone is obtained by using [5]

$$\tilde{E}_j(P_0) = \frac{A}{R'} e^{-i\mathbf{k}\cdot\mathbf{R}'} \int\int_{\zeta_j} C(\varphi) \frac{e^{-i\mathbf{k}\cdot\mathbf{R}}}{R} ds \qquad [30]$$

For the integration over the jth zone, the surface element is

$$ds = R' 2\sin\theta d\theta \, d\phi \qquad [31]$$

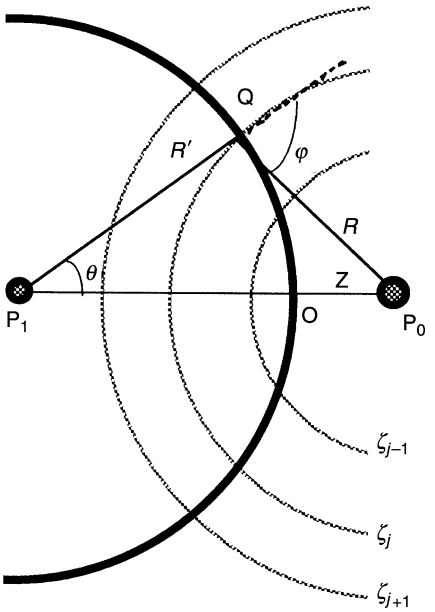

Figure 11 Construction of Fresnel zones observed from a position P_0 on a spherical wave originating from a source at point P_1. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

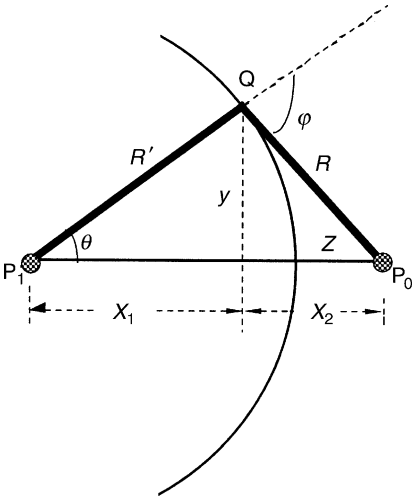

Figure 12 Geometry for finding the relationship between R and R' yielding eqn [32]. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

The limits of integration extend over the range

$$Z + (j-1)\tfrac{\lambda}{2} \le R \le Z + j\tfrac{\lambda}{2}$$

The variable of integration is R; thus, a relationship between R' and R must be found. This is accomplished by using the geometrical construction shown in **Figure 12**.

A perpendicular is drawn from the point Q on the spherical wave to the line connecting P_1 and P_0, in **Figure 12**. The distance from the source to the

observation point is $x_1 + x_2$ and the distance from the source to the plane of the zone is the radius of the incident spherical wave, R'. The distance from P_1 to P_0 can be written

$$x_1 + x_2 = R' + Z$$

The distance from the observation point to the zone is

$$R^2 = x_2^2 + y^2 = [(R' + Z) - x_1]^2 + (R'\sin\theta)^2$$

$$= R'2 + (R' + Z)^2 - 2R'(R' + Z)\cos\theta$$

The derivative of this expression yields

$$R\,\mathrm{d}R = R'(R' + Z)\sin\theta\,\mathrm{d}\theta \qquad [32]$$

Substituting [32] into [31] gives

$$\mathrm{d}s = \frac{R'}{R' + Z} R\mathrm{d}R\mathrm{d}\phi \qquad [33]$$

The integration over ϕ is accomplished by rotating the surface element about the P_1P_0 axis. After integrating over ϕ between the limits of 0 and 2π, we obtain

$$\tilde{E}_j(P_0) = \frac{2\pi A}{R' + Z} e^{-ik\cdot R'} \int_{Z+(j-1)\frac{\lambda}{2}}^{Z+\frac{j\lambda}{2}} e^{-ik\cdot R} C(\varphi)\mathrm{d}R \quad [34]$$

We assume that $R',\ Z \gg \lambda$ so that the obliquity factor is a constant over a single zone, i.e., $C(\varphi) = C_j$. The obliquity factor is not really a constant as we earlier assumed but rather a very slowly varying parameter of j, changing by less than two parts in 10^4 when 'j' changes by 500 (for $Z = 1$ meter and $\lambda = 500$ nm). In fact it only changes by 2 parts in 10^{-7} across one zone. We are safe in applying the assumption that the obliquity factor is a constant over a zone and this allows the integral in [34] to be calculated:

$$\tilde{E}_j(P_0) = \frac{2\pi i C_j A}{k(R' + Z)} e^{-ik(R'+Z)} e^{-ikj\frac{\lambda}{2}} \left[1 - e^{-ik\frac{\lambda}{2}}\right] \quad [35]$$

Using the identity $k\lambda = 2\pi$ and the definition for the distance between the source and observation point [24] modified for this geometry, $D = R' + Z$ [35] can be simplified to

$$\tilde{E}_j(P_0) = 2i\lambda(-1)^j \frac{C_j A}{D} e^{-ikD} \qquad [36]$$

The physical reasons for the behavior predicted by [36] are quite easy to understand. The distance from P_0 to a zone changes by only $\lambda/2$ as we move from zone to zone and the area of a zone is almost a constant, independent of the zone number; thus, the amplitudes of the Huygens' wavelets from each zone should be approximately equal. The alternation in sign, from zone to zone, is due to the phase change of the light wave from adjacent zones because the propagation paths for adjacent zones differ by $\lambda/2$.

To find the total field strength at P_0 due to N zones, the collection of Huygens' wavelets is added:

$$E(P_0) = \sum_{j=1}^{N} \tilde{E}_j(P_0) = \frac{2i\lambda A}{D} e^{-ikD} \sum_{j=1}^{N} (-1)^j C_j \quad [37]$$

To evaluate the sum, the elements of the sum are regrouped and rewritten as

$$-\sum_{j=1}^{N} (-1)^j C_j = \frac{C_1}{2} + \left(\frac{C_1}{2} - C_2 + \frac{C_3}{2}\right) + \left(\frac{C_3}{2} - C_4 + \frac{C_5}{2}\right) + \ldots$$

Because the C's are very slowly varying functions of j, even out to 500 zones, we are justified in setting the quantities in parentheses equal to zero. With this approximation, the summation can be set equal to one of two values, depending upon whether there is an even or odd number of terms in the summation

$$-\sum_{j=1}^{N} (-1)^j C_j = \left\{ \begin{array}{ll} \frac{1}{2}(C_1 + C_N) & N \text{ odd} \\ \frac{1}{2}(C_1 - C_N) & N \text{ even} \end{array} \right\}$$

For very large N, the obliquity factor approaches zero, $C_N \to 0$, as was demonstrated in **Figure 4**. Thus, the theory has led us to the conclusion that the total field produced by an unobstructed wave is equal to one half the contribution from the first Fresnel zone, i.e., $E = E_1/2$. Stating this result in a slightly different way, we obtain a surprising result – the contribution from the first Fresnel zone is twice the amplitude of the unobstructed wave!

The zone construction can be used to analyze the effect of the obstruction of all or part of a zone. For example, by constructing a circular aperture with a diameter equal to the diameter of the first Fresnel zone, we have just demonstrated that it is possible to produce an intensity at the point P_0 equal to four times the intensity that would be observed if no aperture were present. To analyze the effects of a smaller aperture, we subdivide a half-period zone into a number of subzones such that there is a constant phase difference between each subzone. The individual vectors form a curve know as the vibrational curve. **Figure 13** shows a vibrational curve produced by the addition of waves from nine subzones of the first Fresnel zone. The vibrational curve in **Figure 13** is an arc with the appearance of a half-circle.

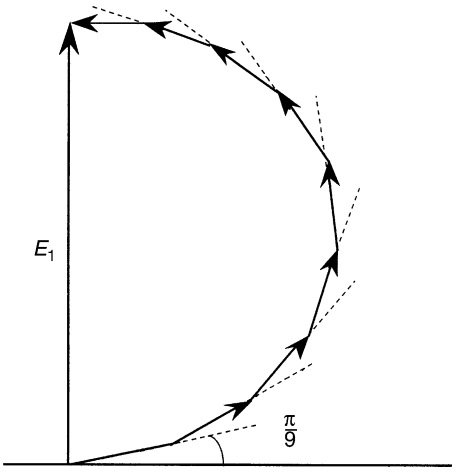

Figure 13 Vector addition of waves from nine subzones constructed in the first Fresnel zone. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

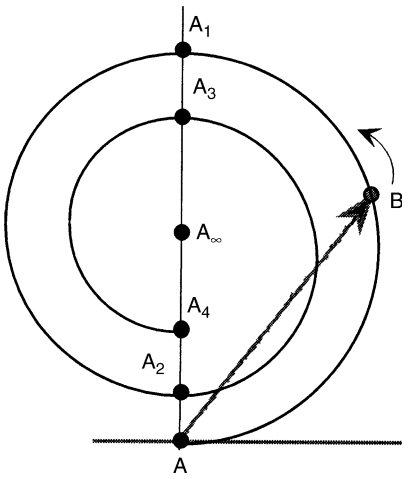

Figure 14 Vibration curve for determining the Fresnel diffraction from a circular aperture. The change of the diameter of the half-circles making up the spiral has been exaggerated for easy visualization. The actual changes are one part in 10^{-5}. The position of point B is determined by the aperture size. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

If the radius of curvature of the arc were calculated, we would discover that it is a constant, except for the contribution of the obliquity factor,

$$\rho = \frac{\lambda R'}{R' + Z} C(\varphi)$$

Because the obliquity factor for a single zone is a constant to 2 parts in 10^{-7}, the radius of curvature of the vibration curve can be considered a constant over a single zone. If we let the number of subzones approach infinity, the vibrational curve becomes a semicircle whose chord is equal to the wavelet produced by zone one, i.e., E_1. If we subdivide additional zones, and add the subzone contributions, we create other half-circles whose radii decrease at the same rate as the obliquity factor. The vibrational curve for the total wave is a spiral, constructed of semicircles which converges to a point halfway between the first half-circle, see Figure 14. The length of the vector from the start to the end of the spiral is $E = E_1/2$, as we derived above. When this same construction technique is applied to a rectangular aperture, the vibrational curve generated is the Cornu spiral.

Circular Aperture

The vector addition technique, described in Figure 13, can be used to evaluate Fresnel diffraction, at a point P_0, from a circular aperture and yields the intensity distribution along the axis of symmetry of the circular aperture. The zone concept will also allow a qualitative description of the light distribution normal to this axis.

To develop a quantitative estimate of the intensity at an observation point on the axis of symmetry of the circular aperture, we construct a spiral, Figure 14, to represent the Fresnel zones of a spherical wave incident on the aperture. The point B on the spiral shown in Figure 14 corresponds to the portion of the spherical wave unobstructed by the screen. The length of the chord, AB, represents the amplitude of the light wave at the observation point P_0. As the diameter of the aperture increases, B moves along the spiral, in a counterclockwise fashion, away from A. The first maximum occurs when B reaches the point labeled A_1 in Figure 14; the aperture has then uncovered the first Fresnel zone. At this point, the amplitude is twice what it would be with no obstruction. Four times the intensity!

If the aperture's diameter continues to increase, B reaches the point labeled A_2 in Figure 14 and the amplitude is very nearly zero; two zones are now exposed in the aperture. Further maxima occur when an odd number of zones are in the aperture and further minima when an even number of zones are exposed. Figure 15 shows an aperture containing four exposed Fresnel zones. The amplitude at the observation point would correspond to the chord drawn from A to A_4 in Figure 14.

The aperture diameter can be fixed and the observation point P_0 can move along, or perpendicular to, the axis of symmetry of the circular aperture. As P_0 is moved away from the aperture, along the symmetry axis, i.e., as Z increases, the radius of the Fresnel zones increase without limit. For small values of n, the radius of the nth zone can be approximated by

$$r_n \approx \sqrt{nZ\lambda} \qquad [38]$$

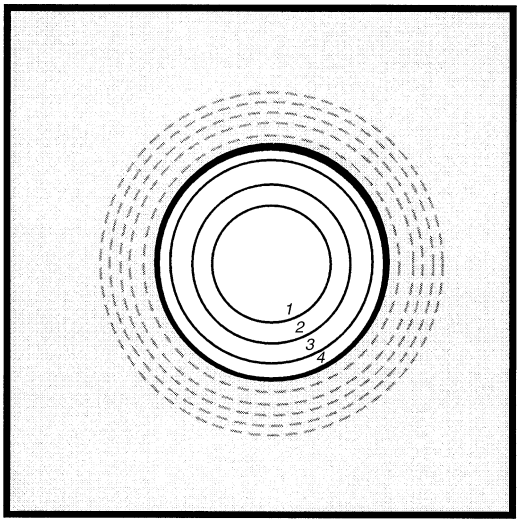

Figure 15 Aperture with four Fresnel zones exposed. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

At Z_{max}, the light intensity is a maximum, given by the chord length from A to A_1 in Figure 14. If $\lambda = 500$ nm and $a = 0.5$ mm then this maximum occurs when $Z = 0.5$ m

$$Z_{max} = \frac{a^2}{\lambda} \qquad [39]$$

If we start at Z_{max} and move toward the aperture, along the axis, as Z decreases in value, a point will be reached when the intensity on the axis becomes a minimum. The value of Z where the first minimum in intensity is observed is equal to

$$Z_{min} = \frac{a^2}{2\lambda}$$

In Figure 14 the chord would extend from A to A_2.

As the observation point, P_0, is moved along the axis toward the aperture, and Z assumes values less than Z_{min}, the point B in Figure 14 spirals inward, toward the center of the spiral and the intensity cycles through maximum and minimum values. The cycling of the intensity, as the observation point moves toward the aperture, will not continue indefinitely. At some point, the field on the axis will approach the field observed without the aperture because the distance between Z_{max} and Z_{min} shrinks to the wavelength of light making the intensity variation unobservable.

For values of Z that exceed Z_{max} of [39], the aperture radius, a, will be smaller than the radius of the first zone, and Fraunhofer diffraction will be observed because the aperture contains only one zone and the phase in the aperture is a constant.

Opaque Screen

If the screen containing a circular aperture, of radius a, is replaced by an opaque disk of radius a, the intensity distribution on the symmetry axis, behind the disk, is found to be equal to the value that would be observed with no disk present. This prediction was first derived by Poisson, to demonstrate that wave theory was incorrect; however, experimental observation supported the prediction and verified the theory.

We construct a spiral, shown in Figure 16, similar to the one for the circular aperture in Figure 14. The point B on the spiral represents the edge of the disk. The shaded portion of the spiral from A to B does not contribute because that portion of the wave is covered by the disk and the zones, associated with that portion of the wave, cannot be seen from the observation point. The amplitude at P_0 is the length of the chord from B to A_∞ shown in Figure 16. If the observation point moves toward the disk, then B moves along the spiral toward A_∞. There is always intensity on the axis for this configuration, though it slowly decreases until it reaches zero when the observation point reaches the disk; this corresponds to point B reaching point A_∞ on the spiral. Physically, zero intensity occurs when the disk blocks the entire light wave. There are no maxima or minima observed as the disk diameter, a, increases or as the observation distance changes. If the observation point is moved perpendicular to the symmetry axis, a set of concentric bright rings are observed. The origin of these bright rings can be explained using Fresnel zones, in a manner similar to the one used to explain the bright rings observed in a Fresnel diffraction pattern from a circular aperture.

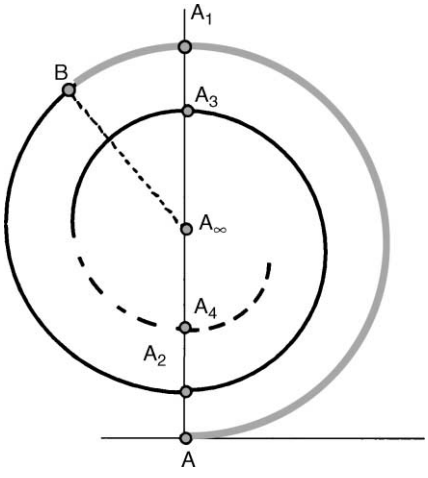

Figure 16 Vibration curve for opaque disk. The shaded region makes no contribution because it is associated with the portion of the wave obstructed by the opaque object. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

Zone Plate

In the construction of Fresnel zones, each zone was assumed to produce a Huygens wavelet, out of phase with the wavelets produced by its nearest neighbors. If every other zone were blocked, then there would be no negative contributions to [37]. The intensity on-axis would be equal to the square of the sum of the amplitudes produced by the in-phase zones – exceeding the intensity of the incident wave. An optical component made by the obstruction of either the odd or the even zones could therefore be used to concentrate the energy in a light wave.

The boundaries of the opaque zones, used to block out-of-phase wavelets, are seen from [38] to increase as the square root of the integers. An array of opaque rings, constructed according to this prescription is called a zone plate, see Figure 17.

A zone plate will perform like a lens with focal length

$$f = \pm \frac{r_1^2}{\lambda} \qquad [40]$$

The zone plate, shown in Figure 17, will act as both a positive and negative lens. What we originally called the source can now be labeled the object point, O, and what we called the observation point can now be labeled the image point, I. The light passing through the zone plate is diffracted into two paths, labeled C and D in Figure 17. The light waves, labeled C, converge to a real image point I. For these waves the zone plate performs the role of a positive lens with a focal length given by the positive value of [40]. The light waves, labeled D in Figure 17, appear to originate from the virtual image point labeled $\mathbb{I}$. For these waves the zone plate performs the role of a negative lens with a focal length given by the negative value of [40].

The zone plate will not have a single focus, as is the case for a refractive optical element, but rather will have multiple foci. As we move toward the zone plate, from the first focus, given by [40], the effective Fresnel zones will decrease in diameter. The zone plate will no longer obstruct out-of-phase Fresnel zones and the light intensity on the axis will decrease. However, additional maxima, of the on-axis intensity, will be observed at values of Z for which the first zone plate opening contains an odd number of zones. These positions can also be labeled as foci of the zone plate; however, the intensity at each of these foci will be less than the intensity at the primary focus.

Lord Rayleigh suggested that an improvement of the zone plate design would result if, instead of blocking every other zone, we shifted the phase of alternate zones by 180°. The resulting zone plate, called a phase-reversal zone plate, would, more efficiently, utilize the incident light. R.W. Wood was the first to make such a zone plate. Holography provides an optical method of constructing the phase-reversal zone plates in the visible region of the spectrum. Semiconductor lithography has been used to produce zone plates in the x-ray region of the spectrum.

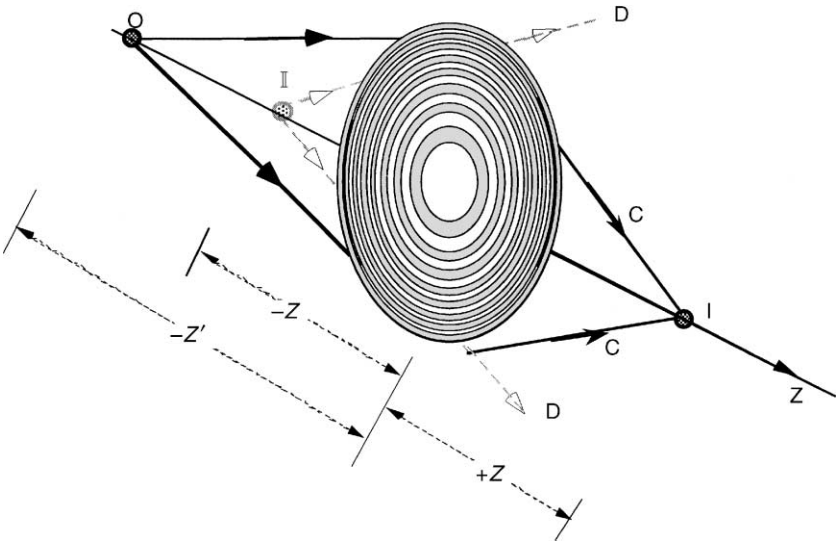

Figure 17 A zone plate acts as if it were both a positive and a negative lens. Light from the object, O, is diffracted into waves traveling in both the D and the C directions. The light traveling in the C direction produces a real image of O at I. The light traveling in the D direction appears to originate from a virtual image at I. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

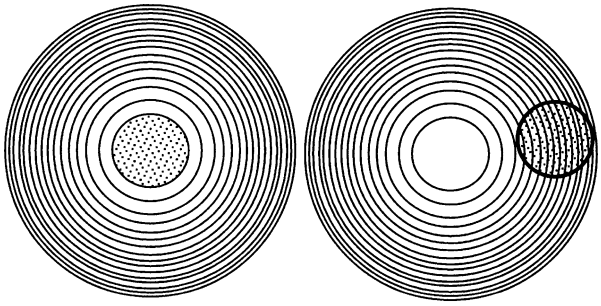

Figure 18 (a) A set of Fresnel zones has been constructed about the optical path taken by some light ray. If the optical path of the ray is varied over the cross-hatched area shown in the figure, then the optical path length does not change. This cross-hatched area is equal to the first Fresnel zone and is described as the neighborhood of the light ray. (b) The neighborhood defined in (a) is moved so that it surrounds an incorrect optical path for a light ray. We see that this region of space would contribute no wave amplitude at the observation point because of the destructive interference between the large number of partial zones contained in the neighborhood. Reprinted with permission from Guenther RD (1990) *Modern Optics*. New York: John Wiley & Sons.

The resolving power of a zone plate is a function of the number of zones contained in the plate. When the number of zones exceeds 200, the zone plate's resolution approaches that of a refractive lens.

Fermat's Principle

The Fresnel zone construction provides physical insight into the interpretation of Fermat's principle which states that, if the optical path length of a light ray is varied in a neighborhood about the true path, there is no change in path length. By constructing a set of Fresnel zones about the optical path of a light ray, we can discover the physical meaning of a neighborhood.

The rules for constructing a Fresnel zone require that all rays passing through a given Fresnel zone have the same optical path length. The true path will pass through the center of the first Fresnel zone constructed on the actual wavefront. A neighborhood must be the area of the first Fresnel zone, for it is over this area that the optical path length does not change. Figure 18a shows the neighborhood, about the true optical path, as a cross-hatched region equal to the first Fresnel zone.

Light waves do travel over wrong paths but we do not observe them because the phase differences for those waves that travel over the 'wrong' paths are such that they destructively interfere. By moving the neighborhood, defined in the previous paragraph as the first Fresnel zone, to a region displaced from the true optical path, we can use the zone construction to see that this statement is correct. In Figure 18b the neighborhood is constructed about a ray that is improper according to Fermat's principle. We see that this region of space would contribute no energy at the observation point because of destructive interference between the large number of partial zones contained in the neighborhood.

This leads us to another interpretation of diffraction. If an obstruction is placed in the wavefront so that we block some of the normally interfering wavelets, we see light not predicted by Fermat's principle, i.e., we see diffraction.

Aberration Correction with Diffractive Elements

N Lindlein, University of Erlangen-Nürnberg, Erlangen, Germany

Diffractive optical elements (DOEs) can be used for the correction of aberrations in optical systems because of two fundamental properties:

1. The phase function Φ of a DOE can be chosen quite arbitrarily so that for a given wavelength λ the DOE can act like an aspheric optical element.
2. The dispersion of a DOE due to the local grating equation is very high and its sign is opposite to that of the dispersion of a refractive optical element with normal dispersion of the refractive index.

The first property allows the correction of monochromatic aberrations in an optical system similar to the case of using an aspheric surface in a refractive optical system. The second property allows the construction of hybrid achromatic optical elements that consist of a refractive lens and a diffractive lens whose optical powers have the same sign (e.g., two positive lenses for a positive achromatic element or two negative lenses for a negative achromatic element).

This article will first describe two methods for the simulation of DOEs by ray tracing because ray tracing is the basic simulation tool for aberration correction. Afterwards, the properties of DOEs for the correction of monochromatic and chromatic aberrations and some applications will be discussed. The name DOE will always mean either binary, or multiple-step or blazed surface relief diffractive optical elements which change only the phase of the incident wave and not the amplitude. All examples will be given for transmission elements but in principle reflective elements can also be described with quite similar formulas.

Ray Tracing Simulation of DOEs

First of all it seems straightforward to use a diffractive analysis to simulate a diffractive optical element. However, the global diffractive analysis of a general DOE with perhaps 1000 or more grating structures and locally changing grating period and especially the diffractive analysis of a complete optical system containing DOEs and other elements is so complex that it can be done only for very simple DOEs and systems. Therefore, the diffractive analysis of a DOE is mostly restricted to a local analysis using some periods (e.g., 10–50 periods) to calculate, e.g., the different local diffraction orders, their diffraction efficiencies and possibly local phase shifts. For the global analysis another simulation method has to be used.

The most important simulation method for the correction of aberrations in traditional optical systems is ray tracing. Therefore, ray tracing methods are also used for DOEs. These methods can calculate the path of a ray for a given diffraction order, but they cannot calculate the diffraction efficiency for this ray. For the calculation of the diffraction efficiency local diffractive analysis methods (scalar or rigorous methods depending on the local grating frequency and the angle of the incident ray) have to be used

in addition. In particular, for applications with a broad wavelength spectrum (e.g., an achromatic lens) or a broad spectrum of angles of the incident rays, the diffraction efficiency has to be analyzed carefully to obtain the energy distribution in the different diffraction orders. But this is beyond the scope of this article about aberration correction and we assume that we know the local diffraction efficiency for each ray.

Sweatt Model for the Ray Tracing Simulation of DOEs

An aspheric refractive surface with height h as a function of the lateral coordinates x and y and a refractive index n below the surface and air (refractive index 1) above the surface can be approximately replaced by a DOE with the phase function (see Figure 1)

$$\Phi(x, y) = 2\pi \frac{(n-1)h(x, y)}{\lambda} \qquad [1]$$

Here, λ is the wavelength of the light for which the DOE is designed and the phase function is a continuous representation of the structure of the DOE. To encode the phase function of the DOE the wrapped phase function $\Phi \bmod 2\pi$ has to be considered. The encoding itself can be done by building a blazed, a multiple-step or a binary structure (see Figure 1), whereby the first-order diffraction efficiency decreases from the blazed to the binary structure (at maximum 100% diffraction efficiency for the blazed structure and about 40% for the binary structure). The replacement of an aspheric refracting surface by a DOE using eqn [1] is only valid in the paraxial approximation since the phase function of the DOE is encoded in a plane whereas the refracting surface of the aspheric is typically curved. But, the agreement between the aspheric surface and the DOE with a phase function calculated with the help of eqn [1] increases with increasing refractive index n since then the curvature of the aspheric is quite small and the refraction also nearly takes place in a plane. Of course, the refractive index of real materials cannot exceed a value of more than about 3.5 (for silicon used in the near infrared). But, in a numerical simulation the refractive index can be arbitrarily high, e.g., several thousand. This is the reason why the so called Sweatt model for tracing rays through DOEs uses a weakly curved aspheric surface with height h_{sweatt} and a very high refractive index n_{sweatt} to simulate a diffractive phase function Φ:

$$h_{\text{sweatt}}(x, y) = \frac{\lambda}{n_{\text{sweatt}} - 1} \frac{\Phi(x, y)}{2\pi} \qquad [2]$$

To take into account the wavelength dispersion of the DOE the refractive index n_{sweatt} in the Sweatt model has to be proportional to the wavelength λ

$$n_{\text{sweatt}}(\lambda) = n_0 \frac{\lambda}{\lambda_0} \qquad [3]$$

where n_0 is the refractive index at the wavelength λ_0.

The validity of the Sweatt model increases with increasing refractive index and becomes nearly exact for $n_{\text{sweatt}} \to \infty$ (in practice values of several thousand for the refractive index are normally sufficient and a rule of thumb is to take the numerical value of the utilized wavelength specified either in nanometers for infrared light or angstroms for visible light). The Sweatt model was introduced as a means to simulate DOEs in ray tracing programs unable to implement DOEs directly but capable of simulating aspheric refractive surfaces. However, a disadvantage of this model is the numerical error generated by the finite value of the refractive index.

Modern ray tracing programs therefore use a more appropriate model based on the local grating equation.

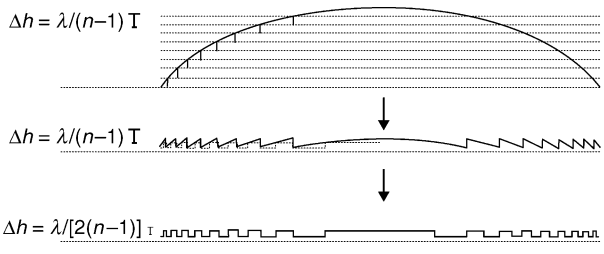

Figure 1 Transition from an aspheric refracting surface to a blazed diffractive optical element and finally to a binary diffractive optical element.

Local Grating Model for the Ray Tracing Simulation of DOEs

The basic equation for the simulation of DOEs by the local grating model is that the phase Φ_{out} of a diffracted ray in the plane of the DOE can be calculated from the phase Φ_{in} of the incident ray by adding the phase function Φ of the DOE multiplied by the diffraction order m:

$$\Phi_{\text{out}}(x, y, z_0) = \Phi_{\text{in}}(x, y, z_0) + m\Phi(x, y) \qquad [4]$$

Here, z_0 is the z-coordinate of the DOE plane which is assumed to be perpendicular to the z-axis (see Figure 2). The diffraction order m will be only one for an ideal blazed DOE but it can have an arbitrary integer value for binary DOEs. In practice, the optical designer will calculate the system for one diffraction order and analyze the system for other diffraction orders afterwards if necessary.

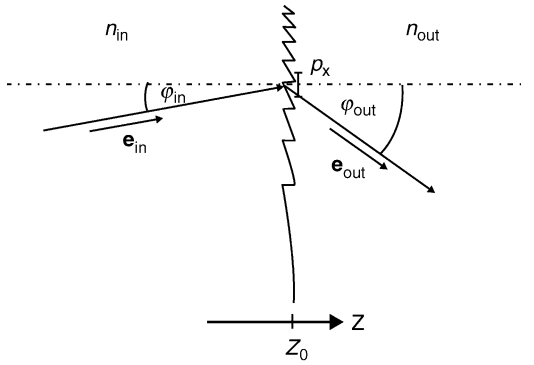

Figure 2 Schematic view in two-dimensions of the path of a ray which is diffracted at a DOE.

For the phases Φ_{in} of the incident and Φ_{out} of the diffracted ray the eikonal equation of geometrical optics is valid,

$$|\nabla\Phi_j|^2 = k_j^2 = \left(\frac{2\pi n_j}{\lambda}\right)^2 \qquad [5]$$

where the index j can have the two values $j \in \{\text{in}, \text{out}\}$. n_{in} or n_{out} are the refractive indices of the materials in which the incident or diffracted rays propagate. λ is the wavelength in vacuum. This form of the eikonal equation is obtained from the more common form $|\nabla L_j|^2 = n_j^2$, which is derived in any textbook of optics, by multiplying it with $(2\pi/\lambda)^2$ and using the definition of the optical phase $\Phi_j = 2\pi L_j/\lambda$. Here, L_j is the optical path length which is often called the eikonal. The curves of constant phase $\Phi_j(x, y, z) = \text{constant}$ are the wavefronts and the gradient $\nabla\Phi_j(x, y, z)$ points in the direction of the local ray which is perpendicular to the wavefront at the point (x, y, z) and describes its direction of propagation. Furthermore, the unit vectors $\mathbf{e}_{in}$ and $\mathbf{e}_{out}$ along the ray direction of the incident and diffracted ray, respectively, can be calculated by normalizing the gradient:

$$\mathbf{e}_j = \frac{\nabla\Phi_j}{|\nabla\Phi_j|} = \frac{\lambda}{2\pi n_j}\nabla\Phi_j\,; \qquad j \in (\text{in}, \text{out}) \qquad [6]$$

Since $\mathbf{e}_j$ is a unit vector, i.e., $e_{x,j}^2 + e_{y,j}^2 + e_{z,j}^2 = 1$, it can be seen from eqn [6] (and also from the original eqn [5]) that the z-component $e_{z,j}$ of the ray direction vector can be calculated (apart from its sign) if the two partial derivatives of the phase with respect to x and y are known. This means that it is sufficient to know the phase in a plane as stated in eqn [4].

By calculating the partial derivatives of eqn [4] with respect to x and y the equations for the ray tracing at a DOE are derived:

$$\begin{aligned}
\frac{\partial\Phi_{out}(x,y)}{\partial x} &= \frac{\partial\Phi_{in}(x,y)}{\partial x} + m\frac{\partial\Phi(x,y)}{\partial x} \\
&\Rightarrow n_{out}e_{x,out}(x,y) \\
&= n_{in}e_{x,in}(x,y) + m\frac{\lambda}{2\pi}\frac{\partial\Phi(x,y)}{\partial x} \\
\frac{\partial\Phi_{out}(x,y)}{\partial y} &= \frac{\partial\Phi_{in}(x,y)}{\partial y} + m\frac{\partial\Phi(x,y)}{\partial y} \\
&\Rightarrow n_{out}e_{y,out}(x,y) \\
&= n_{in}e_{y,in}(x,y) + m\frac{\lambda}{2\pi}\frac{\partial\Phi(x,y)}{\partial y}
\end{aligned} \qquad [7]$$

The local grating frequencies ν_x and ν_y in x and y direction are calculated from the phase function Φ by:

$$\begin{aligned}
\nu_x(x,y) &= \frac{1}{2\pi}\frac{\partial\Phi(x,y)}{\partial x} \\
\nu_y(x,y) &= \frac{1}{2\pi}\frac{\partial\Phi(x,y)}{\partial y}
\end{aligned} \qquad [8]$$

Therefore, given $\mathbf{e}_{in}$ and eqn [6], the ray direction vector $\mathbf{e}_{out}$ of the diffracted ray is

$$\begin{aligned}
n_{out}\mathbf{e}_{out} &= n_{out}\begin{pmatrix} e_{x,out} \\ e_{y,out} \\ e_{z,out} \end{pmatrix} \\
&= \begin{pmatrix} n_{in}e_{x,in} + m\lambda\nu_x \\ n_{in}e_{y,in} + m\lambda\nu_y \\ \sqrt{n_{out}^2 - (n_{in}e_{x,in} + m\lambda\nu_x)^2 - (n_{in}e_{y,in} + m\lambda\nu_y)^2} \end{pmatrix}
\end{aligned} \qquad [9]$$

The dependence of the lateral coordinates x and y is left out in eqn [9] to simplify notation. It can be easily checked that this equation fulfills the required condition for the unit vector: $e_{x,out}^2 + e_{y,out}^2 + e_{z,out}^2 = 1$.

As stated above, for a blazed DOE fabricated to the exact depth and illuminated by the design wavelength only the first diffraction order $m = 1$ is generated. But in practice other diffraction orders m are generated due to fabrication errors or illuminating with other wavelengths. In particular, by using binary DOEs there are inherently different diffraction orders. Therefore, it may be necessary to analyze the optical system for several values m one after the other. Each value m defines one wavefront generated by the DOE and the wavefront can be calculated by evaluating the optical path lengths along the rays at different points. In practice, the optical system has to be analyzed for those values m with sufficiently high

diffraction efficiency. Then, it can be checked whether undesired diffraction orders of the DOE are blocked in the optical system by aperture stops or whether they will disturb the output of the optical system. The local diffraction efficiency of each ray for a value m can be calculated to a good approximation by using a diffractive analysis of the corresponding local grating, i.e., that of an infinitely extended grating which would have the same grating period and the same structure shape (e.g., depth) as the DOE at the specific point.

If the y component of the incident ray and the local grating frequency ν_y are both zero the ray components in the x direction can be expressed via the sine of the angle of incidence φ_{in} or the angle of the diffracted ray φ_{out} (see **Figure 2**). In this case the first row of eqn [9] can be written as

$$n_{\text{out}} \sin \varphi_{\text{out}} = n_{\text{in}} \sin \varphi_{\text{in}} + m\frac{\lambda}{p_x} \qquad [10]$$

where the local grating period $p_x = 1/\nu_x$ has been introduced. This is the well-known grating equation.

In this article eqns [4]–[10] assume that the DOE is on a planar substrate and that x and y are the lateral coordinates on the substrate. However, the equations can also be written in a vector formulation which is valid for DOEs on curved substrates (see Further Reading).

So, we have now a powerful simulation method to design and analyze in the following several optical systems containing DOEs to correct monochromatic or chromatic aberrations.

Correction of Monochromatic Aberrations

For practical applications it is important to have an efficient algorithm to calculate the phase function of a DOE to correct the aberrations in a given optical system. Several different cases have to be distinguished. An easy case is the design of a DOE to produce a desired output wavefront Φ_{out} from a known input Φ_{in}. In this case, eqn [4] can be used to calculate the phase function Φ of the DOE directly. Two examples are given in the following. Afterwards, some aspects of a more general numerical optimization procedure are described.

Aberration Correction for Interferometrically Recorded Holograms

Although the following example of the aberration correction of interferometrically recorded holograms by using DOEs seems to be quite special it shows exemplarily several principal steps which are necessary to design a DOE for correcting monochromatic aberrations.

In this article the name DOE is used for diffractive elements with a microstructured surface (binary, multistep or blazed). Such elements have the property that their diffraction efficiency depends only weakly on the wavelength or the angle of incidence of the illuminating light. Another interesting class of diffractive elements are holograms in volume media, which are recorded interferometrically using two coherent recording waves. The refractive index in a volume hologram is modulated periodically and the thickness has to amount to several periods of the interference pattern along the z-direction in order to have a so-called thick hologram with a high diffraction efficiency. If there are only a few periods along the z-direction the quite small modulation of the refractive index (typically about 0.02) will result in a low diffraction efficiency. Therefore, if the angle between the two recording waves is small the resulting interference pattern will have large periods and only a few periods are recorded in the photosensitive layer along the z-direction. But this means that the holographic optical element (HOE) can only have a small diffraction efficiency. From this fact, it is clear that also by using the recorded HOE the deflection angle between the incident and the diffracted wave must not be smaller than a certain value because otherwise the thickness has to be very big or the diffraction efficiency decreases. Therefore, such elements with high diffraction efficiency, which will be named in the following holographic optical elements (HOE), are always off-axis elements because for on-axis elements all rays in the neighborhood of the axis are only deflected by a small angle and then the diffraction efficiency would be low. For the correct wavelength and angle of incidence, so that the Bragg condition of holography is fulfilled, HOEs, like blazed DOEs, exhibit only one dominant diffraction order $m = m_{\text{dom}}$ (normally $m_{\text{dom}} = 1$). But, if the angle of incidence or the wavelength change, the diffraction efficiency in the order m_{dom} decreases rapidly and light passes through the HOE without being deflected, i.e., most of the light is then in the order $m = 0$. For this reason, a HOE can be used for example for a head-up display to fade in some information under the Bragg angle without hindering the normal view onto the environment.

Traditional materials for HOEs like dichromated gelatin (DCG) are sensitive only in the blue–green spectral region (e.g., for light of an argon ion laser with $\lambda = 488$ nm). However, once recorded it will be illuminated in many applications (e.g., optical interconnects) by a wavelength in the red–infrared spectral region. Unfortunately, the wavelength mismatch between recording and reconstruction illumination introduces aberrations.

If the two desired reconstruction waves at the wavelength λ_2 have the phases $\Phi_{r,\lambda 2}$ and $\Phi_{o,\lambda 2}$ in the surface plane of the HOE (the subscripts r and o refer to interferometry reference and object, respectively), the phase function Φ of the HOE which has to be recorded is

$$\Phi(x, y) = \Phi_{o,\lambda 2}(x, y) - \Phi_{r,\lambda 2}(x, y) \qquad [11]$$

If our discussion here is restricted to holographic lenses, the two reconstruction waves will be spherical (or plane) waves (see Figure 3b) with the center of curvature at the points $\mathbf{r}_{r,\lambda 2}$ and $\mathbf{r}_{o,\lambda 2}$ and eqn [11] is:

$$\Phi(x,\ y) = \frac{2\pi\sigma_{o,\lambda 2}}{\lambda_2}\sqrt{(x - x_{o,\lambda 2})^2 + (y - y_{o,\lambda 2})^2 + z_{o,\lambda 2}^2} - \frac{2\pi\sigma_{r,\lambda 2}}{\lambda_2}\sqrt{(x - x_{r,\lambda 2})^2 + (y - y_{r,\lambda 2})^2 + z_{r,\lambda 2}^2} \qquad [12]$$

The parameters $\sigma_{o,\lambda 2}$ and $\sigma_{r,\lambda 2}$ are either $+1$ for a divergent spherical wave or -1 for a convergent spherical wave. The surface of the HOE itself is in the plane at $z = 0$.

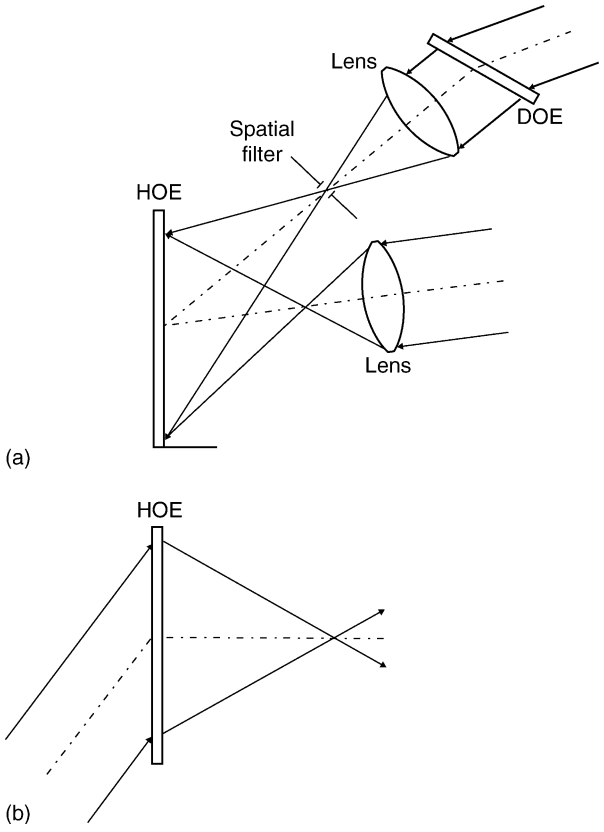

Figure 3 Schematic view of the (a) recording and (b) reconstruction setup for a holographic lens. The recording is made at wavelength λ_1 and the reconstruction at wavelength λ_2.

The task is now to find two recording waves which construct nearly the same three-dimensional interference pattern in the hologram at the recording wavelength λ_1. This means that eqn [12] has to be fulfilled exactly for the difference of the phases of the two recording waves in the plane $z = 0$ and, additionally, the Bragg condition has to be fulfilled at least approximately. So, the next step is to calculate one of the recording waves with phase $\Phi_{r,\lambda 1}$ so that the Bragg condition is fulfilled. This can be done approximately with a third-order theory resulting in a spherical wave or nearly exactly with an iterative numerical procedure resulting generally in an aspheric recording wave. If $\Phi_{r,\lambda 1}$ is known, the other recording wave with phase $\Phi_{o,\lambda 1}$ is calculated by

$$\Phi_{o,\lambda 1}(x, y) = \Phi(x, y) + \Phi_{r,\lambda 1}(x, y) \qquad [13]$$

At least this recording wave will be aspheric. To generate such an aspheric wave it is traced by ray tracing to a plane where the two recording waves are spatially separated. There, either a DOE or a combination of a DOE and a lens are used to generate the aspheric wave. The calculations of the phase function of the DOE are done again by using an equation like [11] whereby one wave is the propagated aspheric wave (possibly propagated also through a lens) and the other is normally a plane off-axis wave with which the DOE will be illuminated in the real recording setup (see Figure 3a). Here, the off-axis angle is necessary to allow spatial filtering of disturbing diffraction orders of the DOE which will be normally fabricated as a binary DOE.

Experiments of our own showed (see the literature) that nearly diffraction-limited holographic lenses with a numerical aperture of NA = 0.4 can be fabricated by correcting the aberrations of about 28 wavelengths peak-to-valley (for the reconstruction at 633 nm wavelength) due to the wavelength mismatch between recording at 488 nm wavelength and reconstruction at 633 nm wavelength by using a DOE in the recording setup.

Testing of Aspheric Surfaces by Using a DOE as Aberration Compensating Element

An important application for DOEs is testing aspheric surfaces and nowadays more and more companies use DOEs to test aspheric surfaces which are used for example in the objectives of lithographic wafer steppers to produce highly integrated microelectronic circuits.

In this testing setup the DOE is illuminated by a wave with phase Φ_{in} to generate a wave with phase Φ_{out} that is incident perpendicular to the aspheric surface (see Figure 4). After reflection at the asphere

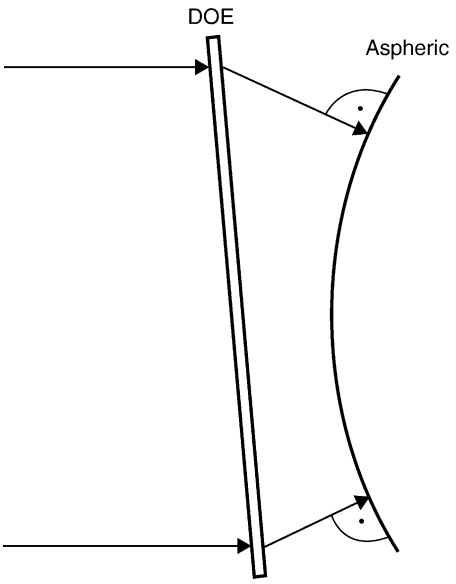

Figure 4 Scheme showing the basic elements for testing an aspheric surface.

the wave is retro-reflected and takes the same path if the asphere has no surface deviations and no misalignments. This means that the setup is completely symmetric for a reflection at the aspheric surface. Therefore, the optical path lengths have to be identical for all rays on the asphere. To calculate the phase function of the DOE the following steps are made:

- A grid of N rays starting perpendicularly on the aspheric surface and having all phase zero (due to the fact that the phase has to be identical it can be set to zero) is traced to the plane of the DOE. N depends on the shape and numerical aperture of the asphere and the grid will be in most cases two dimensional and regular or one dimensional (along one radial section of the asphere) and regular if the asphere and the system are completely rotationally symmetric. As a rule of thumb the number N of rays has to be more than twice the number of polynomial coefficients if the asphere is described by a polynomial.
- The phase of these rays is the function $-\Phi_{\text{out}}$ (the negative sign is necessary because the rays take the opposite direction) and is now known at some points (x_i, y_i) with $i \in \{1, 2, \ldots, N\}$.
- The phase Φ_{in} of the incident wave which is in practice either a plane wave or a spherical wave is calculated in the plane of the DOE. If the incident wave is generated by a lens having aberrations it is again calculated by ray tracing, otherwise it can be calculated analytically.
- Now, the phase function Φ of the DOE can in principle be calculated with the help of eqn [4].

However, the phase Φ_{out} (and possibly also Φ_{in}) is known only at some points (x_i, y_i), but it has to be known at all points of the DOE. Therefore in practice an analytical representation of the phase functions of the incident and output wave has to be calculated. This can be done by fitting a polynomial to the phase values using a least squares fit. In this case the coordinates, at which the phase values are known, can be quite arbitrary as long as the sampling is dense enough. For a rotationally symmetric system the polynomial should also be rotationally symmetric, i.e., a polynomial P_{rot} depending only on the radius coordinate r

$$r = \sqrt{x^2 + y^2} \qquad [14]$$

$$P_{\text{rot}}(r) = \sum_{j=0}^{G} a_j r^j \qquad \text{or} \qquad P_{\text{rot}}(r) = \sum_{j=0}^{G/2} a_{2j} r^{2j} \qquad [15]$$

where G is the degree of the polynomial, i.e., the highest power in r. In these two cases the number N of sampling points lying along one radial section of the rotationally symmetric optical system should be larger than $2G$ or G, respectively.

For general non-symmetric systems a Cartesian polynomial P_{cart} can be used, e.g.,

$$P_{\text{cart}}(x, y) = \sum_{j=0}^{G} \sum_{k=0}^{G-j} a_{jk} x^j y^k \qquad [16]$$

Here, the number of coefficients of the polynomial is $(G + 1)(G + 2)/2$ and the number N of sampling points should again be larger than twice the number of coefficients, i.e., $N > (G + 1)(G + 2)$.

For both types of polynomials the coefficients a_j or a_{jk} have to be calculated so that the merit function M

$$M(\mathbf{a}) = \sum_{i=1}^{N} (P(x_i, y_i) - \Phi_j(x_i, y_i))^2; \quad j \in \{\text{in, out}\} \qquad [17]$$

is minimized. The symbol P means either P_{rot} or P_{cart}. The vector $\mathbf{a}$ symbolizes the coefficients $\mathbf{a}_j$ or $\mathbf{a}_{jk}$. By differentiating M with respect to all coefficients and setting the partial derivatives to zero a system of linear equations is obtained which can be solved by standard procedures. As mentioned before, the number N of independent sampling points has to be at least double the size of the number of coefficients of the polynomial. Otherwise, the polynomial can 'swing' between the sampling points and the polynomial fits well to the desired phase function only at the sampling points but not at other points in between.

For very irregular aspherics with a fast change of the local curvature it might by necessary not to take a

global polynomial fit but a spline fit, i.e., a set of adjacent local polynomials with several continuity conditions at the border area of each local polynomial. In this case the total number of coefficients used to describe the phase functions and Φ_{in} and Φ_{out} of the DOE will be increased compared to the description by a global polynomial. Then, the number N of rays for the calculation has also to be increased accordingly.

So, in this example the DOE acts as a null-compensator for the asphere and at first sight it is not a typical example for aberration correction. However, by regarding the complete system the DOE compensates the aberrations, i.e., deviations from a spherical wave, generated by the asphere which are primary and higher-order spherical aberrations if the asphere is rotationally symmetric and more general aberrations otherwise. This example shows how the phase function of a DOE can be designed straightforwardly for correcting aberrations if there is only one well-defined wavefront propagating through the optical system. This design method can also be used for other optical systems where the input and the output wavefront of the DOE are well defined.

Numerical Optimization of DOEs in Optical Systems

In a general optical system, where a DOE is not only used to compensate the aberrations for one specific incident wave but for different incident waves (optical system with a field), it is not possible to calculate the optimum phase function in such a straightforward way as given above. However, a DOE is in principle similar to an asphere in an optical system, so that the design rules for including aspherics in optical systems can be used in some cases as long as monochromatic aberrations are considered. Nevertheless, one should keep in mind that a DOE is, according to the Sweatt model, an asphere with high refractive index and small height, i.e., the deflection of the light rays occurs in a plane (or on a curved surface if the DOE is situated on a curved substrate). Therefore, the design rules for aspheric surfaces can be used only if the high refractive index of the Sweatt model is used in the design.

In the general case only a numerical optimization can be used. For this, it is very important to select an appropriate mathematical representation of the phase function of the DOE.

For rotationally symmetric optical systems also the phase function of the DOE should be rotationally symmetric. Therefore, in such a case it is useful to write the phase function Φ as a polynomial in the radius coordinate r as given in eqns [14] and [15]. Then, the $(G + 1)$ or $(G/2 + 1)$ coefficients a_j have to be optimized, whereby a_2 is proportional to the focal power of the DOE, whereas the other coefficients represent aspheric terms. Depending on the numerical aperture and on the application the degree G of the polynomial can be increased in order to achieve a better solution. Nevertheless, the degree in the optimization should be as small as necessary in order to avoid 'swinging effects' and numerical instabilities of the polynomial. To determine the smallest adequate degree an iterative method has to be used by starting with a quite small degree (e.g., 4). If the result of the optimization is not good enough the degree has to be increased until the result of the optimization is satisfying.

For non-rotationally symmetric optical systems a Cartesian polynomial like in eqn [16] can be taken and all the $(G + 2)(G + 1)/2$ coefficients a_{jk} have to be optimized. Since the number of free parameters is in this case larger than the number of free parameters in the rotationally symmetric case the convergence of the optimization may take a long time and the risk to break down in a local minimum of the multidimensional parameter space increases.

In principle, the calculation of a DOE used, e.g., for testing an aspheric surface can also be done by optimizing the coefficients of the polynomial representing the phase function of the DOE. Nevertheless, as a general rule it can be said that a direct calculation of the phase function is always more efficient than a numerical optimization, if the direct calculation is possible. In practice, it can be seen that the maximum degree of a polynomial, which is directly calculated by the method described in the last section, is always smaller than the degree which is necessary in a numerical optimization to achieve convergence of the optimization.

Of course, in such cases where several different types of aberrations (on-axis aberrations like spherical aberration, off-axis aberrations like astigmatism and coma or field aberrations like field curvature or distortion) have to be corrected in an optical system a direct calculation of the phase function is not possible so that only the numerical optimization can provide a solution.

Up to now only monochromatic aberrations have been discussed. But as stated at the beginning of this article the strong dispersion of a DOE having opposite sign to the dispersion of a refractive element offers additional applications of DOEs by correcting chromatic aberrations. The principle of doing this is described in the following.

Correction of Chromatic Aberrations

The focal power $1/f$ (f is the focal length of the lens) of a thin refractive lens consisting of two spherical

surfaces with radii of curvature R_1 and R_2 and made of a material (glass) with refractive index n is

$$\frac{1}{f(\lambda)} = (n(\lambda) - 1)\left(\frac{1}{R_1} - \frac{1}{R_2}\right) \qquad [18]$$

where λ is the wavelength of the illuminating light.

This equation is valid for all wavelengths and so also for the commonly used wavelength $\lambda_d = 587.6$ nm (yellow d-line of helium) which is near the center of the visible spectrum. Then $1/R_1 - 1/R_2$ can be expressed as $1/((n_d - 1)f_d)$ and the focal power depends on the wavelength as

$$\frac{1}{f(\lambda)} = \frac{n(\lambda) - 1}{n_d - 1}\frac{1}{f_d} \qquad [19]$$

where n_d and f_d are the refractive index and the focal length at $\lambda_d = 587.6$ nm, respectively. So, by combining two thin lenses made of materials with refractive indices n_1 and n_2 and focal lengths f_1 and f_2 the focal power of the doublet assuming a zero distance between the two lenses is:

$$\begin{aligned}\frac{1}{f_{ges}(\lambda)} &= \frac{1}{f_1(\lambda)} + \frac{1}{f_2(\lambda)} \\ &= \frac{n_1(\lambda) - 1}{n_{1,d} - 1}\frac{1}{f_{1,d}} + \frac{n_2(\lambda) - 1}{n_{2,d} - 1}\frac{1}{f_{2,d}}\end{aligned} \qquad [20]$$

For an achromatic doublet the focal power should be equal for two different wavelengths which are commonly the wavelengths $\lambda_F = 486.1$ nm (blue F-line of hydrogen) and $\lambda_C = 656.3$ nm (red C-line of hydrogen) which mark the limits of the well visible spectrum (of course the visible spectrum itself is broader but the sensitivity of the human eye to wavelengths below λ_F or beyond λ_C is quite bad). Therefore, the following equations result:

$$\begin{aligned}\frac{1}{f_{ges}(\lambda_F)} = \frac{1}{f_{ges}(\lambda_C)} &\Rightarrow \frac{n_1(\lambda_F) - n_1(\lambda_C)}{n_{1,d} - 1}\frac{1}{f_{1,d}} \\ &= -\frac{n_2(\lambda_F) - n_2(\lambda_C)}{n_{2,d} - 1}\frac{1}{f_{2,d}}\end{aligned} \qquad [21]$$

By introducing the Abbe number V_d

$$\begin{aligned}V_d &= \frac{n_d - 1}{n_F - n_C} \\ &= \frac{n(\lambda_d = 587.6\text{ nm}) - 1}{n(\lambda_F = 486.1\text{ nm}) - n(\lambda_C = 656.3\text{ nm})}\end{aligned} \qquad [22]$$

equation [21] can be simplified to

$$V_{1,d}f_{1,d} = -V_{2,d}f_{2,d} \qquad [23]$$

Now, the wavelength dispersion of all conventional materials (glasses, polymers, etc.) is such that the refractive index decreases with increasing wavelength, i.e. the material has a so-called normal dispersion. This means that the Abbe number V_d is always positive and ranges from about 20 for high-dispersive glasses (e.g., SF59) to more than about 80 for low-dispersive glasses (e.g. Ultran 20). So, to fabricate a refractive achromatic doublet with a positive focal power it is necessary to take a positive lens with focal length f_1 made of a low-dispersive glass with a large Abbe number $V_{1,d}$ and a negative lens with focal length f_2 made of a high-dispersive glass with a small Abbe number $V_{2,d}$ (see **Figure 5a**). Therefore, the resulting focal power of the achromatic doublet

$$\frac{1}{f_{ges,d}} = \frac{1}{f_{1,d}} + \frac{1}{f_{2,d}} = \frac{1}{f_{1,d}}\left[1 - \frac{V_{2,d}}{V_{1,d}}\right] \qquad [24]$$

is always smaller than the focal power of the positive lens with focal power $1/f_{1,d}$ alone.

The situation is completely different if a refractive and a diffractive lens are used. From the Sweatt model

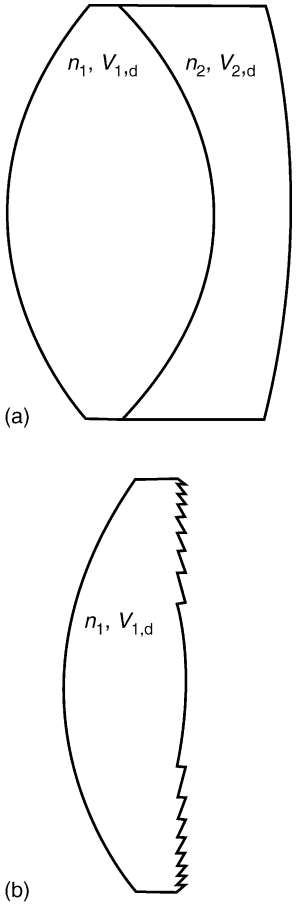

Figure 5 Structure of achromats: (a) refractive achromatic doublet consisting of a positive lens with low dispersion and a negative lens with high dispersion; (b) hybrid achromatic lens consisting of a positive refractive lens and a positive diffractive lens.

of a DOE (eqn [3]) it is known that the refractive index n_{sweatt} is proportional to the wavelength λ

$$n_{\text{sweatt}}(\lambda) = \frac{n_0}{\lambda_0}\lambda = \frac{n_d}{\lambda_d}\lambda \qquad [25]$$

Therefore, the Abbe number of a DOE is

$$\begin{aligned} V_d &= \frac{n_d - 1}{n_F - n_C} \\ &= \frac{\lambda_d}{\lambda_F - \lambda_C}\left(1 - \frac{1}{n_d}\right) \overset{n_d \to \infty}{=} \frac{\lambda_d}{\lambda_F - \lambda_C} \\ &= -3.452 \end{aligned} \qquad [26]$$

Here, we used the fact that the accuracy of the Sweatt model increases with increasing refractive index so that the Abbe number of a DOE is achieved in the limit of an infinite refractive index. So, it can be seen that the Abbe number of a DOE is a small negative constant. This means that the dispersion of a DOE is high and opposite in sign to that of a refractive element. Therefore, according to eqns [23] and [26] a positive refractive lens with a large focal power (i.e., small focal length) and a positive diffractive lens with a small focal power (i.e., long focal length) can be combined to form an achromatic doublet with a focal power larger than the focal power of one of the two lenses alone (see Figure 5b). By using eqns [19] and [25] the focal power of a diffractive lens can be calculated with the Sweatt model (n very big $\rightarrow n - 1 \approx n$):

$$\frac{1}{f_{\text{DOE}}(\lambda)} = \frac{\lambda}{\lambda_d f_d} \qquad [27]$$

In practice, the lenses are neither thin nor is the distance between them zero. In this case the equations for the design of a hybrid achromatic doublet are more complex (see Further Reading). Nevertheless, the given equations can be used for a first design and to understand the principal behavior.

Another advantage of a hybrid achromatic doublet is that the DOE can in addition behave like an asphere. Therefore, e.g., the spherical aberration can be corrected with the aspheric terms of the DOE provided that the spherical aberration is considerably smaller than the phase term encoded in the DOE to correct the chromatic aberrations. Otherwise, the correction of the monochromatic (spherical) aberration will disturb the correction of the chromatic aberrations. A comparison of a simple hybrid achromat, consisting of a planoconvex lens with the diffractive structure made directly onto the plane surface of the refractive lens and a conventional refractive achromatic doublet shows that the optical performance of the hybrid achromat is a little bit worse than that of the refractive achromatic doublet regarding, for example, off-axis aberrations. A simple explanation of this is that a refractive achromatic doublet has three spherical surfaces and two glasses, i.e., in total five parameters, whereas a hybrid achromat has one spherical surface, one glass and the DOE with a paraxial term and an aspheric term, i.e. in total about four parameters. Of course, the merit of these different types of parameters is not identical so that this assessment is only qualitative.

In the case of hybrid achromatic elements for a broad wavelength range (e.g., for the whole visible wavelength range) the dependence of the diffraction efficiency on the wavelength may be a limiting factor because the other diffraction orders behave like stray light and reduce the maximum contrast of the image. Therefore, special laminated blazed diffractive optical elements made of laminae of two or more different materials are described in the literature which show a nearly achromatic behavior of the diffraction efficiency but the 'normal' dispersion of DOEs. DOEs are in the meantime used in zoom lenses (see the cited patent in Further Reading) to correct chromatic aberrations.

Summary

In this article the possibilities of correcting monochromatic and chromatic aberrations in optical systems by using diffractive optical elements have been discussed. There are several advantages and disadvantages of using DOEs.

Advantages:

- DOEs offer many degrees of freedom in the design. By using modern lithographic fabrication techniques the fabrication of a DOE with a strongly aspheric phase function is just as expensive as fabricating a simple Fresnel zone lens with a quadratic phase function. So, DOEs can be used in some cases instead of aspheric surfaces which are more expensive. In addition, the lithographic fabrication technique guarantees a quite good accuracy concerning the phase function of the DOE compared to the more difficult fabrication of well-defined aspheric surfaces.
- The strong chromatic dispersion with the opposite sign to that of a refractive element allows the correction of chromatic aberrations. DOEs also give in this case an additional degree of freedom in the design because aspheric terms of the phase function can correct in addition monochromatic aberrations of the system as long as these aberrations are considerably smaller than the quadratic term of the phase function which corrects the chromatic aberrations.

Disadvantages:

- DOEs often exhibit not only one diffraction order but several diffraction orders due to fabrication errors, a broad spectrum of application wavelengths or because some DOEs naturally have several diffraction orders like, for example, binary DOEs. This can produce disturbing light in the optical system and limit the application.
- The strong dispersion can restrict the application in monochromatic systems because it requires in some cases (e.g., for testing aspheric surfaces) not only a relative constancy, i.e., constant but the absolute value does not have to be hit exactly, of the illuminating wavelength but an absolute constancy because otherwise systematic aberrations are introduced by the DOE.

So, there are many advantages of DOEs compared to other optical elements but on the other hand a DOE is not a magic bullet in correcting aberrations in optical systems. Depending on the system a careful assessment of the advantages and disadvantages has to be performed in order to find the best solution.

List of Units and Nomenclature

Abbe number	real number	V_d
Angle	[rad]	φ
Cartesian coordinates	[m]	x, y, z
Coefficients of a polynomial	different negative powers of m	a
Components of the ray vector	real numbers	e_x, e_y, e_z
Degree of a polynomial	integer number	G
Diffraction order	integer number	m
Focal length	[m]	f
Grating frequencies in x and y direction	[m^{-1}]	ν_x, ν_y
Height of a lens surface	[m]	h
Local grating periods in x and y direction	[m]	p_x, p_y
Merit function	real valued function	M
Modulus of the wave vector	[m^{-1}]	k
Nabla differential operator	[m^{-1}]	∇ $\begin{pmatrix} \partial/\partial x \\ \partial/\partial y \\ \partial/\partial z \end{pmatrix}$
Number of sampling points/rays	integer number	N
Optical phase, phase function	[rad]	Φ
Polynomial	real valued function	P
Radial coordinate	[m]	r
Refractive index	real number	n
Sign variable	either +1 or −1	σ
Symbol for partial differentiation		∂
Unit vector in ray direction	vector with three real components	$\mathbf{e}$
Wavelength	[m]	λ

Introduction

Most aspects of modern life are thoroughly influenced by the micro-electronics industry through microchips, such as microprocessors and memory chips. Optical lithography has been a key factor in the rapid pace of integration that drives the development of the micro-electronics industry. The photolithography process not only facilitates the fabrication of the chips, but also directly influences the limits of the obtainable chip performance in terms of speed or storage capacity, through the minimum feature size that can be created in the lithography steps. The increasing resolution demands of the IC industry, outlined in the International Technology Roadmap for Semiconductors as technology nodes, mean continuing demand for improvements in the photolithography systems.

The challenges to the improvements are encapsulated in the equation for the resolution of an optical lithography system:

$$R = k_1 \lambda / NA \qquad [1]$$

which expresses the resolution R in terms of the smallest resolvable half-pitch as a function of the wavelength λ, the numerical aperture NA of the exposure system and the unit less constant k_1, which is used as a measure of lithographic difficulty, with smaller values indicating a more challenging process. Traditionally, the increase in the resolution has been obtained by decreasing the used wavelength, with the current mark for volume production systems currently standing at 193 nm. Within each wavelength, further reduction has been traditionally obtained by increasing the numerical aperture towards the mathematical limit of 1. Finally, several so-called Resolution Enhancement Techniques (RET) have been introduced to reduce k_1, in order to reach subwavelength technology nodes within each lithography wavelength generation. It is in connection with these techniques that micro-optics has found a role in modern lithography systems.

In this chapter we discuss the ways micro-optics are being utilized in lithography systems. We will start with a brief overview of conventional lithography systems, of the essential parts of such systems as well as the special resolution enhancement techniques utilized in the systems. We will then discuss the utilization of micro-optics within the context of lithography systems, along with the unique challenges in terms of design and fabrication that are associated with such applications. Finally, we will briefly discuss nonconventional lithography applications, especially those based on utilization of micro-optics. It should be noted that the motivation of this article is to describe the issues related to the use of micro-optical elements in a modern lithography system and is not intended as a review of the modern lithography systems, nor is it a review of micro-optics.

Overview of Conventional Lithography Systems

Photolithography is a process whereby a specified pattern or mask is transferred onto a wafer using photons. In the process a photosensitive material, commonly known as a resist, is initially used to record the pattern that is generated when the mask is illuminated. After exposure, the resist is developed. The resist is referred to as positive or negative, depending on whether it is removed or remains, respectively, after the development of the irradiated regions. After its development, the pattern in the resist is then transferred onto the wafer using suitable chemical processes, such as wet chemical etching or dry plasma etching.

Several different lithographical techniques exist. The oldest and simplest is contact printing, where a

photomask is brought into contact with a layer of photoresist on the wafer. Although this technique can reproduce high-resolution features, the contact between the wafer and the mask can lead to problems with cross contamination, and can damage either the wafer or the mask. Contact printing is mainly used nowadays in laboratory environments for small series of photolithography steps. A slightly more complicated technique is proximity printing, in which the photomask is held in close proximity to the surface of the wafer without actual contact. This avoids the problems of contamination and damage, but due to diffraction effects, reduces the maximum resolution of the process. Nevertheless, proximity printing remains a valuable technique for lithography applications, that do not require the highest possible resolution.

Modern volume production photolithography systems are based on the use of a projection system to image a mask onto a wafer through a complex system of lenses. There exist several variations of the basic idea. In some systems the entire mask is imaged at once onto the wafer. This approach works only when the feature size on the mask is reasonably large, in the range of a few microns. Reproducing smaller features with this approach is generally not possible, as the demands on the optical quality of the projection system, in the form of allowed aberrations, become extremely difficult to meet, especially when the physical size of the optical components increases with the reducing feature size. Therefore, so-called wafer steppers are used in modern microchip fabrication. The basic idea of a wafer stepper is to image only a small region of the mask onto the wafer, and pattern the entire surface area in consecutive steps.

The centerpiece of a wafer stepper is the exposure system. Its task is to image desired patterns from the photomask to their proper positions on the surface of the wafer. In many systems this process includes a size reduction between the patterns on the photomask and on the wafer. This reduces the dimensional accuracy requirements, such as feature size and positioning for the mask fabrication by whatever is the de-magnification of the lithography system. However, it also increases the complexity of the exposure system, as significance of aberrations is increased. The requirements of microchip production mean that the image of the photomask with submicron features must be reproduced on the wafer with a dimensional accuracy of only a few tens of nanometers and aligned to a specific position within a fraction of the linewidth. Furthermore, these tolerances must be guaranteed over the entire exposure field that is typically several square centimeters. It is not surprising that the resulting complex piece of optics costs several millions dollars.

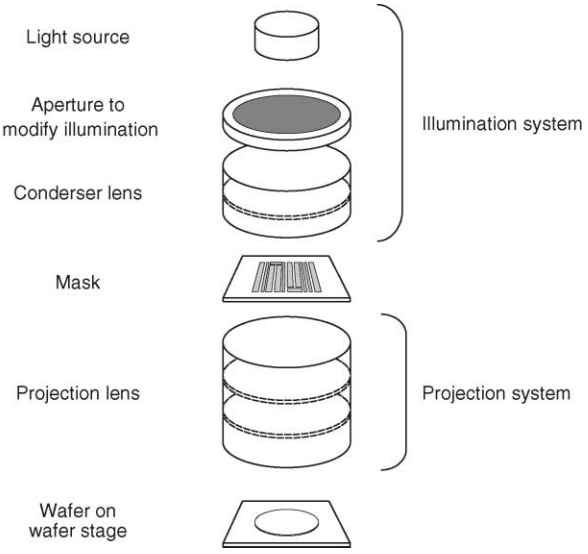

Figure 1 Schematic illustration of the exposure system.

The exposure system consists of a projection lens, illumination system, and wafer management system, as illustrated schematically in Figure 1.

A typical projection lens is a complicated lens system. As the resolution of a lens system is inversely proportional to the diameter of the lenses, the lenses in photolithographic systems can have diameters up to 250 mm, and the whole system is arranged inside a massive barrel-frame. The aim of the projection lens in the entire exposure system is to image the pattern from the photomask to the wafer. The projection lens is primarily responsible for the resolution and must therefore fulfill the highest optical requirements. To produce the smallest possible image, diffraction effects alone must essentially limit the resolution of the system. This means that the optical aberrations over the exposure field of several square centimeters must be virtually eliminated, by the wavefront deviations being less than a fraction of the wavelength.

The illumination system transfers the illumination source through the photomask to the entrance of the projection system. The main requirements for the illumination system are to collect most of the light into the system and to ensure that the irradiance of the photomask is uniform to within a few percent. In addition, resolution enhancement techniques, based on off-axis illumination, require that the illumination pattern on the photomask has a specific shape. We will discuss these requirements later in more detail. In general terms, the illumination system is less complicated than the projection system, especially with regard to the elimination of aberrations, due to the fact that precise imaging is not required in the illumination system.

Although the wafer management system is outside the scope of this article, we note in passing that it maintains the position, orientation, and movement of the wafers through the exposure system. Again, high precision is required to ensure the successful exposure of the desired pattern to the wafer.

Resolution Enhancement Techniques

In most modern lithography systems the achievable maximum resolution is increased via the use of one or more special resolution enhancement techniques (RET). These are essentially creative refinements of the lithography technology, based on theoretical optics papers published often decades before their first application in the lithography process in the late 1980s and early 1990s. There are essentially three RET approaches: Off-Axis Illumination (OAI), Optical Proximity Correction (OPC), and Phase Shifted Masks (PSM).

In optical proximity correction the basic idea is to predistort the mask pattern in order to overcome the proximity effects caused by the optics and the different processes. This is done either using a set of pre-existing rules describing the connection between a mask pattern and its realization on the wafer, using advanced models to predict the proximity effects during the lithography process, or with some combination of both. The key difficulties with OPC are related to the fabrication of the predistorted mask and to the accuracy of the used distortion rules or proximity effect models. Finally, it should be noted that OPC is strictly speaking not a true resolution enhancement technique, as it only enhances the effective resolution and not the theoretical resolution limit of the process defined by the optics.

In phase shifted masks the improvement in the resolution is obtained by altering the phase of light passing through different portions of the mask, creating regions of destructive interference in the image. This leads to higher contrast, which helps to improve the effective patterning resolution. However, as with OPC, there is no true resolution enhancement in terms of the theoretical resolution limit. There are two main difficulties with application of PSM. First, it is not straightforward to introduce required phase shifts into an arbitrary design layout, because some geometrical shapes, such as junctions are harder to realize than others. Another problem lies with the mask fabrication, which requires careful calibration of the material layers and can be very complicated and costly compared to fabrication of conventional binary masks.

For the purposes of this article, only off-axis illumination is discussed, as both OPC and PSM are essentially mask-based techniques and thus provide no opportunity for micro-optics. Off-axis illumination refers to any illumination scheme that significantly reduces or eliminates the light hitting the mask at near normal incidence, leading to the diffraction pattern of the mask being shifted on the projection lens. The principle behind the resolution enhancement, obtained by introducing such a shift, is schematically illustrated in Figure 2 for periodic pattern.

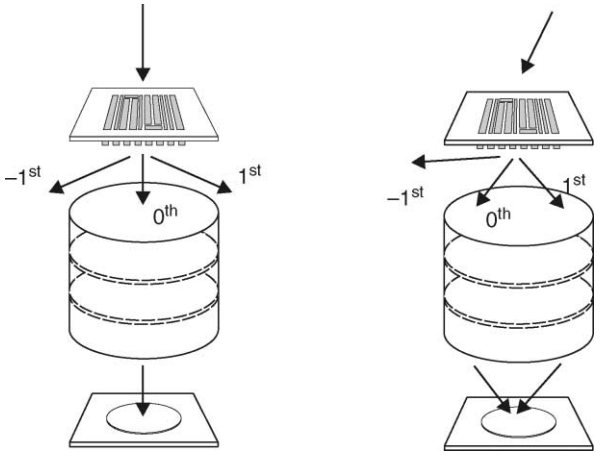

Figure 2 Schematic illustration of effect of off-axis illumination on image formation.

The mask pattern can be imaged if at least two diffraction orders generated by the mask pass through the pupil of the projection lens. Using on-axis illumination, the minimum feature size of the system is reached when the period of the mask pattern is so short that the ± 1st diffraction orders can no longer pass through the pupil. If the illumination is moved off-axis, the diffraction pattern is shifted and the second diffraction order (in this case $+1$st) again passes the pupil. Thus the resolution has been increased. A secondary improvement in contrast may be obtained by shaping the diffraction orders falling onto the pupil, such that the filling of the pupil is optimized, i.e., such that less unwanted light contributing to the background illumination passes the pupil. Finally, the depth of focus of the system can be optimized by ensuring that the contributing orders (in this case 0th and $+1$st) are symmetric with regards to the optical axis.

The conventional way to realize off-axis illumination schemes is to introduce a suitable aperture to the illumination optics between the source and the mask. In order to effectively use off-axis illumination, the shape and size of the aperture, i.e., the illumination pattern, must be optimized for the specific mask shape and pitch. This optimization leads to four basic shapes, as illustrated in Figure 3. In most modern lithography systems these shapes

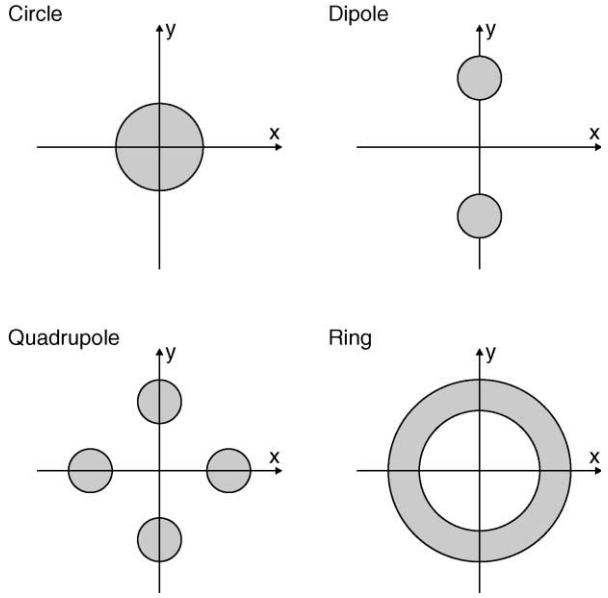

Figure 3 The four typical illumination patterns: disk, ring or annular, quadrupole, and dipole.

are available with different values of partial coherence factor, governed by the ratio of the numerical aperture of the illumination lens and projection lens, allowing control of proximity effects and edge sharpness.

Overview of Micro-Optics

There exists no generally agreed definition of micro-optics, but it typically means optical systems built to significantly smaller scales than conventional table-top systems, using components such as microlenses and microprisms with physical dimensions in the range of a couple of millimeters at most. Micro-optical systems also include so-called diffractive optical elements, which are usually optical components whose operation cannot be explained by Snell's law or the law of reflection. Such elements are usually macroscopically planar microstructures, consisting of features with dimensions from a couple of wavelengths to a few tens of microns, and are designed by advanced numerical algorithms based on diffraction theory.

In the past decade, micro-optics has emerged as a powerful new addition to the field of optics and optical systems, following improvements in micro-optics fabrication techniques, both via adaptation from established microelectronics fabrication processes and development of novel approaches, such as variable dose direct writing using either UV light or an electron beam. Additionally, emergence of replication techniques, such as injection molding or UV casting, allows the low-cost mass production of micro-optical elements, making micro-optics economically feasible for a wide range of consumer applications. Consequently, micro-optical elements, utilizing either refractive or diffractive surfaces, are now found in industrial applications such as material processing, in the optical telecom field, and in consumer electronics such as the digital video camera.

One of the major strengths of micro-optics, as compared to conventional optics, is their ability to realize complex optical functions into a compact form. This is especially true for micro-optics using diffractive optical elements, as diffractive elements may be designed to realize several optical functions such as focusing, filtering, or beam splitting at once allowing integration of several classical optical components into a single diffractive element.

Micro-Optics in Conventional Lithography Systems

The simplicity of contact or proximity printing means that there is little need or opportunity to incorporate additional functionality through inclusion of micro-optical elements. The only exception to this will be discussed in the final section of this article, where we will consider a nonconventional technique, which utilizes micro-optics and can be incorporated into proximity printing systems. However, in this section we will limit the discussion to projection-based lithography systems such as wafer steppers.

Let us consider the possible uses of micro-optics in the three main parts of the exposure system identified in the earlier section. It is obvious that the wafer management system, which is essentially mechanical, cannot be enhanced by inclusion of micro-optics. In principle, micro-optics could be incorporated into the projection system to reduce its weight and, to a lesser degree, complexity. However, it is important to note that using micro-optics to reduce the physical size, i.e., the diameter of the lenses in the projection system is not possible, as such reduction would increase the theoretical minimum feature size the system can resolve which is inversely proportional to the lens diameter. In practical terms, even the most advanced fabrication approaches used to realize micro-optical elements cannot yet produce elements with the precision and quality sufficient to meet the optical requirements associated with a lithographic projection lens. In general, the state of the art in micro-optics is such that it does not make sense to replace refractive lenses with diffractive ones unless the weight of the optics is a critical parameter in

determining the merit of the system. This is not the case for wafer steppers.

Even though the optical requirements for the lenses in the illumination system are not as high as in the projections system, they are in practice still far too demanding for micro-optical elements. Therefore, the only area where micro-optics could be used in the illumination system is the generation of various illumination patterns needed for the off-axis illumination schemes used for resolution enhancement, as well as overall homogenization of light. An element meeting these goals is essentially a custom-designed diffuser, where both the generated angular range and the relative intensity of illumination in any given angular direction are controlled to a high degree.

Custom Diffusers for Illumination

As mentioned earlier, one of the strengths of micro-optics lies in its ability to combine different optical functions into a single element. When used in lithographic illumination systems, micro-optical elements can serve a dual purpose. The element can serve as an artificial aperture, effectively distributing the light over some predetermined angular range and at the same time minimizing light outside the range, allowing generation of various illumination patterns needed for the resolution enhancement via off-axis illumination. Unlike conventional solutions based on the use of actual apertures to generate the desired illumination patterns, distribution of light using micro-optical elements can be done with efficiencies up to 95%, with typical target efficiency being in the range of 90%, depending on the pattern complexity. At the same time, the element can be used to smooth the light distribution, improving the uniformity of the illumination. Typically the required uniformity error, i.e., allowed variations from the average illumination, is in the range of 5%, but can be as low as 1%.

In addition to the above-mentioned high-efficiency and -uniformity targets, optical quality requirements of modern lithography systems introduce unique challenges to the micro-optics used in such systems. First, micro-optical elements used in lithography systems must also exhibit low amounts of stray light, especially in formation of hot-spots. Typically, hot-spots are allowed to be only a few percent of the average illumination level. Because of the fact that the size, shape, and profile of the illumination beam can vary, partly due to variations in the source and partly because such variations improve the functionality of the lithography system, by, for example, controlling the partial coherence factor, the micro-optical elements must be virtually space-invariant. The elements must perform the same function regardless of where and how the illumination coming from the source hits the element. Furthermore, the elements themselves must have very low absorption, because the high power used could otherwise lead to destruction of the elements. This means that the materials must be carefully selected. Finally, the optical wavelengths used in advanced lithography systems are 248 nm or less. Because the feature size of a diffractive element scales down with the wavelength, the features in elements used are much smaller than in the case of elements used for applications in the visible region. Consequently the accurate fabrication of such elements becomes a formidable challenge, because most fabrication errors, such as mask misalignment, etch depth error or the way the sharp corners in diffractive elements get rounded during fabrication, increase in significance when the feature size is decreased.

There exist two distinct approaches for obtaining such custom-designed diffusers. We will now discuss the benefits and weaknesses of these two techniques in terms of efficiency, pattern uniformity, stray light, and ease of fabrication, in order to illustrate the trade-off a designer creating micro-optical elements for a lithography system has to consider.

Aperture Modulated Diffusers

One approach to acquire custom diffusers for illumination systems is to use an array of refractive or diffractive micro-lenses. More generally, the lens phase can be replaced by any phase obtained by geometrical considerations, i.e., by a geometrical map transform between the input and output planes of the optical system. The basic principle of an aperture modulated diffuser is to use the phase function to accurately control the angular divergence of the diffuser, while the shape of the desired intensity distribution is created by introducing a properly shaped aperture in which the phase function is contained. This basic principle is shown in Figure 4.

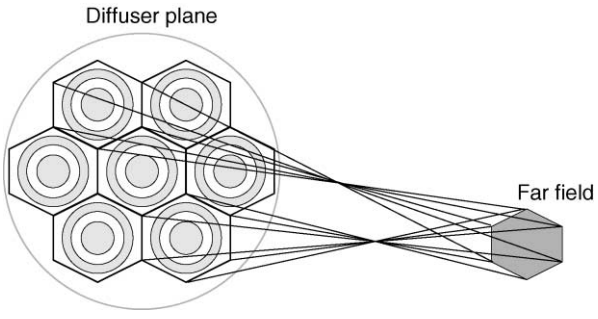

Figure 4 Basic principle of aperture modulated diffuser. The lens f-number determines the angular extend of the far field pattern, while the lens aperture shape determines the shape of the pattern.

The main benefit of using a lens phase lies in the ease of the design process, which essentially consists of selecting the numerical aperture of the lens to meet the angular size of the desired pattern, while more complicated phase profiles can be used to improve some aspects of the performance of the diffuser.

In terms of optical performance, aperture modulated diffusers typically achieve efficiency of up to 95% and low levels of stray light, easily fulfilling the target specifications outlined earlier, especially when refractive surfaces are used. However, since the lens aperture in the element plane controls the shape of the intensity distribution, the range of intensity distribution shapes is limited. This is necessary because it must be possible to tile the required aperture shape in order to realize an array of elements with high fill factor, i.e., to realize a space-invariant diffuser. Furthermore, introducing an aperture into the element plane means that intensity oscillations, due to boundary diffraction at the edge of the apertures, cannot be avoided. Consequently, the uniformity of the generated intensity distributions suffers. This is especially true in cases where the desired intensity pattern has sharp corners, where the intensity oscillations due to boundary diffraction, can easily be up to 50% of the average intensity of the desired intensity pattern. Figure 5 illustrates a typical far field intensity distribution obtainable with aperture modulated diffusers.

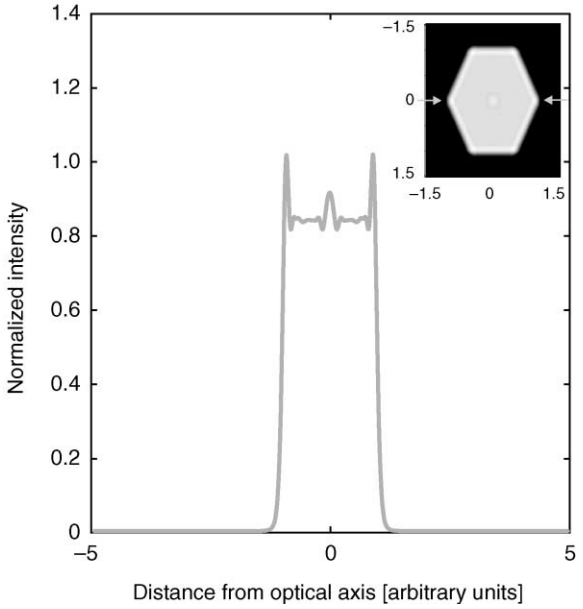

Figure 5 Typical intensity distribution obtainable with an aperture modulated diffuser. The overall distribution is smooth apart from the slow intensity oscillations at the edges resulting from diffraction at the aperture boundary.

One needs to consider several issues with regard to the fabrication of aperture modulated diffusers. For refractive aperture modulated diffusers, the main issue is the accurate realization of the required surface profile. The fabrication of large arrays of refractive elements having arbitrary surface profiles is still challenging. Resist reflow techniques, where the micro-lenses are realized by melting small islands of resist, lead to a spherical lens profile. Complicated and hard-to-control profile reshaping techniques are required if dramatic alterations from the spherical lens profiles are needed. Even though fabrication through direct writing techniques, such as laser writing offers more freedom, realization of arbitrary refractive surface remains a challenge. Therefore, use of refractive elements is mainly limited to cases where the lens profile can be close to the spherical shape. The most important of such cases are patterns with uniform circular or rectangular distributions. The former can be realized by proper selection of the numerical aperture of the lens, while the latter can be realized by combining two properly selected cylindrical lenses on opposite sides of the substrate.

For diffractive aperture modulated diffusers there are considerably less limitations in terms of what phase profiles can be attained. As long as the opening angles, i.e., the angular size of the pattern is below 10 degrees, the phase can be realized as a diffractive element. With diffractive elements, the main issue to consider is therefore the effect of typical fabrication errors such as profile depth and shape errors. First, the typical consequence of fabrication errors in the element is loss of efficiency via increase of stray light. Fortunately the errors do not generate sharp stray light peaks, with the obvious exception of the axis hot-spot. This results from the fact that both lens functions and more complicated phase functions designed by geometrical considerations, exhibit locally periodic structures, and the introduction of common fabrication errors then leads to redistribution of light away from the desired signal orders of these local structures to higher or lower orders. On the level of the whole intensity distribution, such redistribution appears as a constant rise in the background noise level, but will not lead to sharp intensity fluctuations.

Another issue related to the fabrication of aperture modulated diffusers appears when diffuser elements are fabricated using a series of photomasks, as it is typically the case with a relatively large size of the element. Although mask misalignment is essentially a random error, i.e., the direction and amount of the error are difficult to predict before hand, it easily leads to systematic and partly symmetric uniformity problems with aperture modulated diffusers.

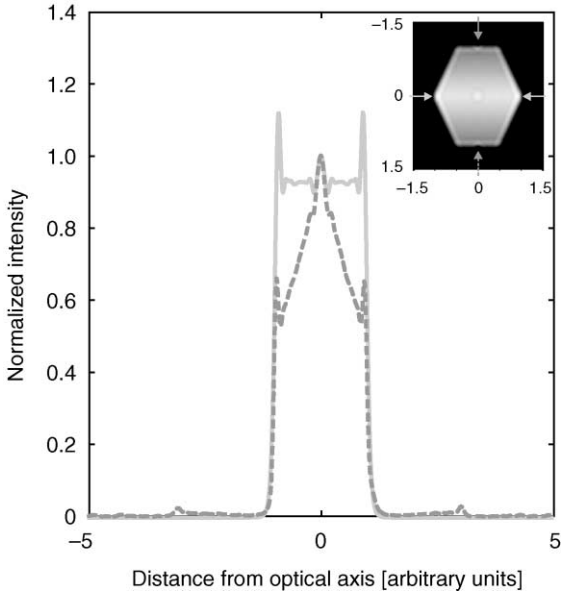

Figure 6 Effect of mask misalignment on the intensity distribution with aperture modulated diffusers. Essentially random error leads to symmetric and systematic uniformity error due to locally periodic nature of the design.

Again the reason for this lies in the locally periodic nature of the elements. A single mask misalignment along some direction results in an erroneous profile shape in the structures, which are periodic in the direction of the alignment error. Consequently, the relative intensity distribution along that direction is changed. On the other hand, structures, where the period is perpendicular to the misalignment, are realized correctly. Furthermore, the local period of the phase function is often changing from the center of the element to the edge, meaning that the relative magnitude of the mask misalignment is different in different parts of the element. These facts lead to asymmetry in the overall intensity distribution, which is especially harmful with off-axis illumination patterns, as the asymmetry results in loss of the resolution gain obtained with off-axis illumination. Furthermore, as the source of the asymmetry is essentially a random error, compensation in the design is very difficult. Figure 6 illustrates the above-mentioned phenomena.

Fan-Out Based Diffusers

An alternative technique uses specially designed fan-out elements to produce a large number of closely spaced diffraction orders arranged in a desired pattern, as illustrated in Figure 7. Such an approach offers all the flexibility of diffractive elements, allowing generation of nearly arbitrary intensity distributions, especially if the elements can be realized

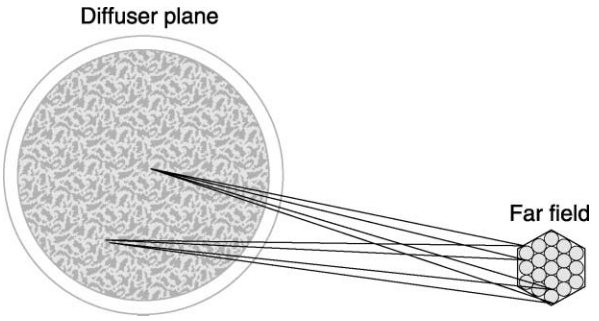

Figure 7 Basic principle of fan-out based diffusers. A grating is used to generate a high number of closely spaced diffraction orders arranged in the shape of the desired pattern.

as so-called multilevel elements, i.e., if the surface profile can have more than two distinct levels.

The flexibility in the design comes at a cost, where specially developed design tools, such as the iterative Fourier transform algorithm, are required. Fortunately such tools are starting to become commercially available as emphasis and interest in wave-optical engineering, an extension of the classical optical engineering approaches, increases.

In terms of optical performance, fan-out based diffusers offer high uniformity as there are no boundary diffraction effects as with aperture modulated diffusers. Furthermore, by choosing the beam separation of the fan-out to be clearly smaller than the divergence of the incidence beam, it is possible to average out any local intensity variations from order to order, leading to a smooth overall intensity distribution. The remaining variations in the intensity distribution generated by a fan-out based diffuser can be as small as 1% of the average intensity.

As a trade-off for the improved performance in terms of uniformity compared to aperture modulated diffusers, fan-out based diffusers typically exhibit lower efficiency and, consequently, higher levels of stray light, even when no fabrication errors are present. This is a result of additional design freedoms being used to remove unwanted intensity oscillations from the far field regions, belonging to the desired intensity distribution, by introducing some noise outside these regions. Typically the efficiency of a fan-out based diffuser is in the range of 85–90%, or 5–10 percentage points lower than the efficiency of a comparable aperture modulated diffuser (should one exist). Furthermore, unlike aperture modulated diffusers, fan-out based diffusers can have stray light that forms hot-spots. If care is not taken during the design, these hot-spots may be up to 10% of the average intensity of the illumination pattern, even in the absence of fabrication errors. Figure 8 illustrates

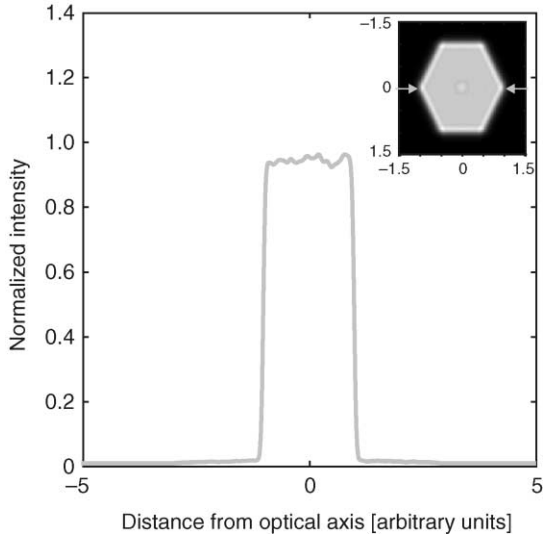

Figure 8 Typical intensity distribution obtainable with a fan-out based diffuser. Overall distribution is smooth, but stray light appears outside the main pattern.

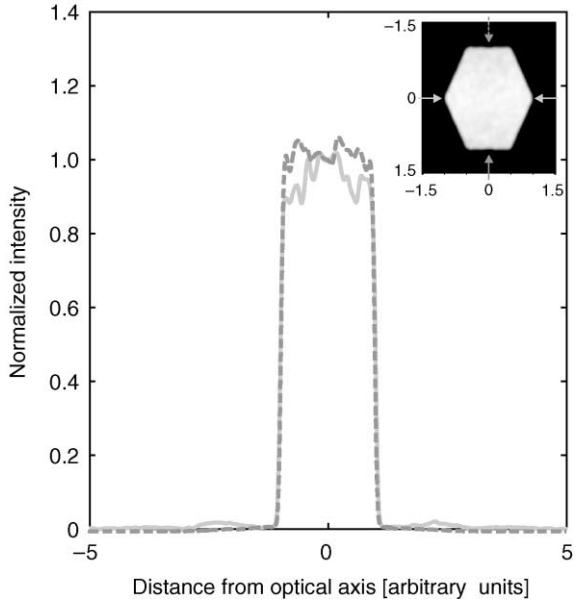

Figure 9 Effect of mask misalignment on the intensity distribution with fan-out based diffusers. The uniformity error appears randomly, allowing statistical compensation schemes.

a typical far field intensity distribution obtainable with fan-out based diffusers.

Fan-out based diffusers offer several advantages in terms of fabrication compared to mapping based diffusers. First, random errors, such as mask misalignment, do not lead to symmetric or systematic uniformity problems, but instead result in random local oscillations in the intensity pattern as illustrated in Figure 9. This allows special compensation schemes where the element is divided into segments, each of which has different fabrication tolerances but generates the same far field intensity distribution. If the fabrication tolerances of the individual designs are balanced correctly against the typical fabrication errors of the used fabrication methods, the loss of uniformity due to fabrication errors can be eliminated almost entirely. Furthermore, the flexibility of diffractive design allows for fabrication error-tolerant designs. This follows from the ability to combine several optical functions in a single optical element. The typical trade-off with designs with relaxed fabrication tolerances is that the optical performance of the element in terms of efficiency is worse than that of a conventional design if fabrication errors are not present.

Micro-Optics and Non-Conventional Lithography

In the previous section we have considered micro-optics in connection with conventional lithography approaches and shown that micro-optical elements can find a significant role in such systems. We conclude this article by considering briefly nonconventional lithography systems, focusing especially on a technique called micro-lens lithography, which is fundamentally based on the use of micro-optical elements.

The most straightforward way to improve existing lithography approaches is to further reduce the wavelength used in the exposure process. In X-ray lithography, the light source used in conventional lithography approaches is replaced by a cyclotron emitting light with wavelengths deep in the X-ray region. This leads to minimum resolution far lower than achievable by conventional techniques, but with the additional difficulty and cost of maintaining and running such a source.

The techniques that are currently considered as serious alternatives for conventional photolithography approaches are based on the use of particles other than photons in the fundamental exposure process. Techniques such as electron- or ion-beam lithography are routinely used to realize structures with feature size and positioning resolution of some tens of nanometers for use in both micro-electronics and micro-optics. The main drawback of these approaches is the cost involved in patterning large surface areas. Unlike optical lithography techniques, particle beam lithography cannot expose large surface areas at once, instead requiring painstaking scanning of the surface area with a relatively small writing beam. This leads to processing times that scale linearly with the required surface area, and consequently the throughput of such techniques is small. Therefore, particle beam lithography is not yet widely used in commercial fabrication of micro-electronics. However, it is worth noting that especially

electron beam lithography is widely used in the origination of micro-optical components, as the relatively high cost of creating the master component can be offset in the final product by the inexpensive replication process. Such an approach allows the replicated end-product to meet the high optical requirements achievable only by high resolution surface control, yet remain affordable for use in, for example, consumer electronics. This has lead some in the micro-optics community to conclude that electrons are better suited for fabrication of components controlling photons, while photons are better suited for fabrication components controlling electrons.

In addition to particle beam lithography, other noteworthy techniques exist. For our purposes, the most interesting technique is the so-called micro-lens array lithography, where one or more micro-lens arrays are used to image the pattern of the photomask to the resist layer on the substrate. Although the resolution of this approach is limited to 3–5 microns, for applications such as with flat panel displays, micromechanics, or multichip module fabrication, this technique is of considerable interest.

It is well known that the geometrical aberrations scale down proportionally with the physical lens size. Thus, large areas can be imaged favorably by use of arrays of micro-lenses, where each lens images only a small section of the whole field. Such a setup is shown in Figure 10.

With this setup it is possible to expose a comparatively large area with a single exposure, thus eliminating the need for costly stepping operations and therefore increasing the throughput of the system. Analysis of the basic system shows that an array based on spherical micro-lenses of 1 mm focal length and 300 micron aperture can produce a nearly diffraction limited resolution on the order of 3–5 micrometers over a 300 micron field.

In terms of conventional lithography systems, the micro-lens array lithography has most in common with proximity printing. Both techniques achieve comparable resolutions, yet avoid damaging the mask or substrate by keeping the two separated by some finite working distance. However, micro-lens array lithography offers two distinct advantages over conventional proximity printing. First, the working distance between the imaging system and the substrate surface can be much larger, which further minimizes the risk of mask or substrate damage. Furthermore, added working distance allows lithography steps on nonflat surfaces, e.g., inside holes or grooves where conventional proximity printing would not be possible. Another advantage of the micro-lens array lithography is the larger depth of focus. With proximity printing, the resolution rapidly decreases with increasing distance. In micro-lens array lithography, the optimum resolution is obtained at the image plane, while a region of reasonable resolution extends forward and backward from this plane (Figure 11). This extension means that in the depth of field, resolution is less sensitive to changes in the working distance, which makes it better suited for practical applications.

In addition to the optical benefits of micro-lens array lithography, there also exist other practical benefits. Many micro-devices have a repetitive and

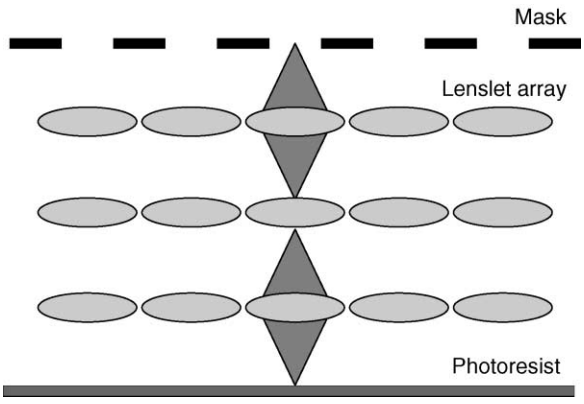

Figure 10 Basic geometry of micro-lens array lithography.

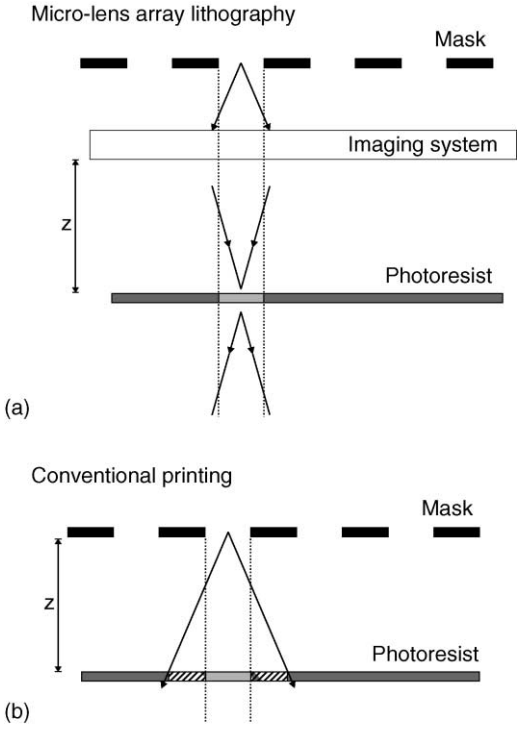

Figure 11 Depth of focus with micro-lens array lithography and conventional printing. (a) With micro-lens array lithography, the image of the mask is extended both forward and backward from the working plane at distance z. (b) In conventional printing, the resolution is rapidly reduced with increasing working distance z.

discrete nature with respect to some unit element. Such a unit element lends itself well to the imaging properties particular to lens arrays, as each lens of the array can be made to correspond to the unit cell of the particular micro-device making the imaging highly efficient. A photograph of a micro-lens projection system is shown in Figure 12.

One could also imagine that instead of an array of imaging systems, an array of pattern generators is used that generates a specific pattern, such as lines or points. In the ideal case such a system would replace the mask and the imaging system altogether. However, this approach is only possible for simple patterns and large production series.

Outlook

As long as optical lithography stays attractive, micro-optics will be used as beam-homogenizers and sophisticated diffusers to generate optimized illumination patterns. How far micro-optics will be used in the imaging system is difficult to predict. However, it can be assumed that the difference between micro-optics and macro-optics fabrication technology will disappear.

Recent research is also investigating near-field optics to further reduce the resolution limit. Micro-optics technology is well suited to realize such systems. A serious problem of near-field optics is the short distance (10 nm–100 nm) between the optical element and the interface to be patterned. In addition, near-field optics is based on scanning systems, which increases the exposure time considerable. However, there is still room for improvements or as Richard Feynman said 'there is plenty of room at the bottom'.

Design and Fabrication of Diffractive Optical Elements

Introduction

Diffractive optical elements (DOEs) are passive devices that redirect and focus light through the division and mutual interference of a propagating electromagnetic wave. This is in contrast to refractive elements, which redirect and focus light through variations in indices of refraction. From a historical perspective, diffraction was traditionally considered a detriment in optics and caused images to blur. However, we now know that it is possible to use diffraction to enhance the performance of optical systems. For example, DOEs can be used to correct chromatic aberrations and to implement optical functions that conventional refractive and reflective optics cannot, such as multiple beamsplitting.

Further, recent advances in computing and fabrication technologies have increased the number of applications in which diffractive elements are used, which has established diffractive optics as yet another tool in an optical designer's kit.

The first modern diffractive element was the hologram. A hologram is a photographic record of the constructive and destructive interference between two coherent beams known as the object and write beams. The object beam contains information about the object recorded. The write beam is necessary to record the hologram but contains no information itself. When the hologram is played back with a third beam, the read beam, the recorded interference pattern diffracts it in such a way that it reconstructs the object beam.

Unfortunately, the functions that a natural hologram can produce are limited to those whose wavefields can be produced in a laboratory. Thus, although it is possible to record a hologram that can focus or deflect a single beam, it is difficult to record a hologram that splits a single beam into multiple foci. However, the advent of computing technology made it possible to design such holograms analytically. The first diffractive element designed with the aid of a computer was demonstrated in 1966. Since then the ability to create elements that respond arbitrarily has had widespread application in imaging systems, telecommunications, and sensing.

The two most basic diffractive elements are the grating and the Fresnel zone plate. The diffractive behavior of a grating is predominately transverse to the optic axis. It causes light to split into discrete beams, referred to as diffraction orders, each with a different angle of propagation relative to the optic axis. The diffractive behavior of a Fresnel zone plate also divides incoming light into discrete orders, however, the orders are produced along the optic axis. This is useful in producing the diffractive equivalent of a refractive lens. Arbitrary transverse and longitudinal behavior is realized by combining characteristics of these basic two diffractive elements. In the remainder of this article, we discuss the design and fabrication of general diffractive elements.

Design

Once an optical system designer determines the functional behavior required for a particular application, for example, focusing or multiple beamsplitting, he or she needs to design a diffractive element that realizes this function. However, unlike refractive and reflective optical elements, whose material properties and surface curvatures determine their functionality, the functionality of a diffractive element is determined by a pattern of wavelength scale features. Determining this pattern is the goal of diffractive design but to do so one must first understand the physical relationship between the DOE and the wavefield it produces.

Scalar diffraction theory is one of the simpler models that relates the effect of a surface relief, or diffractive profile, $d(x, y)$, on an incident wavefield $U_{\text{in}}(x, y)$:

$$U_{\text{out}}(x, y) = \exp[\mathrm{i}\theta(x, y)]U_{\text{in}}(x, y) \qquad [1]$$

where the phase transformation $\theta(x, y)$ is related to the diffractive profile $d(x, y)$ by

$$\theta(x, y) = 2\pi(n - 1)d(x, y)/\lambda \qquad [2]$$

The constant n is the refractive index of the optical substrate and λ is the wavelength of illumination in a vacuum.

The effects of the phase change are not apparent until the wavefield $U_{\text{out}}(x, y)$ propagates over some distance z. In scalar diffraction theory the relationship between $U_{\text{out}}(x, y)$ and the wavefield $U_z(x, y)$ at a plane a distance z away, is described by the Rayleigh–Sommerfeld diffraction equation:

$$U_z(x,y) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U_{\text{out}}(\zeta,\eta) \times \frac{\exp\left\{\mathrm{i}(2\pi z/\lambda)\sqrt{1+(x-\zeta/z)^2+(y-\eta/z)^2}\right\}}{\mathrm{i}z\lambda[1+(x-\zeta/z)^2+(y-\eta/z)^2]}\mathrm{d}\zeta\,\mathrm{d}\eta \qquad [3]$$

Huygens' principle is reflected in this formulation by the convolution between the transmitted field $U_{\text{out}}(x,y)$ and a spherical wave $h(x,y)$, which represents free space propagation over the distance z:

$$U_z(x,y) = U_{\text{out}}(x,y)^{**}h(x,y) \qquad [4]$$

where

$$h(x,y) = \frac{\exp\left\{\mathrm{i}(2\pi z/\lambda)\sqrt{1+(x/z)^2+(y/z)^2}\right\}}{\mathrm{i}z\lambda[1+(x/z)^2+(y/z)^2]} \qquad [5]$$

The Rayleigh–Sommerfeld formulation is valid so long as the angles at which energy diffracts from the aperture are small. If the distance z is sufficiently large that the angles stay clustered about the optic axis, one can replace the spherical wave response of freespace

with a parabolic wave:

$$h(x, y) \approx \frac{\exp(\mathrm{i}2\pi z/\lambda)}{\mathrm{i}z\lambda}\exp[\mathrm{i}(\pi/\lambda z)(x^2 + y^2)] \qquad [6]$$

This simplification is referred to as the paraxial, or Fresnel, approximation. The diffraction integral is now given by:

$$\begin{aligned} U_z(x, y) \approx & \frac{\exp(\mathrm{i}2\pi z/\lambda)}{\mathrm{i}z\lambda}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U_{\text{out}}(\zeta, \eta) \\ & \times \exp\{\mathrm{i}(\pi/\lambda z)[(x-\zeta)^2 + (y-\eta)^2]\}\mathrm{d}\zeta\,\mathrm{d}\eta \\ = & \frac{\exp(\mathrm{i}2\pi z/\lambda)}{\mathrm{i}z\lambda}\exp[\mathrm{i}(\pi/\lambda z)(x^2 + y^2)] \\ & \times \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} U_{\text{out}}(\zeta, \eta)\exp[\mathrm{i}(\pi/\lambda z)(\zeta^2 + \eta^2)] \\ & \times \exp\{-\mathrm{i}2\pi[\zeta(x/\lambda z) + \eta(y/\lambda z)]\}\mathrm{d}\zeta\,\mathrm{d}\eta \end{aligned} \qquad [7]$$

The second representation results from an expansion of the exponent and allows the diffraction integral to be written as a Fourier transform. The quadratic phase terms can be removed if a positive lens with focal length z is placed next to the diffractive element and a second positive lens with focal length z is placed in the image plane (see **Figure 1**). Under these conditions, $U_{\text{out}}(x, y)$ and $U_z(x, y)$ form a Fourier transform pair:

$$\begin{aligned} U_z(x, y) = & \ \mathrm{FT}[U_{\text{out}}(x, y)]|_{u=x/\lambda z, v=y/\lambda z} \\ = & \ \mathrm{FT}\{\exp[\mathrm{i}\theta(x, y)]\}^{**}\mathrm{FT}[U_{\text{in}}(x, y)]|_{u=x/\lambda z, v=y/\lambda z} \end{aligned} \qquad [8]$$

The objective of diffractive design is to find a surface relief $d(x, y)$ that generates a desired response $q(x, y)$ somewhere in the response $U_z(x, y)$. However, eqns [3] and [7] neglect the fabrication process, which affects the fields that can actually be realized. A diffractive optic designer can incorporate fabrication constraints into their design either directly or indirectly. In a direct approach, the designer represents the diffractive structure parametrically, for example, a multilevel phase element can be represented by a discrete set of allowed phase values and a binary phase element can be represented by the contours that separate one phase value from the other. A designer defines the diffractive element by specifying and modifying these parameters.

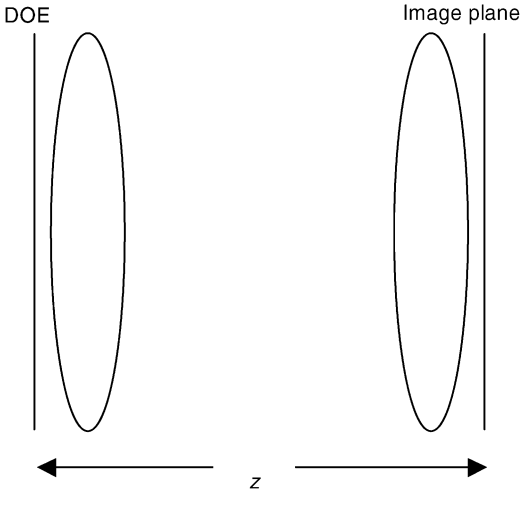

Figure 1 Optical Fourier transform module.

In an indirect approach, the designer first determines an intermediate function without consideration for fabrication and afterward applies the fabrication constraints to this function. For example, if $f(u, v)$ is the desired response one wishes to generate in the z-plane using $U_{\text{in}}(x, y)$ as the input, from eqn [8], the optical function required to do is

$$Q(x, y) = F(x, y)/U_{\text{in}}(x, y) \qquad [9]$$

where $F(x, y)$ is the Fourier transform of $f(u, v)$. The designer must then find a phase $\theta(x, y)$ that satisfies the fabrication constraints and insures that $\exp[\mathrm{i}\theta(x, y)] \approx Q(x, y)$.

For example, fabrication using multiple binary masks yields a phase structure quantized to 2^N levels. An effective design should, therefore, yield a quantized phase structure that minimizes reconstruction error. A naïve approach is to set the magnitude of $Q(x, y)$ in eqn [9] to unity and quantize the phase. However, this introduces considerable error. A direct approach to design searches only over the set of quantized phase structures for the one that, for example, generates the desired response with maximum energy and minimum error. An indirect design seeks first a phase structure whose response produces a minimum amount of error between it and $Q(x, y)$ and then quantizes this structure.

Performance of the element can be improved if one exploits certain freedoms available in design. For example, all systems have a finite-sized detector. It is, therefore, unnecessary to specify the performance of the diffractive element everywhere in the image plane. Its behavior within the detector window is all that is important. If only the intensity of the response is specified, then the phase of the response within the window is also a design freedom. Finally, one can also control the amount of energy contained in the signal window by scaling the amplitude of the response. This allows a designer to balance diffraction efficiency with error in the signal window.

Two general nonlinear optimization algorithms for the design of DOEs are represented in **Figure 2**. Indicative of the nature of data flow, **Figure 2a** is

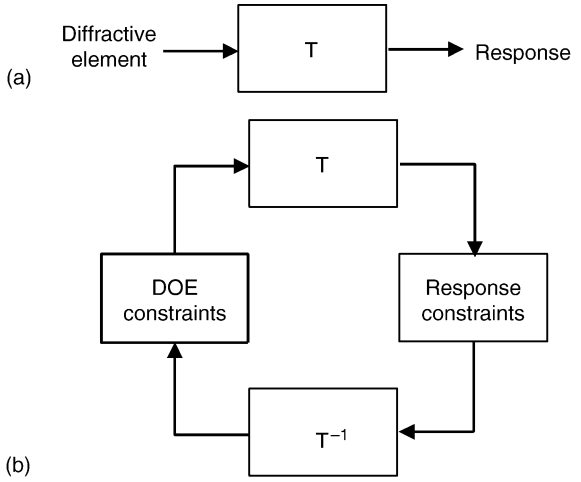

Figure 2 Algorithms used for diffractive design. (a) Unidirectional and (b) bidirectional algorithms.

referred to as a unidirectional algorithm and Figure 2b as bidirectional. In a unidirectional algorithm, changes are made only to the diffractive element. The changes are driven by how well the element performed in a previous iteration. If models exist for both forward and inverse propagation ($\mathbf{T}$ and $\mathbf{T}^{-1}$, respectively), a designer can use a bidirectional algorithm, which allows modification of both the diffractive element and its response. This allows bidirectional algorithms to converge to a solution, in general, more rapidly than unidirectional algorithms. In scalar theory, $\mathbf{T}$ is a Fourier transform but more rigorous models exist. If the model of the optical system cannot be inverted, a unidirectional algorithm must be used.

Fabrication

Regardless of which design algorithm is used to determine $d(x, y)$, ultimately it needs to be realized physically. Although numerous techniques exist for doing so, by far the most common are based on microlithographic processes. The process requires exposing a layer of photoresist deposited on top of an optical substrate and etching the photoresist to transfer the pattern into the substrate. These methods are especially appealing because they leverage the existing manufacturing infrastructure of the microelectronics industry and, as a consequence, have enabled the efficient and economical mass manufacture of DOEs.

Two basic methods exist for patterning photoresist, direct writing using a modulated beam and indirect patterning using masks. Further, the mask process can be either a single or multistep process. The multistep approach uses N masks and N exposures to fabricate a multilevel diffractive element that has 2^N phase levels (see Figure 2). However, profiles that contain very small features are difficult to fabricate in this manner. As a consequence, alternative processes using single-step grayscale lithography have also been developed.

Although grayscale photolithography is more time-efficient and less prone to mask alignment errors than multistep lithography, the photoresist must respond linearly to illumination. Unfortunately, most photoresists used to fabricate microelectronic circuits are highly nonlinear. However, one can obtain a linear response by adjusting the exposure and development process. In the following, we review fabrication using both multiple binary masks and a single grayscale mask.

Multilevel Fabrication Using Binary Masks

In this fabrication method, one must first generate a sequence of N masks that are related, in a recursive manner, to the quantized phase $\theta(x, y)$:

$$m_k(x, y) = \mathrm{mod}(M_k(x, y), 2), \quad k = [1, N] \qquad [10]$$

where

$$M_{k+1}(x, y) = \frac{M_k(x, y) - m_k(x, y)}{2} \qquad [11]$$

and

$$M_1(x, y) = \theta(x, y)\frac{N}{2\pi} \qquad [12]$$

The masks can be produced using either optical or electron beam (e-beam) pattern generators from integrated circuit fabrication. The pattern generators expose a thin layer of photoresist on the surface of a chrome-covered quartz substrate. Development of the photoresist leaves the desired diffractive pattern in the unexposed areas. The diffractive pattern is transferred to the chrome layer by etching any chrome not covered by photoresist. After the chrome etch process is completed, any remaining photoresist is washed away to yield the finished lithographic mask. This process is repeated for each mask.

The completed mask set is used to fabricate the DOE using techniques similar to those used to generate the mask set. An optical substrate is coated with a thin layer of photoresist, placed in intimate contact with the first lithographic mask $m_1(x, y)$, and illuminated with an ultraviolet (UV) exposure lamp. During photoresist development, exposed resist is washed away, which leaves a binary pattern in the remaining developed photoresist.

When the pattern is transferred into the substrate material via etching, the photoresist acts as an etch stop. For the first mask, the etch depth into the substrate corresponds to a π-phase shift. The process is repeated for each subsequent mask, that is, the substrate is coated with a layer of photoresist, UV illumination exposes the photoresist through the mask, the photoresist is developed, and the substrate etched by the remaining pattern. The etch depth of each mask is half that of the previous mask. Figure 3 illustrates this process.

The substrate can be etched using either wet or dry techniques. In wet etching, one uses reactive chemicals, such as hydrofluoric acid, to etch the substrate. However, wet etching is isotropic, that is, substrate etching occurs equally in all directions. As a result, it is difficult to preserve vertical sidewalls and to achieve high fidelity in etching high-aspect ratio features. As a consequence, dry etching is more commonly used.

A dry etch uses a beam of ions to remove substrate material. The process for removal can be either chemical or kinetic. The process used is determined by the value of the plasma power that creates the source of ions relative to the bias power used to accelerate the ions toward the substrate. If the bias power is large and the plasma power small, a small stream of ions are accelerated rapidly toward the substrate. In this case, the operational mode is similar to a micromilling machine, wherein inert particles chip away at the surface by virtue of their kinetic energy. Alternatively, a small bias power and a large plasma power produce a large population of ions with no preferential directionality. This yields an isotropic process similar to wet etching.

Two methods for performing dry etching are reactive ion etching (RIE) and inductively coupled plasma (ICP) etching. However, in RIE systems the bias and plasma power are not independent due to capacitive coupling. Thus, adjusting one affects the other. ICP, on the other hand provides independent control over the bias and plasma powers. Independent control allows one to control precisely the anisotropic nature of an etch process. As mentioned above, this is achieved by varying the bias power relative to the plasma power, which controls the directionality of the acceleration.

Independent control is important because the ideal process for a given DOE depends on the substrate material and the characteristics of the diffractive profile. Independent control allows one to adjust the respective powers, as well as gas flow rates, and their partial pressures, to determine an optimal etch process. Dry etching allows one to incorporate endpoint detection, which provides precise control

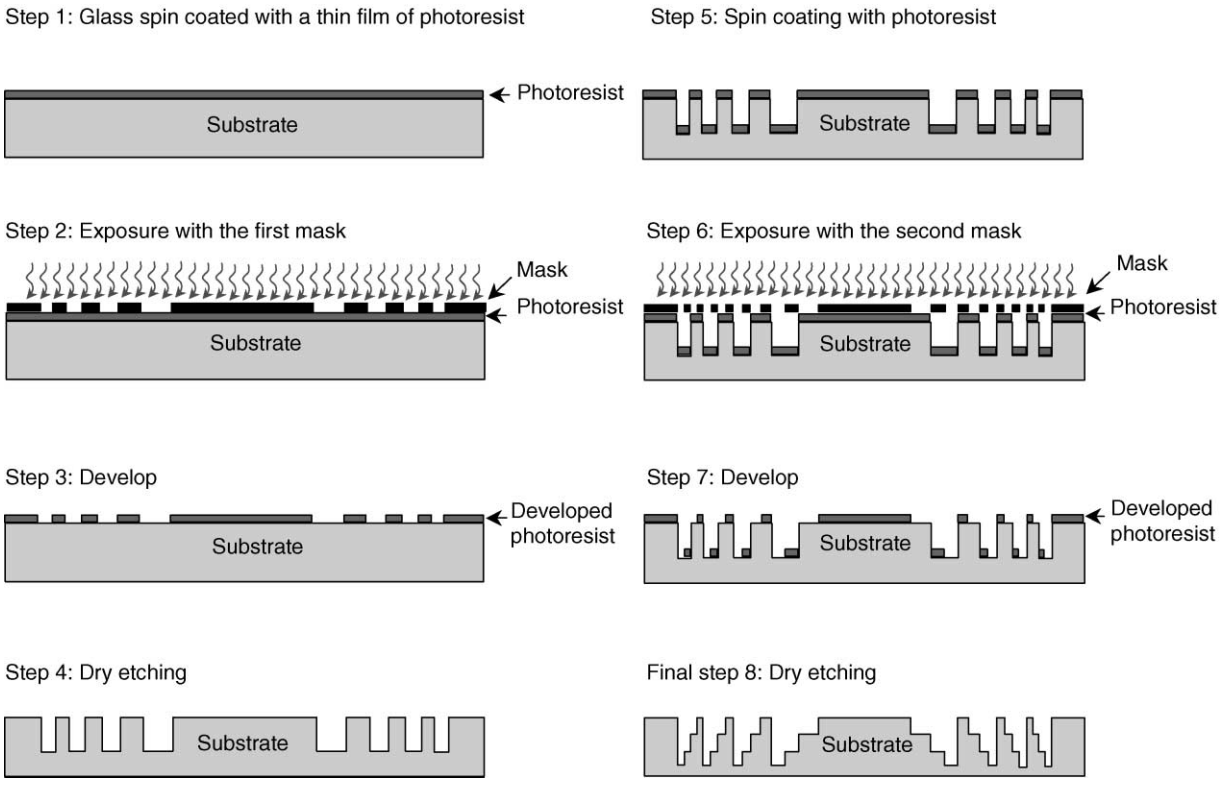

Figure 3 Fabrication of a multilevel quantized phase DOE using binary masks.

over the etch depth. As presented below, achieving the proper etch depth is important to generating responses with high diffraction efficiency.

Care must be used when determining the number of phase levels appropriate for a particular application. The number of phase levels has a direct impact on the portion of input energy one can hope to diffract into the desired response. This is referred to as the diffraction efficiency. According to scalar diffraction theory, the relationship between the maximum diffraction efficiency η and the number of masks N is:

$$\eta = \mathrm{sinc}^2\left(\frac{1}{N}\right) \qquad [13]$$

Thus, using two masks to create a 4-level phase element, as opposed to a single mask to create a binary-phase element, doubles the upper bound on the diffraction efficiency from 41% to 81%. The maximum diffraction efficiency for 8-level and 16-level phase elements is 95 and 99%, respectively.

However, this increase in diffraction efficiency incurs fabrication costs. After the first etch step, each subsequent exposure requires careful mask alignment. Alignment is accomplished using a standard tool from integrated circuit fabrication known as a mask aligner. The quality of a mask aligner is determined by its precision and the majority of commercially available aligners can register a mask and substrate to within less than a micrometer. This degree of alignment accuracy is sufficient to fabricate many useful multilevel diffractive elements.

To summarize, a multilevel surface relief profile uses a set of N masks to generate a surface profile that exhibits 2^N phase levels. The etch depth for the kth mask is $d_k = \lambda/2^k(n-1)$. In the next section, we describe a process for fabricating continuous DOE profiles in a single expose and etch cycle.

Continuous DOE Profiles Using Grayscale Lithography

Grayscale photolithography has become increasingly popular because of its flexibility and convenience in fabricating continuous diffractive profiles. Methods including directly writing partially exposed e-beam resist, resist reflow lithography, and using grayscale masks in a single step exposure. Here we discuss only the latter method because the processes are similar to those used in multiple mask fabrication. Thus, the same facilities can be used to produce both. In particular, we consider the application of high-energy-beam-sensitive (HEBS) glass to grayscale lithography and the fabrication of continuous profile DOEs.

The process for creating a diffractive element using HEBS glass is similar to fabricating a binary-phase element from a single mask. However, mask creation is markedly different. HEBS glass is a white crown glass within which a thin buried layer of silver ions is incorporated. The layer of silver ions is created via ion exchange in an aqueous acidic solution and essentially serves the same function as silver grains in photographic film. When the glass is exposed to a beam of electrons, the silver-containing crystal complexes are chemically reduced and the glass darkens. By controlling the electron dose, one controls the opacity of the glass to produce a grayscale pattern.

Although the attraction of single-step grayscale lithography is reduced costs in fabrication, the process incurs high calibration costs to insure quality pattern transfer through several steps. The parameter that has the greatest impact on the overall process is the desired size of the smallest diffractive feature. The minimum feature size affects the selection of the accelerating potential, beam current, addressing grid, and electron dose of the e-beam used to expose the HEBS glass.

The e-beam accelerating potential sets the resolution limit of the process and affects the sensitivity of the glass to the electron dose, the total charge per area incident upon the glass. For example, for a constant electron dose, increasing the accelerating potential increases the darkening response of the material. The large accelerating potential produces a large flux, which achieves the desired electron dose in a short period using energetic electrons. This, in turn, enhances the sensitivity of the glass. However, increasing the accelerating potential also increases scattering, which limits the minimum feature size achievable. Thus, low beam energies are generally used to write small features. But this, unfortunately, reduces the range of available optical densities because the material is less sensitive at low beam energies. To compensate for the reduced sensitivity, it is possible to increase the electron dose by increasing the exposure time. However, this undermines to some extent using a low energy beam to achieve small features due to broadening that results from long exposure times.

Once the accelerating potential for writing the mask is chosen, the beam current and addressing grid need to be specified. The beam current is related to the spot size and, therefore, affects directly the length of time to write the mask. High current levels produce large spots. Since write times can easily reach into

hours for large structures, high current levels are desirable to reduce them.

The addressing grid represents the physical grid that the electron beam is translated over in order to complete the exposure. This grid should be chosen as finely as possible, however, too fine a grid can significantly increase the required dwell time on each grid point. In this respect, a compromise is required. High beam currents produce short dwell times, which may necessitate using a coarse address grid to insure the beam is capable of performing the exposure.

Once the process parameters are set, calibration between the HEBS transmission and the electron dose is necessary. Analyzing the optical density of written test structures by some experimental means and determining its functional dependence on the electron dose completes the calibration. This allows one to specify the electron doses required to achieve the features dictated by the device design.

If resolution requirements cannot be met through judicious selection of the accelerating potential, then some of the contrast in the mask can be sacrificed for an increase in available resolution. As we have mentioned, reducing the maximum optical density, or contrast, can alleviate scattering-induced broadening. It is possible, however, to compensate to some degree for the reduced contrast during the photolithography process, where UV exposure and develop times provide additional latitude in the pattern transfer process.

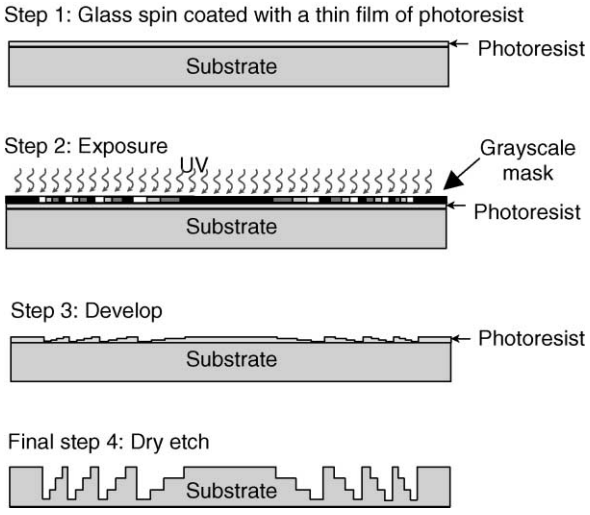

Figure 4 Fabrication of a continuous phase DOE using a grayscale mask.

Figure 4 represents the fabrication of a continuous profile DOE using a grayscale mask. The substrate is spin-coated with a thin film of photoresist, placed in intimate contact with the grayscale mask, and UV illuminated to expose the resist film. The resist is developed and the pattern transferred into the substrate using either wet or dry etching techniques. Because the solubility of the resist is proportional to exposure, developing the photoresist produces a variable height profile.

Grayscale lithography is challenging because modern photoresists are also designed to be highly nonlinear yet linear response is required. Traditional photoresists are also designed to amplify mask contrast and produce the sharpest resist profile, thus they either dissolve away quickly and completely, or remain impervious to developer. The exposure threshold of traditional resists is, therefore, steep and considerable effort is required to

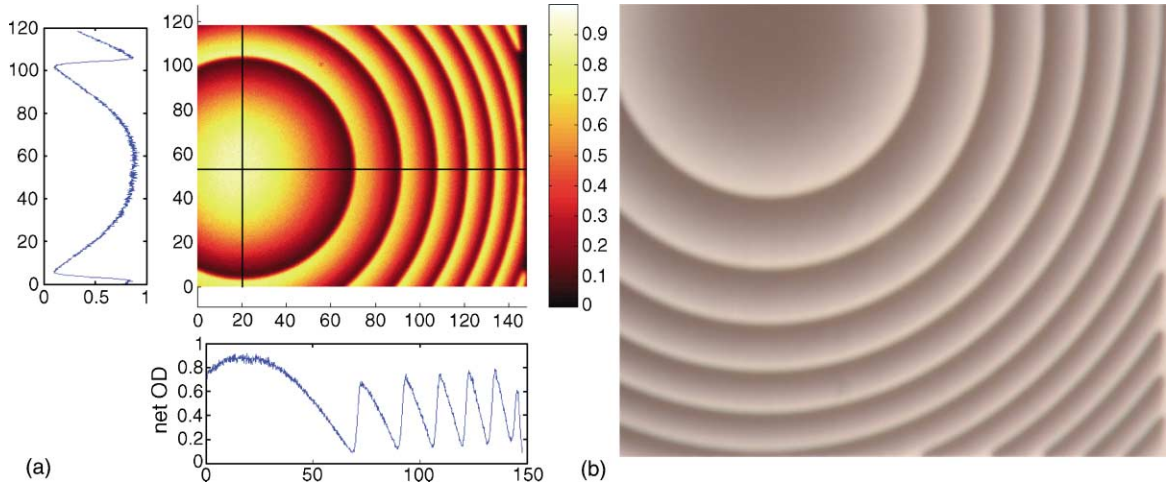

Figure 5 HEBS glass fabrication. (a) Data map of the optical density cross-section of an exposed HEBS grayscale mask and (b) its corresponding visible image.

insure that resist exposure is on the linear portion of the curve.

Although the resist exposure process is sensitive to all parameters, the behavior of a resist can be characterized using simulation models. The details of the photoresist models can be found elsewhere, but the simulations predict that the greatest utilization of the available resist occurs for short exposure times (seconds), and that these short exposures require long developing times (minutes). Further, the models predict that low mask contrast does not adversely affect the usable resist height. It is, therefore, not unreasonable to use a low contrast mask to achieve small features.

Through simulation it is possible to determine process parameters that maximize the linear response range of the photoresist. However, these parameters must be validated in the laboratory. The results presented in Figures 5 and 6 provide convincing evidence of the efficacy of these techniques.

Final Remarks

Advances in passive photonic devices have been made possible by leveraging fabrication processes from the electronics industry. Modifying standard photolithographic techniques and photoresist processes has produced an industrial capacity for fabricating diffractive elements. This capability will no doubt lead to future advances in telecommunications, signal processing, and imaging.

Diffractive Laser Resonators

U D Zeitner, Fraunhofer Institute of Applied Optics and Precision Engineering, Jena, Germany

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

All lasers consist of three basic functional components: an active medium, an optical arrangement to pump the active medium, and a resonator, which we consider in detail here. The basic function of the resonator is to back-couple a portion of the emitted laser light into the active medium for further amplification. Simultaneously, in steady-state laser operation, the geometry of the resonator defines the spatial field distribution of the generated light field.

In the most simple, and most common, case the laser resonator consists of two planar or spherical mirrors. This configuration was proposed in 1958 and has been treated extensively in the literature. However, these configurations are only special cases of a more general resonator concept in which arbitrary mirror surface profiles are used. Historically, resonators consisting of surface profiled mirrors played only a small role in laser physics. This was due, not only to difficulties in their numerical design and analysis, but also to the lack of suitable fabrication methods for the mirrors.

However, since the 1990s, these difficulties have been overcome and in 1992 it was demonstrated for the first time experimentally a stable CO_2 laser resonator that has a user-defined mode shape generated by surface structured mirrors.

In the following we derive the basic design rules for stable and unstable diffractive laser resonators and discuss the advantages and disadvantages of the technology.

Modes in Laser Resonators

Before presenting the details of diffractive laser resonators we look first at some general properties of the electromagnetic field inside a laser resonator. As is typical in laser resonator theory, we use scalar and paraxial descriptions of the fields.

The complex amplitude $U(x, y, z)$ represents one scalar, monochromatic component of the electromagnetic field. To handle wave propagation inside the resonator, we use a general operator formalism in which the influence of each optical component on the wave $U(x, y, z)$ is represented by an operator. One of the most important operators is the so-called round trip operator $\mathbf{Z}$, which describes the effect of a round trip inside the resonator on the wave $U(x, y, z)$.

If $U(x, y, z)$ denotes the wave at the beginning of a resonator round trip, the resulting wave $\tilde{U}(x, y, z)$ at its end is

$$\tilde{U}(x, y, z) = \mathbf{Z}U(x, y, z) \qquad [1]$$

With reference to Figure 1, the round trip operator can be decomposed into a series of operators that represent the different elements in the resonator. For the common two-mirror resonator a round trip from mirror 1 to mirror 2, reflection at mirror 2, back propagation to mirror 1, and final reflection at

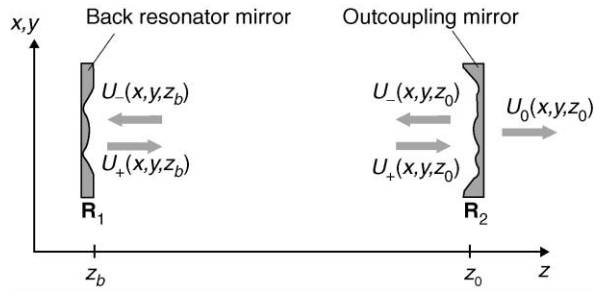

Figure 1 General diffractive laser resonator arrangement.

mirror 1, is represented by

$$\mathbf{Z} = \mathbf{R}_1\mathbf{P}_{\Delta z}\mathbf{R}_2\mathbf{P}_{\Delta z} \qquad [2]$$

The operators $\mathbf{R}_1$ and $\mathbf{R}_2$ represent the reflection at mirrors 1 and 2, respectively, and the propagation along the resonator length Δz is represented by the propagation operator $\mathbf{P}_{\Delta z}$.

In steady-state laser operation, the wave circulating inside the resonator reproduces itself, up to a constant factor γ, after a complete round trip:

$$\tilde{U}(x, y, z) = \gamma U(x, y, z) \qquad [3]$$

Together eqns [1] and [3] give the eigenvalue equation:

$$\gamma U(x, y, z) = \mathbf{Z}U(x, y, z) \qquad [4]$$

which, in general, has a set of solutions $U_p(x, y, z)$.

Thus, in steady-state, the waves $U_p(x, y, z)$ circulating inside the resonator are eigenfunctions of the round trip operator $\mathbf{Z}$ with the connected eigenvalue γ_p. The eigenfunctions of the resonator are called modes and the real-valued eigenvalues γ_p are connected with the round trip losses V, according to the equation:

$$V = 1 - |\gamma_p|^2 \qquad [5]$$

As we can see, the spatial properties of the modes are determined by the optical elements in the resonator. In the simple two-mirror resonator, the mirror profiles, which are related to the operators $\mathbf{R}_1$ and $\mathbf{R}_2$, can be used to specify the shape of the modes.

To derive the rules for resonator design we must look closer at the orthogonality of the resonator modes. The normalized eigenfunctions of the round trip operator $\mathbf{Z}$ do not obey the usual power-orthogonality relationship:

$$\int\int U_m(x, y, z)U_n^*(x, y, z)\,\mathrm{d}x\,\mathrm{d}y = \delta_{mn} \qquad [6]$$

but instead satisfy the biorthogonality relationship:

$$\int\int U_{m;+}(x, y, z)U_{n;-}(x, y, z)\,\mathrm{d}x\,\mathrm{d}y = \delta_{mn} \qquad [7]$$

The δ_{mn} is the so-called Kronecker symbol and $*$ denotes the complex conjugate. In eqn [7], $U_{m;+}(x, y, z)$ is the mode in plane z traveling in the $+z$ direction and $U_{m;-}(x, y, z)$ is the mode in the same plane z propagating in the opposite direction. The physical reason for the difference between eqns [6] and [7] are diffractive mode losses at limiting apertures. However, if a mode $U_{m;+}(x, y, z)$ travels without losses through the whole resonator, a power normalization:

$$\int\int U_m(x, y, z)U_m^*(x, y, z)\,\mathrm{d}x\,\mathrm{d}y = 1 \qquad [8]$$

is valid in all planes z. Equations [7] and [8] will be used in the next section to derive the design strategy for resonators with predefined fundamental modes.

If the mirrors, either planar or spherical, are assumed to be infinite in extent, it is possible to derive analytic solutions for the modes. This yields either the Gauss–Hermite or Gauss–Laguerre modes, which are orthogonal in the sense of eqn [6]. For resonators whose mirror shape differs from either a plane or sphere, the analytical calculation of its eigenfunctions or resonator modes is difficult and in most cases even impossible.

However, in such cases the analysis can be performed numerically. One of the most common methods is the Fox-Li-algorithm which uses the physical propagation of the modes through the resonator. The algorithm begins with a random field distribution in some plane of the resonator. This field is then numerically propagated through the resonator until a round trip is completed. The effect of the resonator optical elements must be accounted for in this procedure. At the end of the resonator round trip, the starting field will have changed due to diffraction and serve as a new starting wave for a succeeding round trip calculation. This procedure is repeated until a static field distribution is obtained, which is then an eigenfunction of the resonator.

Design Principles

The condition in eqn [7] on the biorthogonality of resonator modes, together with the eqn [8] valid for lossless modes, can be used to develop principles to design resonators with an arbitrary fundamental mode shape. Consider a stable laser resonator characterized by negligible diffraction loss of the fundamental mode. Following the discussion above, its lossless modes must simultaneously satisfy

eqns [7] and [8]. A comparison of both equations yields:

$$U_+(x, y, z) = U_-^*(x, y, z) \qquad [9]$$

For reasons of simplicity we neglect here, and in the following, the subscript m for the mode order if only one mode is considered. Because this equation must hold in all planes z, it is satisfied in the mirror resonator planes z_0 and z_b. Further, by definition of the operators $\mathbf{R}_1$ and $\mathbf{R}_2$:

$$U_+(x, y, z_b) = \mathbf{R}_1 U_-(x, y, z_b) \qquad [10]$$

$$U_-(x, y, z_0) = \mathbf{R}_2 U_+(x, y, z_0) \qquad [11]$$

The combination of eqns [10] and [11] with eqn [9] yields the following expressions for the mirror operators:

$$\mathbf{R}_1 = \frac{U_+(x, y, z_b)}{U_+^*(x, y, z_b)} \qquad [12]$$

$$\mathbf{R}_2 = \frac{U_-(x, y, z_0)}{U_-^*(x, y, z_0)} \qquad [13]$$

Equations [12] and [13] imply that lossless modes are phase-conjugated on reflection at the resonator mirrors. Because we have not made any assumptions on the shape of the mode, these equations represent a general property of lossless resonator modes. Furthermore, they provide a general design rule for the construction of stable laser resonators with predefined fundamental mode shape.

If one considers limiting apertures inside the resonator, an equivalent statement for lossy modes can be made by making assumptions about phase conjugation in a lossy system and showing that they lead to a contradiction. Without loss of generality, we assume an aperture on the outcoupling resonator mirror that clips the mode. We now consider the wave $U_-(x, y, z_0)$ after reflection at this mirror and assume this wave is still phase-conjugated after propagation through the resonator during its reflection at the back resonator mirror according to:

$$U_+(x, y, z_b) = U_-^*(x, y, z_b) \qquad [14]$$

If now the wave $U_+(x, y, z_b)$ is back propagated to the outcoupling mirror, we end up with the wave $U_+(x, y, z_0)$ which must, because of the phase conjugation in z_b, have the same amplitude as the wave $U_-(x, y, z_0)$ we started with. As a result, because both waves are connected to each other via the reflection operator of the outcoupling mirror by eqn [11], $\mathbf{R}_2$ cannot influence the amplitude distribution which, however, is a contradiction to the assumption of a limiting aperture. Thus, we finally can state that lossy modes do not have the property to be phase conjugated during their reflection at both mirrors. As a consequence, the design of diffractive mirrors for unstable laser resonators, in general characterized by energy outcoupling via diffractive losses, is more complex than simply calculating a phase-conjugating mirror structure for stable laser resonators.

Up to now, design methods described in the literature for unstable laser resonators with user-defined output beam shapes have all been based on an iterative calculation of the mirror reflection function. Because a detailed description of these methods is rather complex, we restrict ourselves to a sketch of the principal ideas behind them.

Without loss of generality, we consider an unstable laser resonator from which the light is coupled out by a mirror with spatially varying transmission and reflection. The second mirror is fully reflective within its aperture. The particular application defines only few design constraints which are in most cases the light wavelength, the dimensions of the resonator, and the shape of the outcoupled beam $U_0(x, y, z_0)$. As a consequence of the outcoupling principle, the shape of the mode inside the resonator is not finally defined by the outcoupled beam. In regions where the outcoupling mirror is reflective and not transmissive, the mode amplitude can be chosen freely. Also the amplitude of the mode in the plane of the back resonator mirror is not fixed but influenced by the amplitude and phase of the mode in the plane of the outcoupling mirror.

The general starting situation for an unstable resonator design is sketched in Figure 2. The design procedure must yield the complex amplitudes of four waves: the mode directly in front of the outcoupling mirror $U_-(x, y, z_0)$, the mode after reflection at the outcoupling mirror $U_+(x, y, z_0)$, and the complex amplitudes of the forward and reverse modes in the plane of the back resonator mirror $U_+(x, y, z_b)$ and $U_-(x, y, z_b)$, respectively. Since we assume no losses at

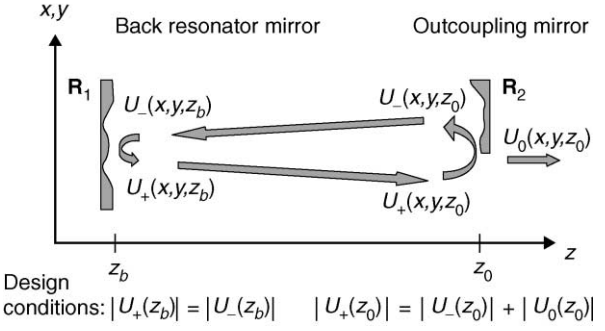

Figure 2 Starting situation for design of an unstable diffractive laser resonator.

this mirror, the amplitudes must satisfy the condition:

$$|U_+(x, y, z_b)| = |U_-(x, y, z_b)| \quad [15]$$

If we further assume no absorption at the outcoupling mirror, the amplitudes of the three waves in z_0 are related according to:

$$|U_-(x, y, z_0)| + |U_0(x, y, z_0)| = |U_+(x, y, z_0)| \quad [16]$$

To design the resonator one starts with the choice of initial intensity distributions for the wavefields $U_-(x, y, z_0)$ and $U_+(x, y, z_b)$. In order to obtain a good filling of the available mode volume, a homogeneous intensity across the mirror apertures is recommendable. To avoid strong diffraction effects at the mirror edges, the corresponding intensity distributions should be smoothed out. Together with the desired outcoupled beam amplitude $|U_0(x, y, z_0)|$ one can calculate the two remaining amplitudes for the wave fields $U_-(x, y, z_b)$ and $U_+(x, y, z_0)$ according to eqns [15] and [16].

An iterative algorithm, such as the well known Gerchberg–Saxton algorithm, can be used to find the phases of the beams $U_-(x, y, z_0)$ and $U_+(x, y, z_0)$ that insure the wavefields have almost equal amplitudes once they are propagated or back-propagated, respectively, to the plane z_b. In order to find wavefields that satisfy eqns [15] and [16], two successive iteration runs with different constraints on the complex amplitudes have to be performed. During the first iteration run no change in the initial amplitudes in plane z_0 are allowed. The iteration only look for phases for $U_-(x, y, z_0)$ and $U_+(x, y, z_0)$ which result in the amplitude $|U_+(x, y, z_b)|$ once they are propagated and back-propagated, respectively, to plane z_b. Usually the results of a Gerchberg–Saxton algorithm, with such constraints, are wavefields $U_+(x, y, z_b)$ and $U_-(x, y, z_b)$ with similar but not equal amplitude. Thus, in order to determine wavefields that satisfy eqn [15], a second iteration run with the Gerchberg–Saxton algorithm has to be added in which slight variations in wavefield amplitudes also in plane z_0 are allowed. Because the application of the constraints to ensure convergence of the iteration is rather complex, we do not go into details here but refer the reader to the Further Reading at the end of this article.

Upon completion of the iterations, the mirror reflectance operators $\mathbf{R}_1$ and $\mathbf{R}_2$ are calculated according to:

$$\mathbf{R}_1 = \frac{U_+(x, y, z_b)}{U_-(x, y, z_b)} \quad [17]$$

$$\mathbf{R}_2 = \frac{U_-(x, y, z_0)}{U_+(x, y, z_0)} \quad [18]$$

The design method described so far yields a mathematical expression for the resonator mirror reflection operator. Practical realization of the resonator requires this expression be converted into a description of a physical property of the mirror. In most practical cases this is the surface profile. Since the design method considers only phase-only functions, the physical description of the reflection operators are:

$$\begin{aligned} \mathbf{R}_1 &= \exp[-\mathrm{i}\phi_1(x, y)] \text{ and} \\ \mathbf{R}_2 &= \exp[-i\phi_2(x, y)] \end{aligned} \quad [19]$$

Using the so-called thin-element-approximation, the surface profiles $h_1(x, y)$ and $h_2(x, y)$ of the two mirrors follow directly from the phases $\phi_1(x, y)$ and $\phi_2(x, y)$:

$$\begin{aligned} h_1(x, y) &= -\frac{\lambda}{4\pi}\phi_1(x, y) \text{ and} \\ h_2(x, y) &= -\frac{\lambda}{4\pi}\phi_2(x, y) \end{aligned} \quad [20]$$

with λ being the laser wavelength. The expressions in eqn [20] contain a factor of 1/2 due to reflection. These surface profiles are commonly fabricated by microlithographic techniques. For stable laser resonators, where the mirrors perform a static phase conjugation, the mirror profile is a surface of equal phase of the fundamental mode.

Use of General Resonator Modes

Applications of diffractive laser resonators can be classified into beam shaping for a particular task external to the laser and resonator optimization via modifying the eigen-space of the round trip operator.

Internal beam shaping for external tasks is relevant to applications where it is advantageous to use a fixed beam profile other than a Gaussian, as is the case for instance in materials processing. Shaping the beam internally, avoids the energy losses usually associated with external beam shaping techniques. However, lasers that have a nonGaussian outcoupled beam profile are often less flexible in their general applicability.

However, there is considerable potential for diffractive laser resonators to enhance resonator characteristics and thereby improve the lasing operation itself. The conventional Gaussian-shaped fundamental mode in customary laser resonators varies considerably in intensity from its central maximum to its outer wings. The transfer of energy from the pumped active medium into the propagating mode is dependent upon the local transverse intensity and is

optimal for homogeneous illumination. As a result, the efficiency with which energy is transferred into the fundamental mode can be increased by using diffractive resonator mirrors to match the shape of the lateral fundamental mode to that of the cross-section of the active medium.

An important resonator property, especially in high power laser systems, is the difference of round trip losses V between the fundamental mode and the higher, usually undesired, laser modes. This difference is referred to as modal discrimination. With no limiting apertures, the wavefronts of all Gauss–Hermite or Gauss–Laguerre modes of common laser resonators are phase conjugated upon reflection at the spherical mirrors. As we have shown above, there is a tight connection between the phase conjugation property of resonator modes and their property of having no round trip losses. Thus, the phase conjugation property of Gauss–Hermite and Gauss–Laguerre modes directly implies small round trip losses. In fact, in resonators without apertures they all have an eigenvalue $\gamma_p = 1$ and according to eqn [5] the round trip losses are zero. High-order modes, whose diameters are large, can be suppressed by decreasing the size of the mirror aperture, however, because the difference in mode diameter between modes of neighboring order m is small, the achievable discrimination is limited to a maximum ratio $V_{m+1}/V_m \approx 10$. The structured surface profile of the mirrors in a diffractive laser resonator whose fundamental mode is nonGaussian is tightly adapted to the phase of the design mode. The wavefront of the higher-order modes in these resonators often do not fit the mirror profile and it can be observed that their round trip losses are significantly higher. Thus, diffractive laser resonators usually show an improved modal discrimination compared to resonators with spherical mirrors. This effect can be further improved by inserting into the resonator additional phase plates with diffuser-like properties.

Shaping the surface profile of resonator mirrors or insertion of additional phase plates significantly improves the flexibility for the resonator design. As is demonstrated by the examples below, there are resonator configurations in which high modal discrimination or adaptation of the mode volume to the cross-section of the active medium are combined with a Gaussian shape of the outcoupled beam.

In the design procedure described so far, the resonators were treated as passive optical systems. The propagation of the mode through the resonator has not been influenced by the active medium. However, in real laser systems, this simplification is often not applicable. Due to the pumping process and the connected heat insertion, the refractive index distribution inside the active medium is not homogeneous, which affects the propagation of the modes. Furthermore, changes or fluctuations in the pump energy and cooling mechanisms introduce temporal changes in the optical function associated with the refractive index of the active medium. Further, although static or averaged, optical power of the active medium are included in the round trip operator and calculation of the mirror profiles, experiments with lasers that have diffractive resonator mirrors indicate that the temporal fluctuations can strongly influence the shape and round trip losses of the fundamental resonator mode. In general, diffractive laser resonators are more sensitive to deviations from design than conventional resonators.

Examples

We consider as an example the adaptation of fundamental mode shape to the cross-section of the active medium. In solid state lasers, such as Nd:YAG lasers, the active medium is often a crystal rod with a circular cross-section. Instead of using this sharp-edged cross-section shape as intensity distribution for the desired fundamental mode, a smoothed version, which is approximated by a super-Gaussian intensity distribution in the center plane of the rod, is chosen to be the fundamental mode. The super-Gaussian intensity distribution has a more desirable propagation characteristic than a sharp circular one. However, even these modes do not exhibit the advantageous property of propagation-invariant beam shape characteristic of Gaussian beams.

In our first example, we consider the design of a stable diffractive laser resonator with a super-Gaussian fundamental mode shape inside the active medium and a Gaussian beam coupled out from the resonator. The resonator configuration is based upon a beam shaping arrangement for a Gauss to super-Gauss beam transformation. Its optical setup is sketched in Figure 3. In the plane of the outcoupling

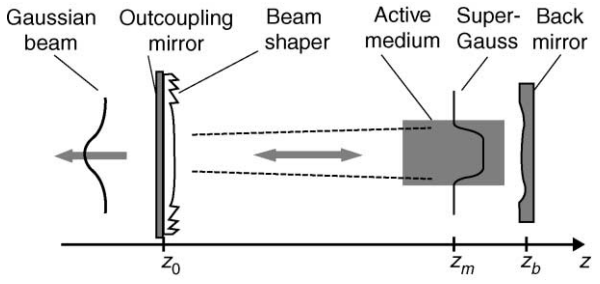

Figure 3 Setup for the Gauss-to-super-Gauss resonator.

mirror z_0, the fundamental mode has a Gaussian amplitude $U_g(x, y, z_0)$. A phase element, which is located directly in front of the outcoupling mirror, shapes the mode amplitude into a super-Gaussian one $U_{sg}(x, y, z_m)$ in the center plane z_m of the active medium. For this special beam shaping problem it is possible to calculate a phase plate surface profile that transforms the beams without energy losses. The corresponding calculation procedure is described in the Further Reading section at the end of this article.

The mirror profiles have to be realized to satisfy the previously derived phase conjugation property for the described beam. Since the Gaussian beam has its minimum waist at the outcoupling mirror, its phase is planar in that plane. Thus, to insure phase conjugation a plane mirror is all that is required in front of the beam shaping phase plate. In the plane of the back resonator mirror the beam has a modulated wavefront due to its transformation from a Gaussian to a super-Gaussian amplitude distribution. Thus, a surface modulated mirror profile is required to phase conjugate this beam during reflection. Figures 4a and b represent the phase profile of the beam shaping element and the back resonator mirror, respectively, for the following set of parameters: laser wavelength $\lambda = 1064$ nm, radius of the Gaussian and super-Gaussian beams in the plane z_0 and z_m, respectively, $w_g = 1$ mm and $w_{sg} = 1$ mm, order of the super-Gauss $n = 10$, distance $z_m - z_0 = 200$ mm, and resonator length $z_b - z_0 = 250$ mm. The amplitude distribution for the fundamental mode in this resonator simulated with the Fox–Li-algorithm is shown in Figure 4c for the plane of the outcoupling mirror and in Figure 4d for the center of the active medium.

In our second example, the flexibility of diffractive laser resonators is demonstrated by a resonator with a user-defined far-field intensity distribution. In our case the far-field intensity $|U_f(x, y, z_f)|^2$ is shaped like the Greek letter lambda, λ. Because we are concerned only with the intensity of the wavefield, the phase $\phi_f(x, y, z_f)$ of the far-field $U_f(x, y, z_f)$ can be chosen freely. As shown in the following, this phase freedom can be used to improve the interaction of the mode with the active medium, as was the case in our first design example. Again, the mode shape in the center of the active medium has a super-Gaussian intensity distribution, which insures high extraction efficiency. We used an iterative Fourier-transform algorithm to calculate a far-field phase that yields a nearly super-Gaussian intensity distribution in the outcoupling plane of the resonator. The resulting wave:

$$U_0(x, y, z_0) = a_0(x, y, z_0) \exp[i\varphi_0(x, y, z_0)] \qquad [21]$$

is generated directly as the laser output. The amplitude $a_0(x, y, z_0)$ is generated as a mode inside the cavity using a surface-modulated back resonator mirror. This performs a static phase conjugation of the desired mode in the mirror plane. The phase $\varphi_0(x, y, z_0)$ is provided by an additional element on the outside of the outcoupling mirror. A sketch of the resonator configuration is shown in Figure 5.

For the experimental realization of this example the thermal index gradient of the active medium was included into the resonator design and the two diffractive elements were fabricated on a quartz substrate using electron beam lithography and ion-beam etching. The measured mode shape in the plane of the outcoupling mirror and the far-field

intensity distribution are shown in **Figures 6a** and **b**, respectively. The mode in the outcoupling plane of the resonator fills an area of about 2 mm diameter with nearly homogeneous intensity. The far-field shows the desired λ-shaped intensity distribution. The variations in intensity are due to the nonlinear response of the active medium. As mentioned above, the response can be improved if these effects are included in the design of the resonator mirrors.

Conclusion

Diffractive laser resonators are a generalization of common spherical mirror resonators. The use of arbitrary resonator mirror profiles and additional internal phase plates offer a huge flexibility for the generation of user defined mode shapes and optimization of resonator properties like extraction efficiency and modal discrimination. The drawback of the use of structured mirrors is an increased adjustment effort, because the diffractive mirrors have more degrees of freedom to be aligned. Furthermore, diffractive resonators tend to be more sensitive against changes of the optical properties of the active medium than spherical mirror resonators. Such changes may occur due to temporal fluctuations in pump power or cooling power.

Most promising applications for diffractive resonators are:

- lasers for materials processing which require a fixed intensity pattern for the sample treatment and a fixed laser power;
- high efficient homogeneous laser illumination, for example, for data projection or sensing applications; and
- suppression of higher order modes and maintaining single-mode operation for high brightness lasers.

Some example applications and solutions have been presented here which cannot be achieved by conventional resonator optics. For stable laser resonators, the phase-conjugation property of the

modes is used for a straightforward calculation of the required diffractive mirror profiles. Unstable resonator geometries with diffractive outcoupling require more complex iterative design procedures. However, especially for high-power and high-gain lasers, the latter sometimes have more advantageous properties, such as better discrimination of undesired higher-order modes and more simple mirror cooling options.

Diffractives in Animals

A R Parker, University of Oxford, Oxford, UK

Introduction

Structural coloration involves the selective reflectance of incident light by the physical nature of a structure. Although the color effects often appear considerably brighter than those of pigments, structural colors often result from completely transparent materials. In addition, animal structures can be designed to provide the opposite effect to a light display: they can be antireflectors, causing 'all' of the incident light to penetrate a surface (like glass windows, smooth surfaces cause some degree of reflection).

The study of natural structural colors began in the seventeenth century, when Hooke and Newton correctly explained the structural colors of silverfish (Insecta) and peacock feathers (Figure 1), respectively. Nevertheless, accurate, detailed studies of the mechanisms of structural colors did not begin until the introduction of the electron microscope in 1942.

Structural colors generally may be formed by one of three mechanisms: thin-film reflectors, diffraction gratings, or structures causing scattering of light waves. This is a simplistic characterization resulting from the application of geometric optics to the reflective elements. Some structures, however, rather fall between the above categories, such as photonic crystals (Figure 2) – these become apparent when quantum optics is considered. In some cases, this has led to confusion over the reflector type. For example, the reflectors in some scarab beetles have been categorized by different authors as multilayer reflectors, three-dimensional diffraction gratings, photonic crystals, and liquid crystal displays. Perhaps all are correct! Since the above categories are academic, I place individual cases of structural colors in their most appropriate, not unequivocal, category. Also, in this article I will employ geometric optical treatments only.

The array of structural colors found in animals today results from millions of years of evolution. Structures that produce metallic colors have also been identified in extinct animals. Confirmation of this

Figure 1 Newton's subject.

fact, from ultrastructural examination of exceptionally well-preserved fossils, such as those from the Burgess Shale (Middle Cambrian, British Columbia), 515 million years old, permits the study of the role of light in ecosystems throughout geological time, and consequently its role in evolution. In some cases, such as for ostracod crustaceans, diffraction gratings have been found to increase in their optical sophistication throughout 350 million years of evolution.

Multilayer Reflectors

Light may be strongly reflected by constructive interference between reflections from the different interfaces of a stack of thin films (of actual thickness d) of alternately high and low refractive index (n). For this to occur, reflections from successive interfaces must emerge with the same phase and this is achieved when the so-called 'Bragg Condition' is fulfilled. The optical path difference between the light reflected from successive interfaces is an integral number of wavelengths and is expressed in the equation:

$$2nd \cos \Theta = (m + 1/2)\lambda \qquad [1]$$

from which it can be seen that the effect varies with angle of incidence (Θ, measured to the surface normal), wavelength (λ), and the optical thickness of the layers (nd). There is a phase change of half a wavelength in waves reflected from every low to high refractive index interface only. The optimal narrowband reflection condition is therefore achieved where the optical thickness (nd) of every layer in the stack is a quarter of a wavelength. In a multilayer consisting of a large number of layers with a small variation of index the process is more selective than one with a smaller number of layers with a large difference of index. The former therefore gives rise to more saturated colors corresponding to a narrow spectral bandwidth and these colors therefore vary more with a change of angle of incidence. Both conditions can be found in animals – different colored effects are appropriate for different functions under different conditions. For an oblique angle of incidence, the wavelength of light that interferes constructively will be shorter than that for light at normal incidence. Therefore, as the angle of the incident light changes, the observed color also changes (Figure 3).

Single layer reflectors are found in nature, where light is reflected, and interferes, from the upper and lower boundaries (Figure 4). A difference in the thickness of the layer provides a change in the color observed from unidirectional polychromatic light. The wings of some houseflies act as a single thin film and appear different colors as a result of this phenomenon. A single quarter-wavelength film of guanine in cytoplasm, for example, reflects about 8% of the incident light. However, in a multilayer reflector with ten or more high index layers, reflection efficiencies can reach 100%. Thus, animals possessing such reflectors may appear highly metallic.

The reflectance of the multilayer system increases very rapidly with increasing number of layers. If the dimensions of the system deviate from the quarter-wave condition (i.e., nd is not equal for all layers), then the reflector is known as 'nonideal' in a theoretical sense (may be 'ideal' for some natural situations). 'Nonideal' reflectors have a reduced proportional reflectance (not always a significant reduction) for a given number of layers and this

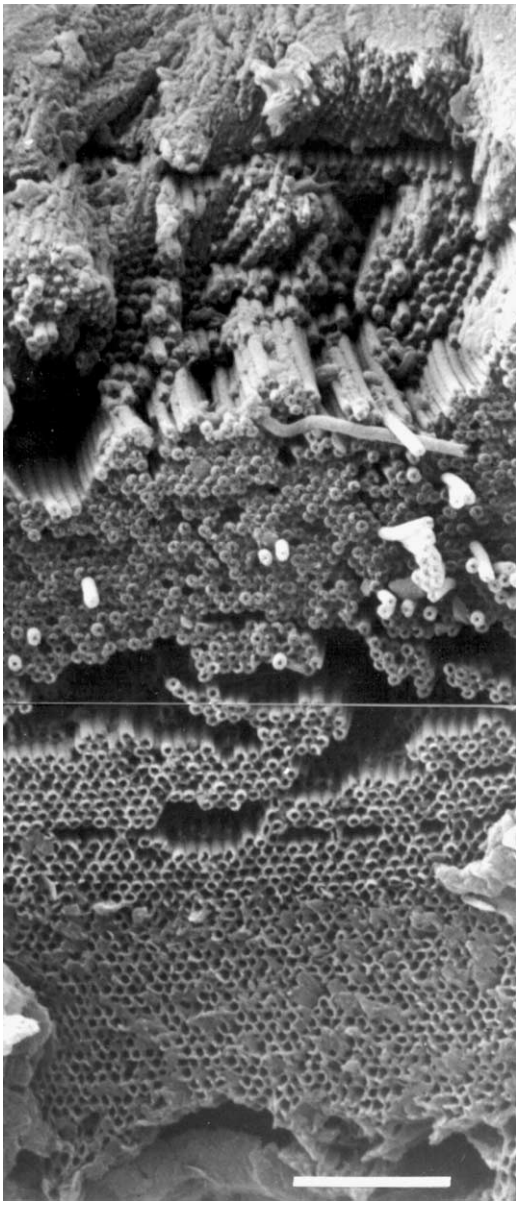

Figure 2 Scanning electron micrograph of a cross-section of the wall of a cylindrical spine of the sea mouse *Aphrodita* sp. (Polychaeta). The wall is composed of small cylinders with varying internal diameters (increasing with depth in the stack), arranged in a hexagonal array, that form a photonic crystal fiber. The opal-type photonic crystal – hexagonally packed nano-spheres (250 nm diameter) – are also found in animals (e.g. weevils). Scale bar represents 8 μm.

reflectance has a narrower bandwidth. A narrow bandwidth, less conspicuous reflection is sometimes selected for in animals, this will be discussed later in this article. Multilayer reflectors polarize light incident at Brewster's angles. This is about 54° for a quarter-wave stack of guanine and cytoplasm. At very oblique angles, all wavelengths are strongly reflected.

Multilayer reflectors are common in animals. They are usually extra-cellular, produced by periodic secretion and deposition, but sometimes occur within cells. Guanine ($n = 1.83$) is a common component in invertebrate reflectors because it is one of very few biological materials with a high refractive index and is readily available to most invertebrates as a nitrogenous metabolite. However, arthropods, including insects, crustaceans, and spiders, have largely ignored guanine in favor of pteridines. Also surprising is that the reflector material of closely related species, e.g., the molluscs *Pecten* (scallop) and *Cardium* (cockle), may differ.

Multilayers produce effects in beetle cuticle from highly metallic colors ('ideal' system) to rather dull greens ('nonideal' system in combination with scattering; Figure 5), and colors from the wings of many butterflies. Often in butterflies, layers of chitin ($n =$ about 1.56) are supported by vertical vanes of the scales. Air ($n = 1.0$) fills in the spaces and provides the alternate layers of the system. Under white light at normal incidence, the blue color of the butterfly *Arhopala micale* turns to green when the air is replaced by acetone. This is due to an increase in the refractive index of the low n layer (the actual thickness of this layer remains the same but the optical thickness increases) that effectively makes the system less 'ideal'. If the refractive indices of both layers were made equal, there would be no internal interference. A layer of melanin often underlies the reflector and intensifies the metallic colored effect by absorbing the transmitted portion of incident light. For example, in beetles, the elytra of *Anopognathus parvulus* appears metallic gold, green, or yellow in reflected light, and diffuse brown in transmitted light. Individual butterfly scales have been examined in detail to reveal a number of variations of quarter-wave stacks, sometimes in combination with other optical structures, to provide a range of colored effects.

The crustaceans *Limnadia* (Conchostraca), *Tanais tennicornis* (Tanaidacea), *Ovalipes molleri* (Decapoda), and the males of *Sapphirina* (Copepoda) all bear multilayer reflectors in their cuticles, in different forms (Figure 6). In contrast to the usual continuous thin layers, male sapphirinids have ten to fourteen layers of interconnecting hexagonal platelets within the epidermal cells of the dorsal integument. The reflector of *O. molleri* comprises layers that are corrugated and also slightly out of phase (Figure 7). At close to normal incidence this structure reflects red light, but at an angle of about 45° blue light is reflected. The corrugation, however, functions to broaden the reflectance band, at the expense of reducing the intensity of reflection.

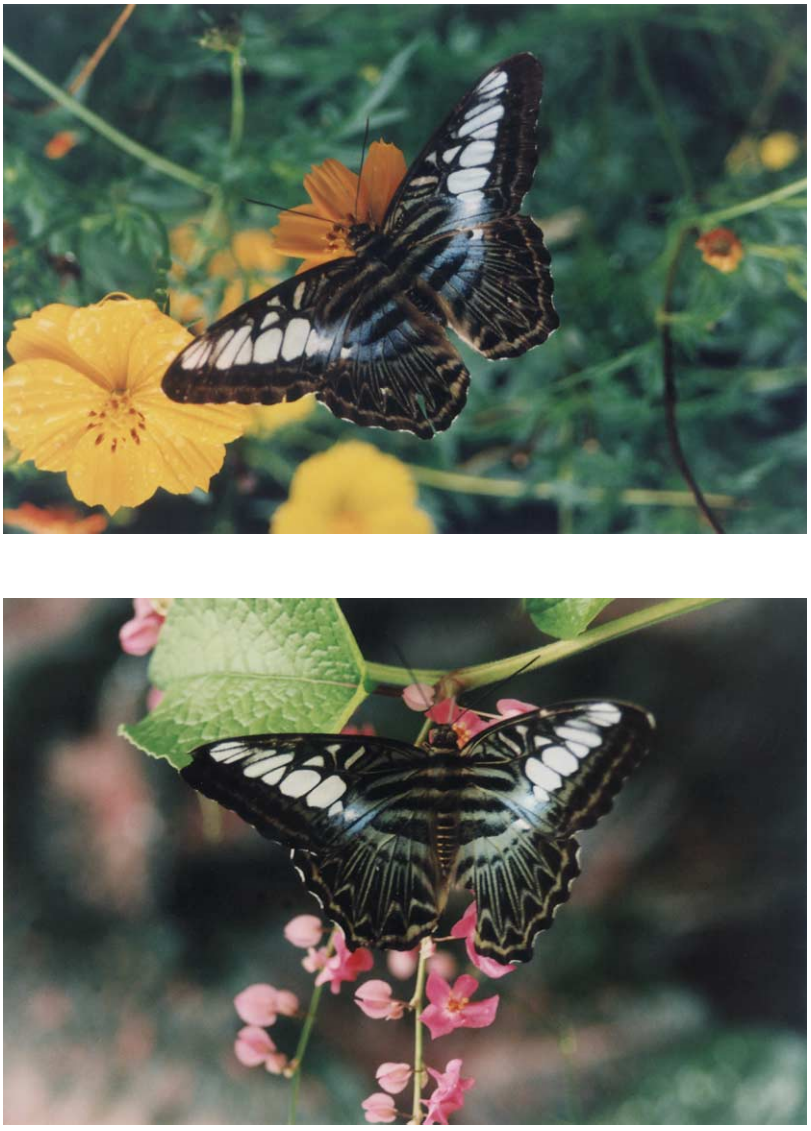

Figure 3 Butterfly (*Parthenos sylvia* (Nymphalidae) from Malaysia), showing the change in color with angle of wings. This animal may have evolved a temporal signal rather than a static one.

A broadband wavelength-independent reflectance, appearing silver or mirror-like to the human eye, can be achieved in a multilayer stack in at least three ways in invertebrates (Figure 8). These are (a) a composite of regular multilayer stacks each tuned to a specific wavelength, (b) a stack with systematically changing optical thicknesses with depth in the structure, termed a 'chirped' stack, and (c) a disordered arrangement of layer thicknesses about a mean value, termed a 'chaotic' stack (Figure 8). The nauplius eye of the copepod *Macrocyclops* (Crustacea) has regularly arranged platelets ~100 nm thick in stacks of 20–60, achieving the first condition. Silver beetles and the silver and gold chrysalis of butterflies in the genera *Euoplea* and *Amauris*, owe their reflection to the second condition. The mirror-like reflectors in the scallop *Pecten* eye comprise alternating layers of cytoplasm ($n = 1.34$) and guanine crystals ($n = 1.83$) and approximate an 'ideal' quarter-wave system in the same manner as within fish skin using the third mechanism. The ommatidia of the superposition compound eyes of *Astacus* (Crustacea) are lined with a multilayer of isoxanthopterin (a pteridine) crystals, which again fall into the third category. Multilayer reflectors can also be found in the eyes of certain spiders, butterflies, and possibly flies, where they assist vision, as discussed further below.

Squid and cuttlefish, for example, possess mirror-like reflectors in photophores (light organs) and

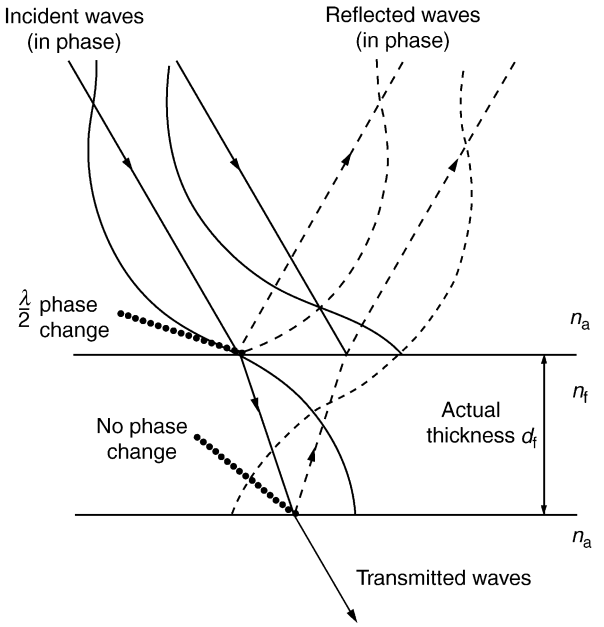

Figure 4 Schematic diagram of thin-film reflection. The direction of wave (straight line) and profile of electric (or magnetic) component are illustrated. Incident waves are indicated by a solid line, reflected waves by broken lines. Refraction occurs at each media interface. The refractive index of the film (n_f) is greater than the refractive index of the surrounding medium (n_a). Constructive interference of the reflected waves is occurring. As the angle of incidence changes, different wavelengths constructively interfere. At normal incidence constructive interference occurs where $n_f \times d_f = \lambda/4$.

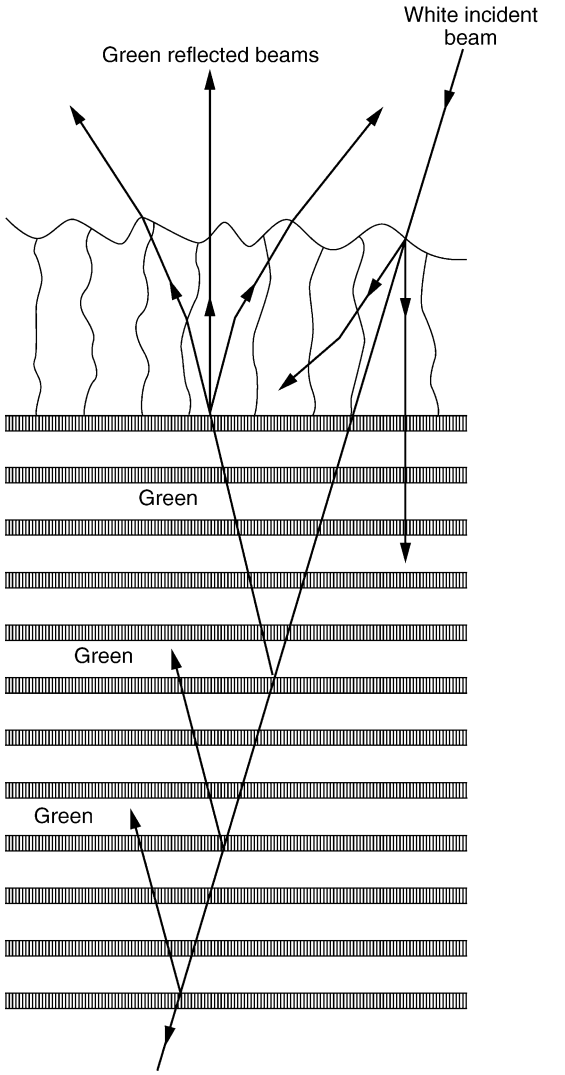

Figure 5 Generalized diagram of a multilayer reflector in the cuticle of the green beetle *Calloodes grayanus* (high refractive index material is shown shaded). Outer layer causes scattering.

iridophores. Iridophores are cells that, in this case, contain groups (iridosomes) of flexible layers of thin lamellae with cytoplasm between, forming a quarter-wave stack. The platelets of both squids and octopods develop from the rough endoplasmic reticulum and are separated by extracellular space. Euphausiid crustaceans possess photophores with very elaborate mirror-like reflectors. Up to 60 dense layers, about 70 nm thick and 75–125 nm apart, are formed from the aggregation of granules (probably a type of chitin) and surround the main photogenic mass. An intricate ring consisting of very flattened cells, forming the dense layers of a multilayer reflector (about 175 nm thick, separated by 90 nm) surrounds the lens of the photophore and reflects blue light at acute angles of incidence.

Dead invertebrates may not display their original colors. Following death, one (or both) of the layers in a multilayer reflector may become gradually reduced. For example, water may be lost from the system. This occurs in beetles of the genus *Coptocycla*; their brassy yellow color quickly changes through green, blue, and violet until the brown of melanin is finally observed. The color progression may subsequently be reversed by water uptake. This is an important consideration when examining fossils for multilayer reflectors. Multilayer reflectors have been identified in the shells of some ammonites, preserved as fossils.

Diffraction Gratings

When light interacts with a periodic surface consisting for example of a series of parallel grooves, it may be deviated from the direction of simple transmission or reflection. For this to happen, light which is scattered or diffracted from successive grooves should be out of phase by integral values of 2π. This occurs when, for a given direction of propagation, the optical path difference via successive grooves is $M\lambda$, where M is an integer known as the circle number.

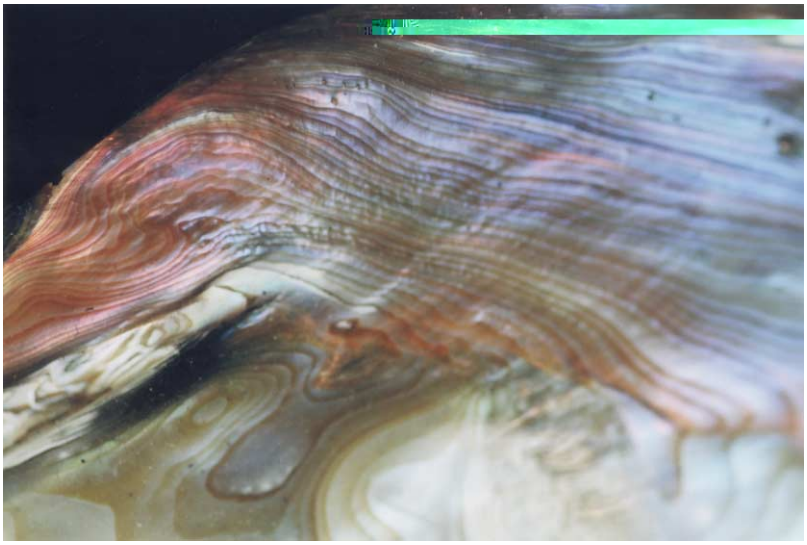

Figure 6 Bivalve shell with outer pigment removed to reveal an incidental multilayer reflector. Layers evolved to provide strength and prevent crack propagation.

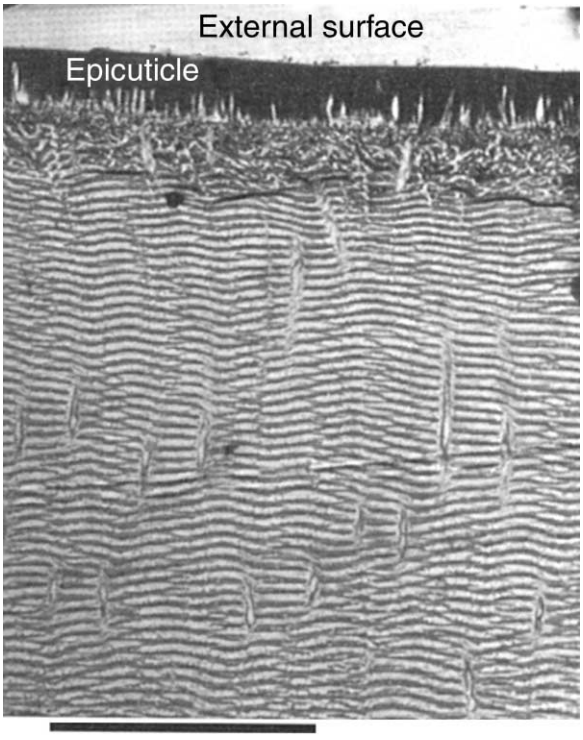

Figure 7 Transmission electron micrograph of a multilayer reflector in the cuticle of a swimming paddle of the crab *Ovalipes molleri* (Crustacea: Decapoda). Layers of reflector are slightly sinuous and out of phase; note the unusual side branches of each high refractive index (dark) layer, which provide support for these solid layers within a liquid matrix. Scale bar represents 5 μm.

This may be expressed by the grating equation:

$$2d(\sin\alpha - \sin\beta) = M\lambda \qquad [2]$$

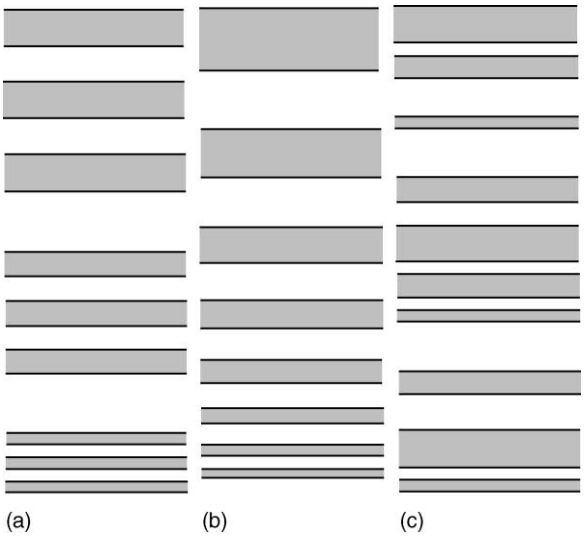

Figure 8 Three ways of achieving a broadband, wavelength-independent reflector in a multilayer stack (high refractive index material is shown shaded). (a) Three quarter-wave stacks, each tuned to a different wavelength. (b) A 'chirped' stack. (c) A 'chaotic' stack.

where α and β are angles of incidence and diffraction, and d is the period.

As with multilayers, the effect gives rise to coloration because different wavelengths are diffracted into different directions. Although the effect changes with angle of incidence, it is less critical than it is with thin films and the visual appearance is different. For a parallel beam of white light incident upon a multilayer, one wavelength will be reflected as determined by the Bragg Condition. The same beam

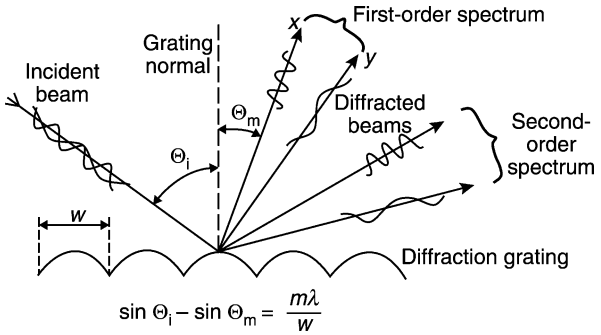

Figure 9 Reflection-type diffraction grating (w = periodicity, m = order of reflected beam). For white light of fixed angle of incidence (Θ_i), the color observed is dependent on the point of observation (e.g., violet light can be seen at point *x*, red at point *y*, within the first order spectrum).

incident upon a grating will be dispersed into spectra (e.g., Figure 9). The complete spectrum reflected nearest to the perpendicular (grating normal) is the first order. The first-order spectrum is reflected over a smaller angle than the second-order spectrum, and the colors are more saturated and appear brighter within the former. Diffraction gratings have polarizing properties, but this is strongly dependent on the grating profile.

Diffraction gratings were believed to be extremely rare in nature, but have recently been revealed to be common among invertebrates. They are particularly common on the seate or setules (hairs) of Crustacea, such as on certain first antennal setules of male Myodocopina ostracods or 'seed shrimps' (Crustacea) (Figure 10). Here, the grating is formed by the external surface of juxtaposed rings with walls circular in cross-section (Figure 11). The width of the rings, and consequently the periodicity of the grating, is about 700 nm in *Azygocypridina lowryi*. Different colors are viewed with varying angles of observation under a fixed light source. The ostracod *Euphilomedes carcharodonta*, for example, additionally houses a diffraction grating on the rostrum, a continuous flattened area of the carapace that is corrugated to form periodic ridges. The dark brown beetle *Serica sericea*, bears gratings on its elytra with 800 nm periodicity, which causes a brilliant iridescence in sunlight.

Many polychaetes possess gratings on their setae (hairs). For example, the opheliid *Lobochesis longiseta* bear gratings with periodicities in the order of 500 nm (Figure 12), appearing iridescent. The wings of the neurochaetid fly *Neurotexis primula* bear diffraction gratings only on their dorsal surfaces, and the iridescent effect remains after the insect is gold coated for electron microscopy. These gratings cause iridescence with a higher reflectance than the

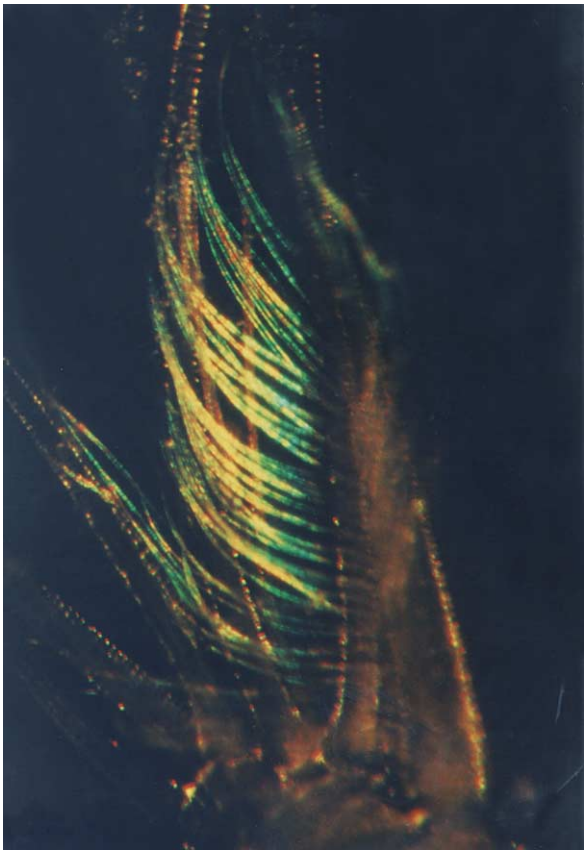

Figure 10 Diffraction gratings on the halophores (hairs) on the first antenna of the seed shrimp *Azygocypridina lowyri* (Ostracoda).

iridescence of the membranous wings of other insects, which reflect light by interference. Iridescence caused by interference disappears after gold coating because transmission of light through the outer surface is prevented.

Very closely spaced, fine setules may also form the ridges of a diffraction grating. Cylindroleberidid

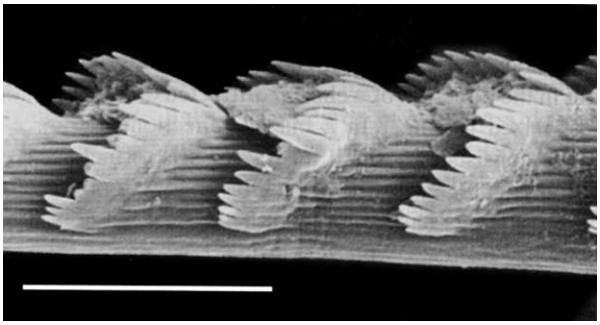

Figure 12 Scanning electron micrograph of diffraction gratings on a hair of *Lobochesis longiseta* (Polychaeta). Scale bar represents 10 μm.

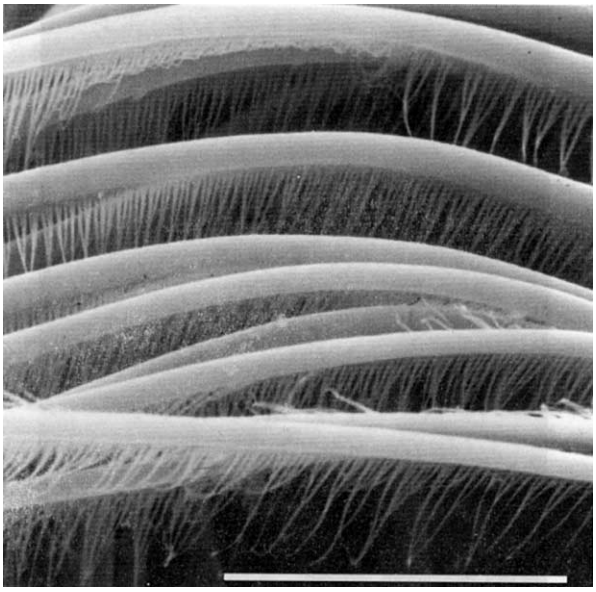

Figure 13 Scanning electron micrograph of *Tetraleberis brevis* (Ostracoda), hairs of comb of maxilla; setules (orientated vertically) form the ridges of a grating. Scale bar represents 2 μm.

ostracods (seed-shrimps) possess a comb on their maxilla bearing numerous setules on each seta (hair), collectively forming a grating with a periodicity of about 500 nm (Figure 13).

The 'helicoidal' arrangement of the microfibrils comprising the outer 5–20 μm of the cuticle (exocuticle) of certain scarabeid beetles, such as *Plusiotis resplendens*, also gives rise to metallic colors. Here, the fibrils are arranged in layers, with the fibril axis in each layer arranged at a small angle to the one above, so that after a number of layers the fibrillar axis comes to lie parallel to the first layer. Thus, going vertically down through the cuticle, two corresponding grating layers will be encountered with every 360° rotation of the fibrils – the 'pitch' of the system. Polarized light encounters an optically reinforcing plane every half turn of the helix. The system can be treated as a three-dimensional diffraction grating, with a peak reflectance at $\lambda = 2nd$, where d is the separation of analogous planes, or half the pitch of the helix. The diffracted light resembles that from a linear grating except for the polarization; the three-dimensional grating reflects light that is circularly or elliptically polarized. It should be noted that the diffracted color does not depend on the total film thickness as it does in interference, but on the layer repeat distance within the film as in the diffraction grating (analogous to 'liquid crystals').

When each groove of a grating is so formed that it independently, by means of geometrical optics, redirects the light in the direction of a chosen diffracted order, it is known as a blazed grating. In a blazed reflection grating, each groove consists of a small mirror (or prism) inclined at an appropriate angle (i.e., the grating has a 'saw-tooth' profile). Blazed gratings have been identified on the wing scales of the moth *Plusia argentifera* (Plusinae).

When the periodicity of a grating reduces much below the wavelength of light, it becomes a zero-order grating and its effect on light waves changes. This difference in optical effect occurs because when the periodicity of the grating is below the wavelength of light the freely propagating diffracted orders are suppressed and only the zero-order is reflected when the illumination is normal to the plane of the grating. To describe accurately the optical properties of a zero-order grating, rigorous electromagnetic theory is required. In contrast to gratings with freely propagating orders, zero-order structures can generate saturated colors even in diffuse illumination. Such structures occur on the setae (hairs) of the first antenna of some isopod crustaceans, such as the giant species of *Bathynomus*. Here, there are diffracted orders and the spectral content of the light within the grating is controlled by the groove profile. In an optical system that only accepts the zero-order, what is seen is white light minus that diffracted into the ± 1 orders.

A zero-order grating can cause total transmission (i.e., there is no reflection). Such antireflective structures are found on the corneal surfaces of each ommatidium (visual unit) in the eye of *Zalea minor* (Diptera) (Figure 14). The periodicity of the corneal gratings of this fly is 242 nm. Another form of antireflection grating is formed on the transparent wings of the hawkmoth *Cephonodes hylas* on the corneal surface of each visual unit (ommatidium) of the eyes of moths and butterflies (Figure 15). Here, optical-impedance matching is achieved by means of a hexagonal array of tapered cylindrical protuberances, each of about 250 nm diameter, thus forming a 'tri-grating' with grooves transecting at 120°.

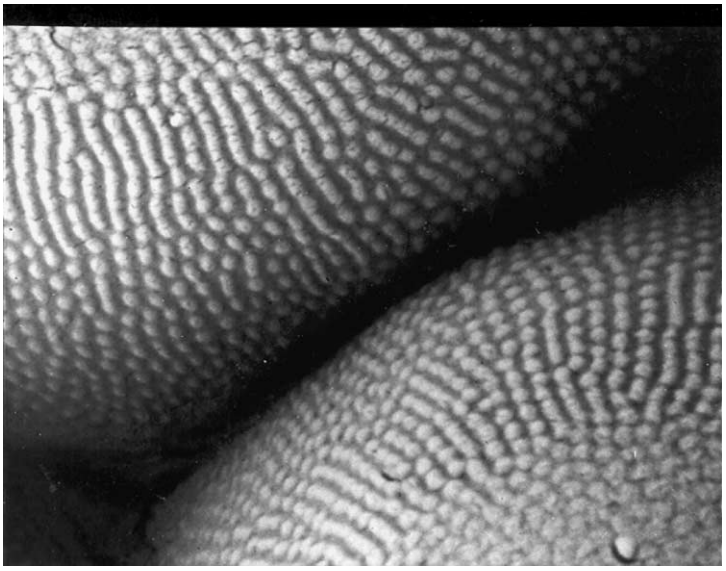

Figure 14 Scanning electron micrograph of the compound eye of *Zalea minor* (Diptera). The corneal surface at the junction of two ommatidia is shown with antireflection gratings (positioned on sloping regions, i.e., at high angles to the normal of the eye) phasing into moth-eye-type protuberances. Scale bar represents 2 μm.

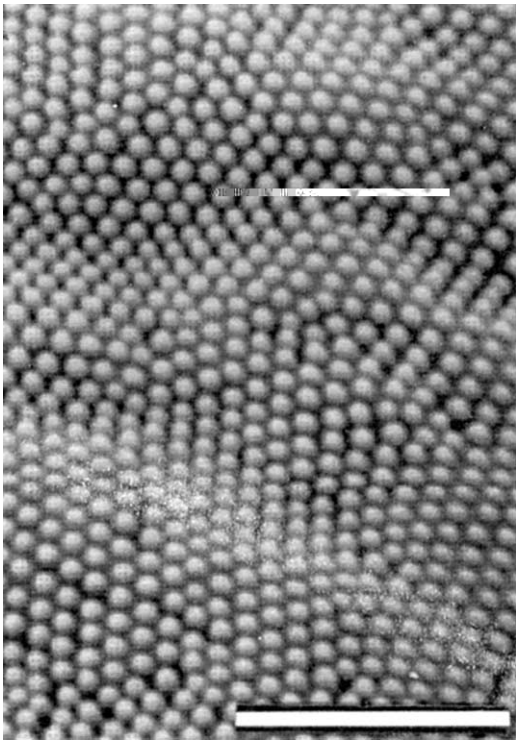

Figure 15 Tri-grating (antireflector) on the corneal surface of a butterfly eye. Scale bar represents 2 μm.

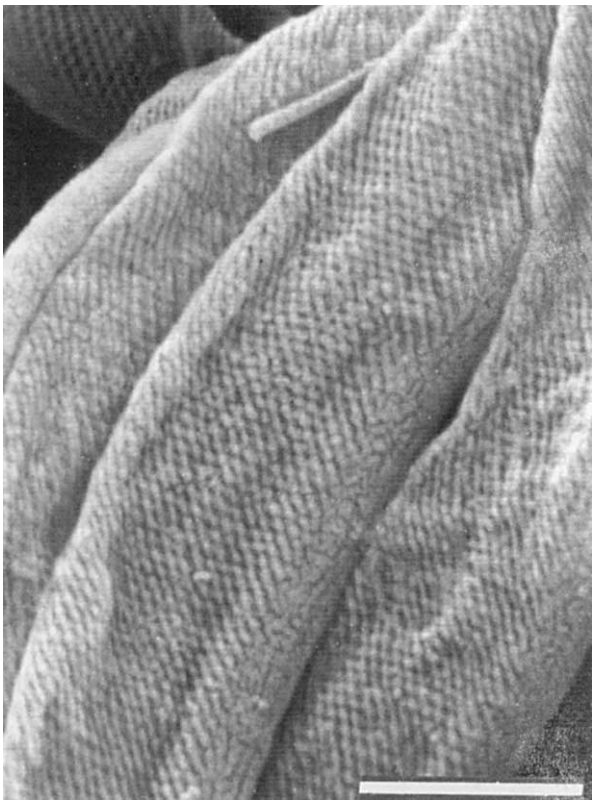

Figure 16 Bi-grating on the callynophores (hairs) of the amphipod crustacean *Waldeckia australiensis*. Scale bar represents 2 μm.

The protuberances provide a graded transition of refractive index between the air and the cornea/wing. Hence the refractive index at any depth is the average of that of air and the corneal/wing material.

The grooves of a grating may also create parallel rows in two directions, forming a bi-grating. Bi-gratings can be found in some crustaceans and flies. In the amphipod crustacean *Waldeckia australiensis*, two effectively superimposed gratings subtend angles of about 60/120° (Figure 16).

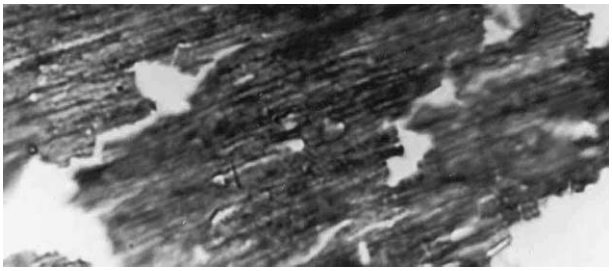

Figure 17 Light micrograph of the surface of a hair of *Canadia spinosa* (Middle Cambrian, 515 million years old, British Columbia), isolated by acid maceration of the rock matrix, showing gratings running longitudinally. Periodicity 0.9 μm.

In terms of fossil colors, diffraction gratings are responsible for the nacreous luster of brachiopod shells, such as those from the Devonian, around 360 million years old. Here, tabular aragonite platelets averaging 600 nm in thickness, each comprising a linear diffraction grating, form layers and consequently a three-dimensional diffraction grating. Antireflective, zero-order gratings have been identified on the eye of an Eocene fly, 45 million years old, preserved in Baltic amber. Linear diffraction gratings causing color have been discovered on the sclerites of *Wiwaxia corrugata* from the Burgess Shale (Middle Cambrian, 515 million years old) (Figure 17). This finding has led to the 'light switch theory', in that the evolution of the first eye caused the big bang in animal evolution.

Scattering (Incoherent Reflectors)

Simple, equal scattering of all spectral wavelengths results in the observation of a diffuse white effect. This commonly arises from the effects of a nonperiodic arrangement of colloidally dispersed matter where the different materials involved have different refractive indices (Figure 18), or from solid colorless materials in relatively concentrated, thick layers. In the colloidal system, the particles are larger than the wavelength of light and can be thought of as mirrors oriented in all directions. The reflection is polarized unless the incident light is at normal incidence on the system and, in the colloidal system, spherical or randomly arranged particles are involved.

The colloidal system involves either a gas-in-solid, gas-in-liquid, liquid-in-liquid (emulsions), or solid-in-liquid. For example, the gas-in-liquid system is partly responsible for the white body and/or tentacles of certain anemones. Light is reflected and refracted at the surfaces of the particles of matter or spaces (with dimensions >1 μm), regardless of the color of the materials involved (except opaque brown and black compounds, such as melanin). In insects, the

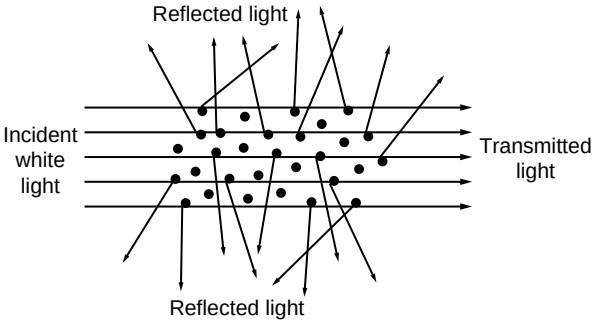

Figure 18 Scattering of white light by small particles (represented by black circles). The reflected light is randomly directed at different angles.

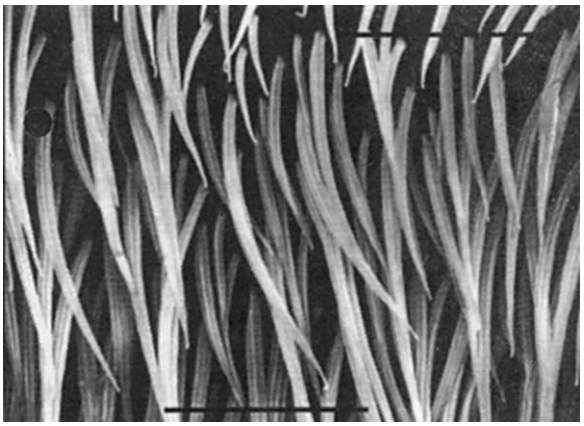

Figure 19 Scanning electron micrograph of a section of a white reflecting patch on the abdomen of the fly *Amenia* sp., showing closely packed, randomly arranged hairs that scatter incident light in all directions (Figure 11). Scale bar represents 20 μm.

materials involved typically have very low transparencies.

An unordered (as opposed to periodic) group of closely spaced setae (hairs), such as those in patches on the fly *Amenia* sp., may form a white reflection via random scattering or reflection (Figure 19). However, if the arrangement becomes periodic to some degree, a diffraction grating may be formed, such as the grating of *Tetraleberis brevis* (Ostracoda) (Figure 13).

From some scales of butterfly wings, light is scattered uniformly and completely in all directions, due to the chaotic disposition of the surfaces. Matt or pearly whites may be observed depending on the complexity of the arrangement of the structures, which affects the relative degree of scattering. The structures may be so small that the molecular topography of the surface has an effect. The chromatic effects of the butterfly scales are greatly intensified if a dark, absorbing pigment screen lies beneath. This screen prevents reflection of white or

colored light from the background that would dilute or alter the color. Additionally, if a dark pigment such as melanin is interspersed with the scattering elements, the reflection will appear a shade of gray or brown. The cells of the reflector in the photophore of a beetle ('fire-fly') are packed with sphaerocrystals of urate that cause a diffuse reflection (Figure 20).

Reflection and refraction that occur at the interfaces of strata with different refractive indices may result in the display of white light. The degree of whiteness depends upon the difference in refractive indices. This mechanism is evident in the shells of many lamellibranch molluscs. Between the outer, often pigmented layer and the mantle, is a thick middle layer of crystalline calcium carbonate. The inner surface of this (nacreous) layer is lined with multiple laminations of the same salt. In most species these laminations are sufficiently thick (>1 μm) to render the inner lining white, although in some species they become thin so as to form a multilayer reflector. Calcium carbonate similarly produces whiteness in Foraminifera and in calcareous sponges, corals, echinoderms, and crustacean cuticles. Also, in the class of white solids is silica in diatom tests and skeletons of hexactinellid sponges.

Other forms of scattering also exist and result in a blue colored effect (red when the system is viewed in transmission). Tyndall or Mie scattering occurs in a colloidal system where the particle size approximates the wavelength of light. Here, diffraction is important. Rayleigh scattering occurs in molecules in a two-photon process by which a photon is absorbed and raises the molecule to an excited electronic state from which it re-radiates a photon when it returns to the ground state. Diffraction is not involved here.

Tyndall scattered light is polarized under obliquely incident light. The intensity of the resultant blue is increased when it is viewed against a dark background, such as melanin. The relative sizes of particles determine the shade of blue. If the particles responsible for the scattering coalesce to form particles with a diameter greater than about 1 μm, then white light is observed (see above). A gradation from blue to white scattering ('small' to 'large' particles) occurs on the wings of the dragonfly *Libellula pulchella*.

Scattered blues can also be found in other dragonflies. In the aeschnids and agrionids, the epidermal cells contain minute colorless granules and a dark base. The males of libellulids and agrionids produce a waxy secretion that scatters light similarly over their dark cuticle. The green of the female *Aeschna cyanea* is the combined result of Tyndall scattering and a yellow pigment, both within the epidermal cells (degradation of the yellow pigment turns the dead dragonfly blue).

Scattered blues are also observed from the skin of the cephalopod *Octopus bimaculatus*, where a pair of ocelli are surrounded by a broad blue ring. Blue light is scattered from this region as a result of fine granules of purine material within cells positioned above melanophore cells. The color and conspicuousness of the ring are controlled by the regulation of the melanophores, by varying the distribution of melanin

and consequently the density of the absorbing screen. The squid *Onychia caribbaea* can produce rapidly changing blue colors similarly. The bright blue patterns produced by some nudibranch molluscs result from reflecting cells containing small vesicular bodies, each composed of particles about 10 nm in diameter and therefore appropriate for Rayleigh scattering.

Microstructure Fibers

R S Windeler, OFS Laboratories, Murray Hill, NJ, USA

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Microstructure fibers have unique properties that cannot be obtained from traditional fibers (i.e. all glass, doped silica fibers) and can deliver functionalities superior to many of today's best transmission and specialty fibers. Their unique properties are obtained from an intricate cross-section of high and low index regions that traverse the length of the fiber. The vast majority of fibers consist of silica for the high-index region and air for the low-index region. These fibers are known by several different names including microstructure fiber, holey fiber, and photonic crystal fiber. The term microstructure fiber is used in this chapter because it is the most generic, encompassing all the fiber types.

Microstructure fiber properties vary greatly and are determined by the size and arrangement of air holes in the fiber. For example, fibers have been fabricated such that the numerical aperture of the core or cladding approaches one. They have been fabricated with unique dispersion profiles, such as a zero-group velocity dispersion in the near visible regime or an ultraflat dispersion over hundreds of nanometers wide. They have been fabricated to generate a super continuum over two octaves wide. Some guide light with an air core via bandgap guidance. In addition, the air holes in these microstructure fibers can be filled with highly tunable materials, giving one the capability of controlling the fiber properties for use in energy efficient devices.

Microstructure fibers can have doped regions like traditional fibers. These hybrid fibers combine the benefits of traditional and microstructure fibers. The doped core typically guides most of the light, but its guidance properties can be strongly influenced by the air regions. Applications for hybrid fibers include dispersion compensation, polarization maintaining, and bend insensitive fibers.

Loss is always an important factor when determining whether a microstructure fiber will compete with or replace a traditional optical fiber. The index profiles that make these fibers so special can also lead to fibers that have an inherently high loss at connections or along the length of the fiber. Loss at connections typically occurs due to mode mismatch between the two fibers, undesired hole collapse, or poor alignment. Loss along the fiber length can occur due to impurities, hole surface roughness, or poor confinement.

The dispersion profile (zero dispersion wavelength, dispersion slope, normal or anomalous) of microstructure fibers can be optimized more than a traditional fiber, because the hole size and placement

can be arranged to make the cladding index strongly wavelength dependent. Dispersion causes a pulse to spread because the phase velocity is wavelength dependent. Normal dispersion is when longer wavelengths travel faster than shorter wavelengths. Anomalous dispersion is just the opposite – shorter wavelengths travel faster than longer wavelengths. Dispersion determines the amount of interaction between different wavelengths. For applications such as transmission fiber, one wants little interaction and for high nonlinear applications, one wants significant interaction.

This chapter examines the methods for fabricating microstructure fibers and reviews the different types of microstructure fibers and their properties. Fibers that guide by total internal reflection are reviewed separately from bandgap guided fibers because their properties are significantly different. Lastly, a description and example of an active device is presented in which the air regions of a microstructure fiber are filled with controllable material.

Microstructure Fiber Fabrication

At first glance, fabrication of microstructure fibers looks similar to traditional fibers in that the fibers are fabricated in a two-step process. First a preform is fabricated and then it is drawn (stretched) into a fiber. However, when the process is examined in more detail, both the preform fabrication and draw depart significantly from traditional methods. First, a novel preform fabrication method is used to incorporate air holes that run the length of the preform. Second, novel drawing procedures are used to keep the air holes open as the preform diameter is reduced by several orders of magnitude during draw.

Preform Fabrication

Microstructure preforms are cylinders of amorphous material usually less than a few centimeters in diameter that have an index profile running the length of the preform similar to the desired fiber. The most common preform consists of air and a single material such as silica, polymer, or high nonlinear glass. These air-containing preforms are relatively easy to fabricate but are difficult to draw because the structures can deform.

The basic parameters of the fiber are usually determined by the geometry of the holes in the preform. These include hole diameter (d), hole position, pitch (center-to center hole spacing, Λ), core diameter (a), and number of layers. However, changes in the size and shape of the holes in the fiber can be made purposely or accidentally during draw, which will cause deviations between the fiber and preform profiles.

Several methods are used to fabricate microstructure preforms including stacking, casting, extrusion, and drilling. Each process has its advantages and disadvantages. By far, the most common method is stacking in which tubes, rods, and core rods (rods containing doped cores fabricated by traditional optical fiber techniques) are stacked in a close packed pattern such as a triangular or hexagonal lattice (Figure 1). The bundle of tubes and rods is then bound together with a large tube, called an overclad tube. Fibers can be made with complicated or asymmetric index profiles by strategically placing tubes with the same outer diameter (for good stacking) but a different inner diameter to change the index in that location. For example, a fiber with smaller holes on opposite sides of the core produces high birefringence.

The main advantages of stacking are that no special equipment is needed for fabricating microstructure preforms and that doped cores are easily added. However, there are several disadvantages. First, the stacking method is limited to simple geometries of air holes because the tubes are stacked in a close pack arrangement. Second, unless hexagonal tubes are used, interstitial areas are created between the tubes that may not be desired in the final fiber. Third, the method is labor intensive and requires significant glass handling.

A variation of the stacking method is used for fabricating air-clad fibers. Air-clad preforms are created by placing a layer of small tubes around the perimeter of a large core rod. The assembly is then overcladed for strength (Figure 2).

Extrusion and casting of glass powder, polymer, or sol–gel slurry are also used for making single material

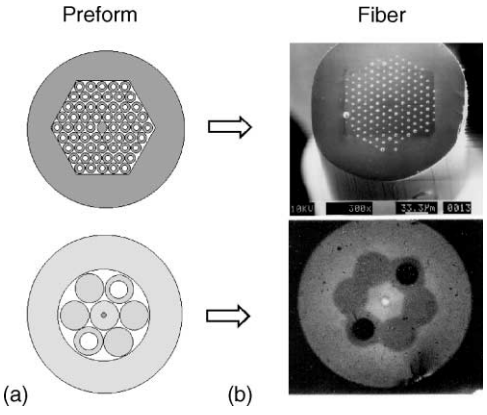

Figure 1 (a) Tubes, rods, and core rods are stacked together in a close packed arrangement and held together with an overclad tube. (b) During draw the desired air region stay open forming a microstructure fiber.

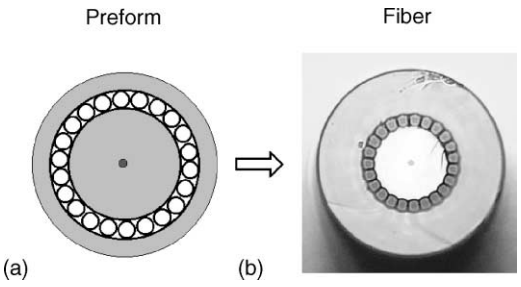

Figure 2 (a) An air-clad preform is fabricated by stacking a ring of small, thin walled tubes around a large core rod. (b) Photograph of the resulting fiber.

microstructure preforms. The main advantage of extrusion and casting is that complicated structures can be fabricated in which the position, size, and shape of the air regions are independent of one another. The disadvantage of this method is that preform fabrication is more difficult compared to the other fabricate methods. This method may become more common as complex air structures are needed to make advanced microstructure fibers.

The last method consists of drilling holes in a preform or rod. Drilling is well understood and used for other specialty fibers. The advantage of this method is that it is easy to drill holes of various sizes in any position in a preform, including doped regions. The disadvantages of drilling are that the holes cannot be drilled very deep compared to a traditional preform length; the distance between holes may be limited due to cracking; and the fiber may experience high loss due to surface roughness of the holes and impurities incorporated during drilling.

Fiber Draw

It is significantly more difficult to draw a microstructure preform with air holes than a traditional preform. This is because the air holes tend to close due to surface tension. This force can be overcome or minimized using two different techniques. The first is to draw the preform under very high tension (low temperature). Minimal hole collapse occurs when the draw tension is significantly larger than the surface tension. The problem with this method is that the break rate increases substantially at higher tension.

The second method is to apply an external pressure to the holes to counteract the surface tension. If a single pressure source is used, the holes can be made larger or smaller during draw by changing the pressure as needed. However, the process can become unstable because a large hole needs a lower pressure to maintain its size than a small hole. If holes of different sizes exist, a larger hole will grow at the expense of a smaller one regardless of the pressure used. To minimize the instability, this method is typically performed in conjunction with high-tension drawing.

To alleviate the draw problem, a second solid material can be used in the preform to obtain the desired index profile. With the air regions removed from the preform, the drawing process becomes significantly easier. In addition, when a preform consists of two solid materials, one of the materials does not have to be continuous, as in single material preforms. This allows for simpler designs such as concentric rings, which may be easier to fabricate and model (Figure 13c). The disadvantage of this approach is finding two materials that have compatible physical and chemical properties, have low loss, and have a large index of refraction difference.

Microstructure Fiber Types

Microstructure fibers are categorized by their method of guidance, properties, and function. Index guided microstructure fibers most closely resemble traditional fibers and are described first. These fibers guide light by total internal reflection and have a core index of refraction greater than the cladding. Bandgap fibers are examined next. The unique guidance of bandgap fibers allows the core index to be lower than the cladding index. Tunable microstructure fibers are described last. These microstructure fibers are filled with tunable materials so that the fiber's properties can be actively manipulated.

Index Guided Fibers

Most microstructure fibers guide light by total internal reflection. The size and spacing of air holes determine the guiding properties. For example, a solid silica core surrounded by a cladding consisting of small air holes that are spread apart creates a small core-to-cladding index difference similar to what can be achieved in traditional fibers. At the other extreme, a solid silica core surrounded by a cladding of large holes, which are closely spaced together, forms a large core-to-cladding index difference. This structure creates a large numerical aperture in the core and optically isolated regions within the fiber. The ability to create regions of significantly different indices in various parts of the fiber distinguishes the index guided microstructure fibers from traditional fiber. Different types of microstructure fiber are formed by varying the size, spacing and pattern of the air holes.

Different techniques are used to model these fibers, depending on spacing and size of the air holes relative to the wavelength of the guided light. If the hole diameter and spacing is much smaller than the

wavelength of the guided light, the cladding index can be modeled as an average index weighted by the volume fraction of the two materials (typically air and silica). As the hole diameter or spacing approaches the wavelength of the guided light, complicated models are used such as finite difference method, finite element method, beam propagation method, or multipole method.

Endlessly single-mode fiber

The endlessly single-mode fiber consists of a solid core surrounded by a two dimensional array of small air holes in the cladding (Figure 3). The size and position of the air holes are arranged such that only the fundamental mode exists in the core regardless of the wavelength of the guided light.

The prevention of higher order modes can be understood by examining the V number. The V number is a dimensionless parameter that describes the guiding nature of the waveguide. In traditional fiber, when the V number is less than 2.405, the fiber will guide only the fundamental mode. The V number is given by

$$V = \frac{2\pi a}{\lambda}(n_{\text{core}}^2 - n_{\text{clad}}^2)^{1/2} \qquad [1]$$

where a is the core diameter, λ is the wavelength of the guided light, and n_{core} and n_{clad} are the index of refractions of the core and cladding, respectively. In traditional fiber, the core and cladding index (n_{core} and n_{clad}) are for the most part constant, so the V number increases as the wavelength decreases.

However, for the endlessly single mode microstructure fiber, the V number does not increase indefinitely with decreasing wavelength, but approaches a constant value. Obtaining a V number independent of wavelength is understood by examining the distance the light propagates into the cladding as a function of wavelength. As the wavelength becomes shorter, light penetrates a shorter distance into the cladding, interacting with less of the air regions. This causes the effective cladding index (n_{clad}) to increase with decreasing wavelength, such that V approaches a constant value.

Microstructure fibers are made endlessly single-moded over all wavelengths by properly designing the hole diameter-to-pitch ratio (d/Λ). When the d/Λ is low enough, the microstructure fiber guides light only in the single mode regardless of wavelength and core size (Figure 4). However, these large core diameter fibers are limited by long wavelength bend loss in the same way as large core single mode traditional fibers.

High delta core fiber

High delta core microstructure fibers (HDCMF) consist of a small (typically less than 2 microns) solid silica core surrounded by one or more layers of large air holes closely spaced together (Figure 5). This creates a very large index difference between the core and cladding. A core-to-cladding index difference of 0.4 is easily achieved in a HDCMF, which is an order of magnitude larger than can be achieved with traditional fiber.

Even though the core is very small, these fibers are almost always multimoded due to the large index difference between the core and cladding. However, because of its small core, it is difficult to launch anything other than the fundamental mode into the fiber. Once a mode is guided in the fiber it remains in that mode due to the large difference in effective indices between modes (Figure 6). When higher-order modes are purposely generated in the fiber, they also

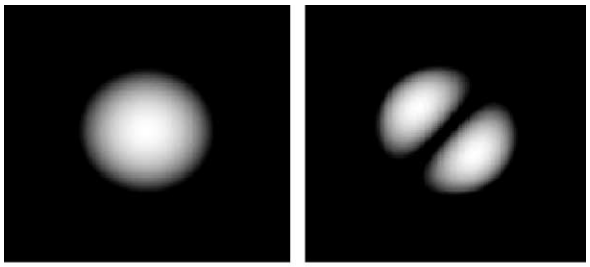

Figure 6 Individual modes do not couple well due to large differences in effective indices between modes. The figure shows the mode profile and effective index of the fundamental and the next higher mode for a fiber with a two-micron diameter core with a core-to-cladding index difference of 0.45 (Reprinted with permission from Ranka JK, Windeler RS and Stentz AJ (2000) Optical properties of high-delta air-silica microstructure optical fibers. *Optics Letters* 25: 796–798).

guide over long lengths without coupling to other modes (Figure 7). This strong guidance makes the fiber extremely bend insensitive.

HDCMF can have a unique dispersion profile because it can guide the fundamental mode exclusively in the multimode regime. This allows greater flexibility in controlling the shape of the dispersion profile, especially the ability to move the zero dispersion to shorter wavelengths. The HDCMF is the first silica fiber with anomalous dispersion of single-mode light below 1270 nm (the wavelength at which the material dispersion of silica is zero). These fibers are often made to have a zero-group velocity dispersions around 770 nm for use with Ti-sapphire lasers.

HDCMF is ideal for performing nonlinear experiments in the near-visible regime because the fiber's small, high-index core creates high intensity light, and the fiber's low dispersion creates long interaction times. For example, a broadband continuum can be generated over two octaves using less than a meter of HDCMF fiber (Figures 8 and 9).

Tapered microstructure fiber (TMF)

Coupling light in and out of HDCMF is difficult and results in a large loss due to its small core. When free space optics are used to couple the light, frequent realignment of the beam is required to minimize loss due to drifts in the equipment. Splicing HDCMF fiber to traditional fiber also results in high loss due to a large modal mismatch. These coupling problems are solved with tapered microstructure fibers.

Tapered microstructure fibers (TMF) consist of a traditional germanium single-mode core surrounded by a small silica cladding (Figure 10). The inner

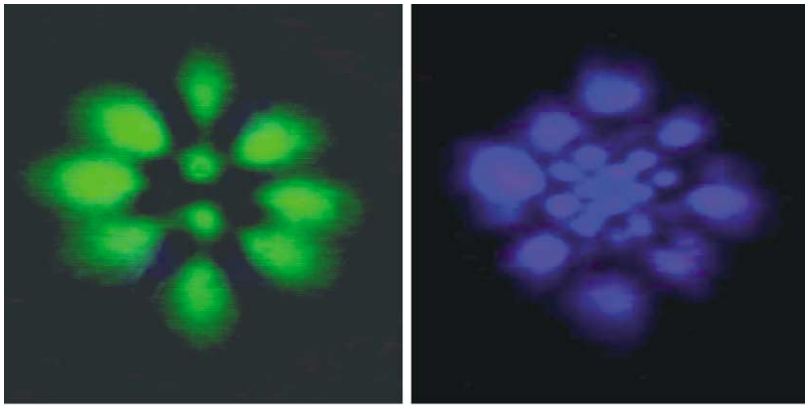

Figure 7 Far-field patterns show that higher order modes propagate long distances in the HDCMF without coupling to other modes (Reprinted with permission from Ranka JK, Windeler RS and Stentz AJ (2000) Optical properties of high-delta air-silica microstructure optical fibers. *Optics Letters* 25: 796–798).

cladding is surrounded by a layer of air holes and then a protective outer silica cladding for strength. Since the core of the TMF is very similar to a traditional single-mode fiber core, the splice loss is low. Splice losses below 0.075 dB are typical.

Properties similar to the HDCMF are obtained by adiabatically tapering the TMF while maintaining the cross-sectional profile of the fiber. In the taper region, the fundamental mode is no longer guided by the germanium core and evolves into the fundamental mode of the silica region, where it is confined by the ring of air holes. The taper waist is typically ten to twenty centimeters long and has properties identical to the HDCMF. When the fiber is adiabatically expanded back to its original size, the light is guided back into the standard diameter germanium core, making it easy to splice to traditional fiber with low loss.

The same effect can be obtained by stretching a traditional fiber from 125 microns down to 2 microns. However, there are several disadvantages compared to the tapered microstructure fiber. The taper region is much longer in the traditional fiber; the optimal diameter of the silica core is harder to maintain; the taper region must remain clean and uncoated; and the taper region is much weaker.

Air-clad fiber

Air-clad fibers consist of a doped core surrounded by a silica inner cladding. The inner cladding is surrounded by a ring of air, which in turn is surrounded by an outer silica cladding for strength (Figure 2). Thin silica webs connect the inner and outer claddings to hold the inner fiber region in place. The region consisting of air and thin silica webs creates an optical barrier, preventing most of the light from escaping the inner cladding. Such fibers are referred to as double clad fiber.

In traditional double-clad fibers, a material of lower index (typically another layer of glass or a layer of polymer) immediately surrounds the inner silica cladding. A key optical parameter describing the light guiding properties of the inner cladding is the numerical aperture (NA). The NA is defined as the sine of the largest (acceptance) angle of light that will be guided in the inner cladding. The upper NA values of traditional double-clad fibers (~0.22 and ~0.45 for glass and polymer outer claddings, respectively) are limited by the refractive indices of the available cladding materials.

For the air-clad fiber, the NA is determined by the ability of light to escape from the inner cladding through the silica webs. The NA of the air-clad fiber can be calculated by modeling the web as an infinitely long slab waveguide. As seen in Figure 11, the NA increases as the webs become thinner or the wavelength of light becomes longer. To obtain NA similar to what is achieved by coating a traditional fiber with a low index polymer (NA ~0.45), the web thickness must be about equal to the wavelength of the light. The NA of the air-clad fiber increases dramatically as the web thickness becomes less than half the wavelength of the guided light. Numerical apertures above 0.90 have been experimentally demonstrated.

The large NA values achievable with air-clad fibers are an important advantage for advanced double-clad

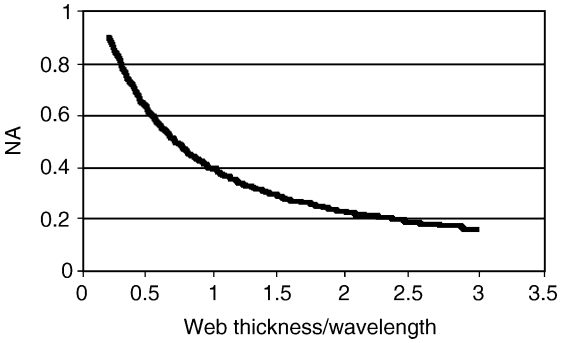

Figure 11 Predicted NA as a function of the web thickness divided by the wavelength using an infinite slab model.

amplifiers and lasers. A double-clad amplifier or laser (also known as cladding pumped amplifier or laser) contains a double-clad fiber with a rare earth doped core. High-power pump light, launched into and guided within the inner cladding, excites the rare earth ions as the pump light crosses through the core. The excited ions, which emit light with the same wavelength and phase as the signal, amplify the signal. The fiber's efficiency and the rare earth inversion level increase with the amount of pump light absorbed by the core. The light absorbed by the core, in turn, increases with the core-to-inner cladding area ratio and the pump light intensity in the inner cladding.

Traditional fibers have a practical limit to their core-to-cladding ratio. The maximum core diameter is limited by bend loss. And, while ultimately the minimum fiber diameter is limited by draw capabilities, in practice it is limited by the ability to couple pump light into a fiber having a limited inner-cladding NA. For a pump source of given brightness, the product of beam diameter and NA cannot be increased. Such light can be successfully coupled into a larger inner cladding with smaller NA or a smaller inner cladding with larger NA.

Air-clad fibers have other advantages over traditional double-clad fibers. The outer glass cladding in air-clad fibers is optically inactive. This allows the inner cladding diameter to be decoupled from the physical fiber diameter, eliminating draw-related constraints on minimum inner cladding size. Since only the inner cladding is optically active, its size can be optimized (made smaller) while keeping the total fiber diameter at the standard 125 microns. In addition, the pump light does not interact with the polymer coating, which can be important if the polymer properties are affected by the surroundings.

Bandgap Guided Fibers

Bandgap fibers guide light in the core (also referred to as a defect) by confining the light through constructive interference due to Bragg scattering (Figure 12). Unlike traditional fibers, this mechanism allows light to propagate in a core that has an index lower than the cladding. Bandgap fibers with an air core could theoretically be very low loss, propagate high powers, have a large effective area core, and

exhibit very low nonlinearities. In addition, the fibers can be used in novel devices by filling the core with special gasses or liquids for nonlinear processes.

Bandgap fibers can be generalized into three types (Figure 13). The first type of fiber has an air core surrounded by a cladding that consists of a periodic array of air holes in silica. Fibers of this type have been designed to guide a single mode and hold the greatest promise of guiding light over long distances with very low loss. The second type of bandgap fiber consists of a silica core and a silica cladding with a periodic array of holes which are filled with a high-index, tunable liquid. This design allows the bandgap properties to be tuned and is of interest for use in devices. The third fiber type consists of rings of alternating high- and low-index dielectric material with a center air core. They typically have a large, multimode core which is ideal for sending high powers. In addition, very little light is in the dielectric materials so the fiber can be designed to guide any wavelength with relatively little loss.

The spectrum of a bandgap fiber is quite different than an index guided fiber (Figure 14). Frequencies that lie within the bandgap cannot propagate in the cladding and are confined to the defect in the lattice (the core). Bandgap fibers with ideal geometry are predicted to have losses over an order of magnitude lower than can be obtained in an ideal traditional fiber. Although the loss of bandgap fibers has not been demonstrated to be less than traditional fiber at telecommunication wavelengths, bandgap fibers have been shown to have much lower loss than traditional fibers at other wavelengths.

Tunable Microstructure Fiber Devices

Unique tunable devices are made by filling the air holes of microstructure fibers with materials whose properties can be controlled actively (Figure 15). The materials can be positioned in the core or cladding to affect the corresponding modes. Most commonly, the index of refraction is changed using temperature sensitive liquids or polymers, although

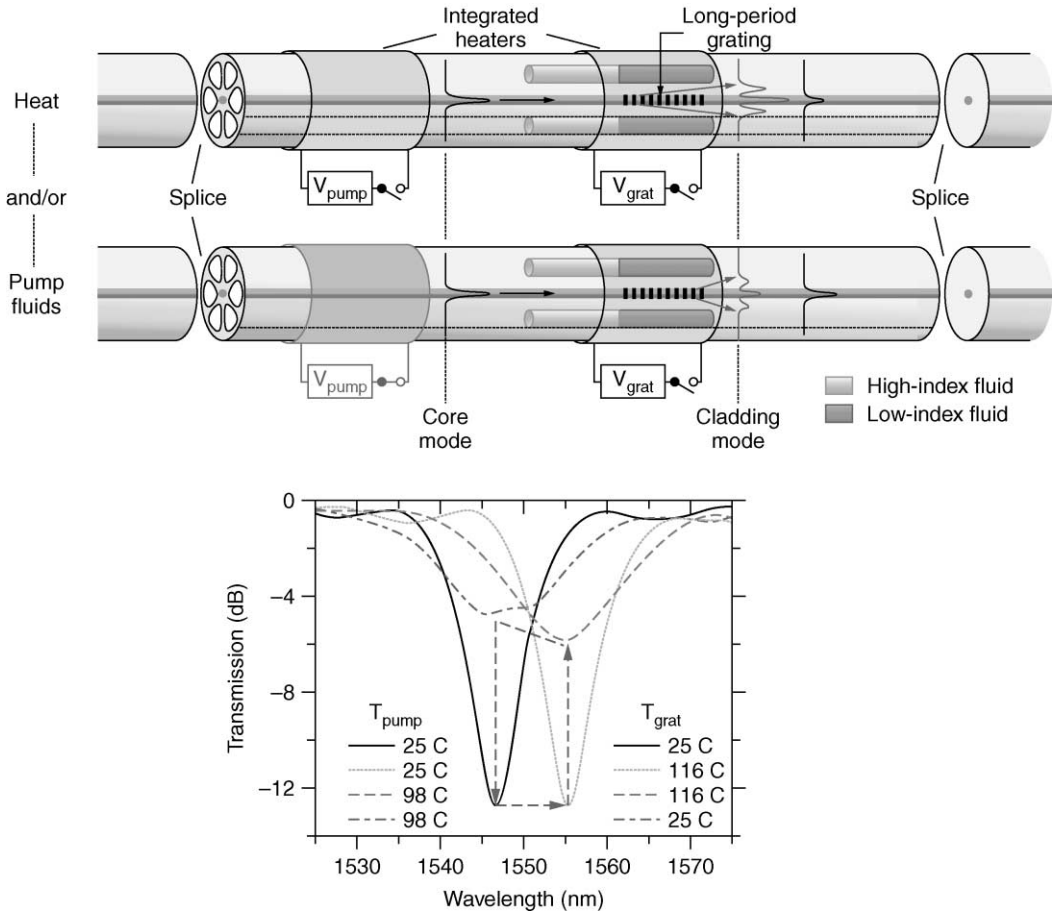

Figure 18 Schematic of a tunable device using both high and low index liquids with two heaters. The plot shows that the position and strength of the spectrum are adjusted independently (Reproduced with permission from Mach P, Dolinski M, Baldwin KW, Rogers JA, Kerbage C, Windeler RS and Eggleton BJ (2002) Tunable microfluidic optical fiber. *Applied Physics Letters* 80(23). Copyright (2002) by the American Physical Society).

materials that respond to electric or magnetic fields enable a quicker response time. These material-filled active fibers can be used to fabricate devices like tunable filters, switches, broadband attenuators, and fibers with tunable birefringence. Below, a few examples of tunable filters are presented in which the device properties depend on the type and position of the liquid inserted in the fiber holes.

A microstructure tunable filter works by controlling the spectral position, shape, or strength of a longitudinal long-period grating written in the fiber. A grating is written in the fiber before filling the holes with tunable liquid. The position of the peak absorption wavelength is controlled by placing a liquid, with an index close to silica and strongly temperature dependent, in air holes in the cladding region over the grating (**Figure 16**). The cladding index is tuned by varying the temperature of the liquid, using a small thin film heater located over the liquid. The position of the peak absorption wavelength moves as the cladding index is changed.

The strength or depth of the filter is controlled by inserting a moveable plug of high-index fluid in a sealed air section of a microstructure fiber (**Figure 17**). The strength of the grating is determined by the fraction of the grating surrounded by high index fluid. The position of the liquid plug relative to the grating can be finely adjusted with a thin film heater located over the air region adjacent to the material plug. As heat is applied to the air, the air expands and pushes the liquid plug over the grating, decreasing the coupling of the fundamental mode to higher order cladding modes. **Figure 18** shows an example in which the position and strength of a filter are varied independently using two heaters and two adjacent materials.

Omnidirectional Surfaces and Fibers

Omnidirectional Reflecting Mirrors

Mirrors are probably the most prevalent of optical devices. Known to the ancients and used by them as objects of worship and beauty, mirrors are currently employed for imaging, solar energy collection, and also in laser cavities. Their intriguing optical properties have captured the imagination of scientists as well as artists and writers.

One can distinguish between two types of mirrors, the age-old metallic, and the more recent multilayer dielectric. Metallic mirrors reflect light over a broad range of frequencies incident from arbitrary angles (i.e., omnidirectional reflectance). However, at infrared and optical frequencies a few percent of the incident power is typically lost due to absorption.

Multilayer dielectric mirrors are used primarily to reflect a narrow range of frequencies incident from a particular angle or particular angular range. Unlike their metallic counterparts, dielectric reflectors can be extremely low loss. The ability to reflect light of arbitrary angle of incidence for all-dielectric structures has been associated with the existence of a complete photonic bandgap, which can exist only in a system with a dielectric function that is periodic along three orthogonal directions. In fact, a sufficient condition for the achievement of omnidirectional reflection in a periodic system with an interface, is the existence of an overlapping bandgap regime in phase space above the light cone of the ambient media.

Consider a system that is constructed of alternating dielectric layers coupled to a homogeneous medium – characterized by n_0 (such as air with $n_0 = 1$), at the interfaces. Electromagnetic waves are incident upon the multilayer film from the homogeneous medium. While such a system was analyzed extensively in the literature the possibility of omnidirectional reflectivity was not recognized until recently.

The generic system is described by the index of refraction profile in Figure 1, where h_1 and h_2 are the layer thickness, and n_1 and n_2 are the indices of refraction of the respective layers. The incident wave has a wavevector $\vec{k} = k_x\hat{e}_x + k_y\hat{e}_y$, and frequency of $\omega = c|k|$. The wavevector together with the normal to the periodic structure defines a mirror plane of symmetry which allows us to distinguish between two independent electromagnetic modes: transverse electric (TE) modes and transverse magnetic (TM) modes. For the TE mode the electric field is perpendicular to the plane, as is the magnetic field for the TM mode.

General features of the transport properties of the finite structure can be understood when the properties of the infinite structure are elucidated. In a structure with an infinite number of layers, translational symmetry along the direction perpendicular to the layers leads to Bloch wave solutions of the form:

$$u_K(x, y) = E_K(y)\, e^{iKy}\, e^{ik_x x} \qquad [1]$$

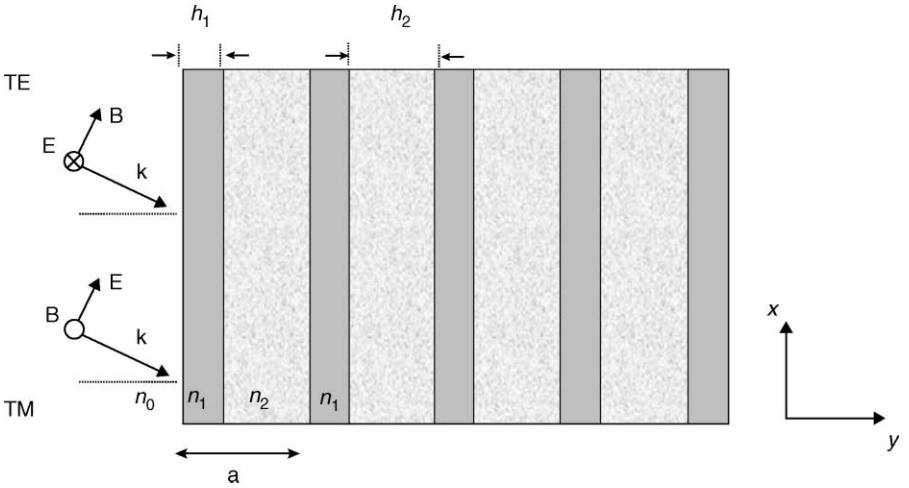

Figure 1 Schematic of the multilayer system showing the layer parameters (n_α, h_α – index of refraction and thickness of layer α), the incident wavevector $\vec{k}$ and the electromagnetic mode convention.

where $E_K(y)$ is periodic, with a period of length a, and K is the Bloch wave number. These waves represent solutions to an eigenvalue problem and are completely and uniquely defined by the specification of K, k_x and ω.

Solutions can be propagating or evanescent, corresponding to real or imaginary Bloch wave numbers, respectively. It is convenient to display the solutions of the infinite structure by projecting the $\omega(K, k_x)$ function onto the $\omega - k_x$ plane; Figure 2a,b are examples of such projected structures.

The gray background areas highlight phase space where K is strictly real, that is, regions of propagating states, while the white areas represent regions containing evanescent states. The shape of the projected bandstructures for the multilayer film can be understood intuitively. At $k_x = 0$, the bandgap for waves traveling normal to the layers is recovered. For $k_x > 0$, the bands curve upward in frequency. As $k_x \to \infty$, the modes become largely confined to the slabs with the high index of refraction and do not couple between layers (and are therefore independent of k_x).

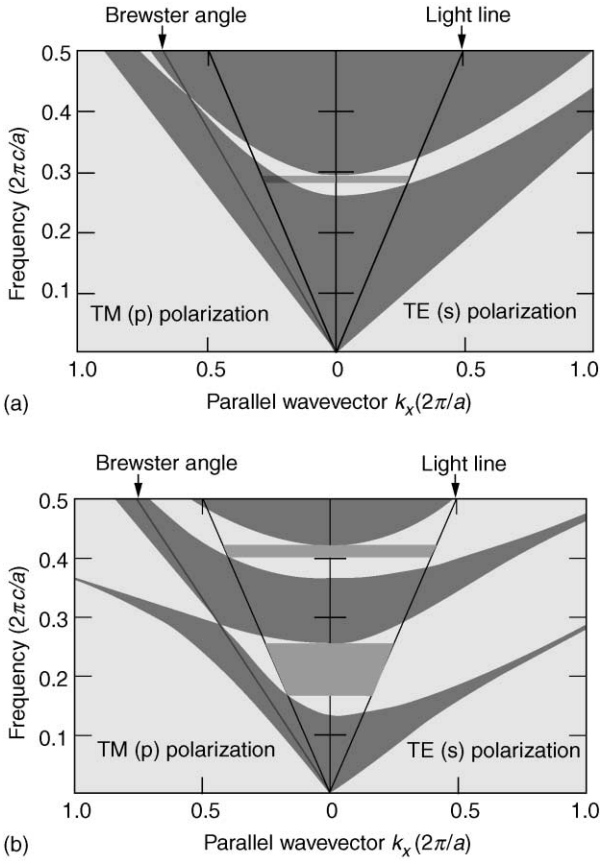

Figure 2 (a) Projected bandstructure of a multilayer film with the light line and Brewster line, exhibiting a reflectivity range of limited angular acceptance with ($n_1 = 2.2$ and $n_2 = 1.7$ and a thickness ratio of $h_2/h_1 = 2.2/1.7$). (b) Projected bandstructure of a multilayer film together with the light line and Brewster line, showing an omnidirectional reflectance range at the first and second harmonic (propagating states – dark gray, evanescent states – white, omnidirectional reflectance range – light grey). The film parameters are $n_1 = 4.6$ and $n_2 = 1.6$ with a thickness ratio of $h_2/h_1 = 1.6/0.8$. These parameters are similar to the actual polymer–tellurium film parameters measured in the experiment. Reproduced with permission from Fink Y, Winn JN, Fan S, *et al.* (1998) A dielectric omnidirectional reflector. *Science* 282: 1679–1682. Copyright 1998 American Association for the Advancement of Science.

In a finite structure, the translational symmetry in the directions parallel to the layers is preserved, hence k_x remains a conserved quantity and can be used to label solutions even though these solutions will no longer be of the Bloch form. The relevance of the band diagram to finite structures is that it allows for the prediction of regions of phase space where waves are evanescently decaying in the multilayer structure.

Since we are primarily interested in waves originating from the homogeneous medium external to the periodic structure, we will focus only on the portion of phase space lying above the light line. Waves originating from the homogeneous medium satisfy the condition $\omega \geq ck_x/n_0$, where n_0 is the refractive index of the homogeneous medium, and therefore they must reside above the light line. States of the homogeneous medium with $k_x = 0$ are normal incident, and those lying on the $\omega = ck_x/n_0$ line with $k_y = 0$ are incident at an angle of 90°.

The states in Figure 2a, that are lying in the restricted phase space defined by the light line and that have a (ω, k_x) corresponding to the propagating solutions (gray areas) of the crystal can propagate in both the homogeneous medium and in the structure. These waves will partially or entirely transmit through the film. Those with (ω, k_x) in the evanescent regions (white areas) can propagate in the homogeneous medium but will decay in the crystal – waves corresponding to this portion of phase space will be reflected off the structure.

The multilayer system leading to Figure 2a represents a structure with a limited reflectivity cone, since for any frequency one can always find a k_x vector for which a wave at that frequency can propagate in the crystal – and hence transmit through the film. The necessary and sufficient criterion for omnidirectional reflectivity at a given frequency is that there exists no transmitting state of the structure inside the light cone – this criterion is satisfied by frequency ranges marked in light gray in Figure 2b. In fact, the system leading to Figure 2b exhibits two omnidirectional reflectivity ranges.

The omnidirectional range is defined from above by the normal incidence bandedge $\omega_h(k_y = \pi/a, k_x = 0)$ (Figure 2b) and below by the intersection of the top of the TM allowed bandedge with the light line $\omega_l(k_y = \pi/a, k_x = \omega_l/c)$ (Figure 2b).

A dimensionless parameter used to quantify the extent of the omnidirectional range is the range to mid-range ratio defined as $(\omega_h - \omega_l)/\frac{1}{2}(\omega_h + \omega_l)$.

Figure 3 is a plot of this ratio as a function of n_2/n_1 and n_1/n_0, where ω_h and ω_l are determined by solutions of eqn [2] with quarter wave layer thickness. The contours in this figure represent various equi-omnidirectional ranges for different material index parameters and could be useful for design purposes.

At normal incidence, there is no distinction between TM and TE modes. At increasingly oblique angles, the gap of the TE mode increases, whereas the gap of the TM mode decreases. In addition, the center of the gap shifts to higher frequencies. Therefore, the criterion for the existence of omnidirectional reflectivity can be restated as the occurrence of a frequency overlap between the gap at normal incidence and the gap of the TM mode at 90°. Analytical expressions for the range to mid-range ratio can be obtained by setting:

$$\begin{aligned}\omega_h &= \frac{2c}{h_2 n_2 + h_1 n_1}\cos^{-1}\left(-\left|\frac{n_1 - n_2}{n_1 + n_2}\right|\right)\\ \omega_l &= \frac{2c}{h_2\sqrt{n_2^2 - 1} + h_1\sqrt{n_1^2 - 1}}\\ &\quad\times\cos^{-1}\left(\left|\frac{n_1^2\sqrt{n_2^2 - 1} - n_2^2\sqrt{n_1^2 - 1}}{n_1^2\sqrt{n_2^2 - 1} + n_2^2\sqrt{n_1^2 - 1}}\right|\right)\end{aligned} \quad [2]$$

Moreover, the maximum range width is attained for thickness values that are not equal to the quarter wave stack though the increase in bandwidth gained by deviating from the quarter wave stack is typically only a few percent.

In general, the TM mode defines the lower frequency edge of the omnidirectional range; an example can be seen in Figure 2b for a particular choice of the indices of refraction. This can be proven by showing that:

$$\left.\frac{\partial\omega}{\partial k_y}\right|_{TM} \geq \left.\frac{\partial\omega}{\partial k_y}\right|_{TE} \quad [3]$$

in the region that resides inside the light line. The physical reason for eqn [3] lies in the vectorial nature of the electric field. In the upper portion of the first band the electric field concentrates its energy in the high dielectric regions. Away from normal incidence, the electric field in the TM mode has a component in the direction of periodicity, this component forces a larger portion of the electric field into the low dielectric regions. The group velocity of the TM mode is therefore enhanced. In contrast, the electric field of the TE mode is always perpendicular to the direction of periodicity and can concentrate its energy primarily in the high dielectric region. While the omnidirectional reflection criteria can be used to confine light in various geometries, it is the cylindrical fiber configuration that appears to present significant application opportunities.

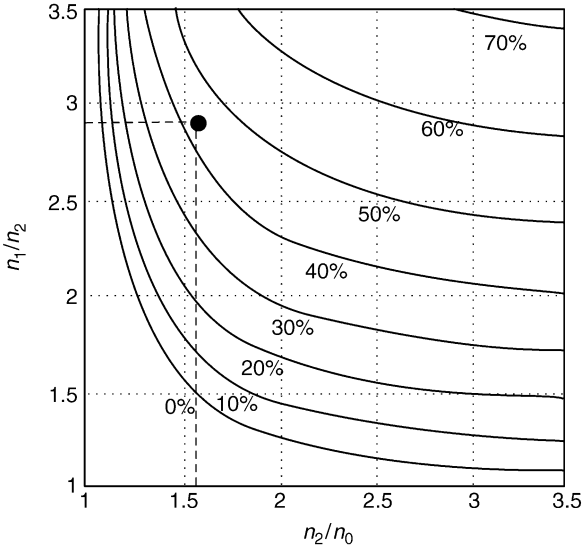

Figure 3 The range to mid-range ratio $(\omega_h - \omega_l)/\frac{1}{2}(\omega_h + \omega_l)$, for the fundamental frequency range of omnidirectional reflection, plotted as contours. Here, the layers were set to quarter wave thickness and $n_1 > n_2$. The ratio for our materials is approximately 45%. ($n_1/n_2 = 2.875$, $n_2/n_0 = 1.6$) is located at the intersection of the dashed lines (black dot). Mesostructured Fibers for External Reflection Applications

Polymer fibers are ubiquitous in applications such as textile fabrics, due to their excellent mechanical properties and the availability of low-cost, high-volume processing techniques; however, the control over their optical properties has so far remained relatively limited. Conversely, dielectric mirrors are used to precisely control and manipulate light in high performance optical applications, but the fabrication of these typically fragile mirrors has been mostly restricted to planar geometries and typically involves multiplicity of deposition sequences in a high vacuum thin film deposition system.

Fabrication Approach

The fabrication of extended lengths of omnidirectionally reflecting fibers with large bandgaps and

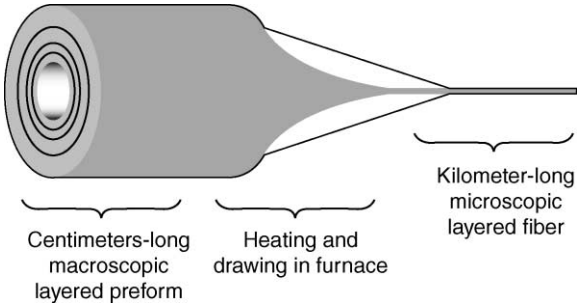

Figure 4 Conceptual preform based fabrication process for meso-structured fibers.

high layer counts poses considerable challenges. To illustrate the nature of this formidable task, one needs to consider the necessity of maintaining the uniformity of sub-100 nm layer thicknesses over kilometer-length scales; creating continuous layers with an aspect ratio of $\sim 10^{10}$ in a single process! To meet this and other challenges associated with the fabrication of mesostructured fibers, we have developed a preform-based fabrication approach (Figure 4). A scaled-up version of the final fiber, called a preform, is fabricated which shares the geometry and materials of the final fiber but exhibits macroscopic lateral features. The preform is heated up and drawn under tension into the fiber using a simple cylindrical furnace. The macroscopic layers are reduced in the process to microscopic dimensions while maintaining the overall geometry and symmetry of the original preform. Conservation of mass determines the final length of the fiber – typically this length is equal to the lateral reduction factor squared multiplied by the length of the preform. The nature of the process and requirements on the fiber's optical properties lead to the definition of materials selection rules. First, in order to achieve omnidirectional reflectivity, one needs to identify two solid materials exhibiting an index contrast given by the plot in Figure 3. Second, to enable the codrawing of the two dissimilar materials both will need to have viscosities that are lower than $\sim 10^8$ poise at the drawing temperature. In order to maintain high draw speeds, the majority component needs to be amorphous and the adhesion between these two materials needs to be sufficient to prevent delamination. Finally, their thermal expansion coefficients need to be close or alternatively at least one of the materials needs to be capable of relieving the stress due to CTE mismatch.

Materials Selection Criteria

Pairs of materials that are compatible with the process and fiber property requirements have been

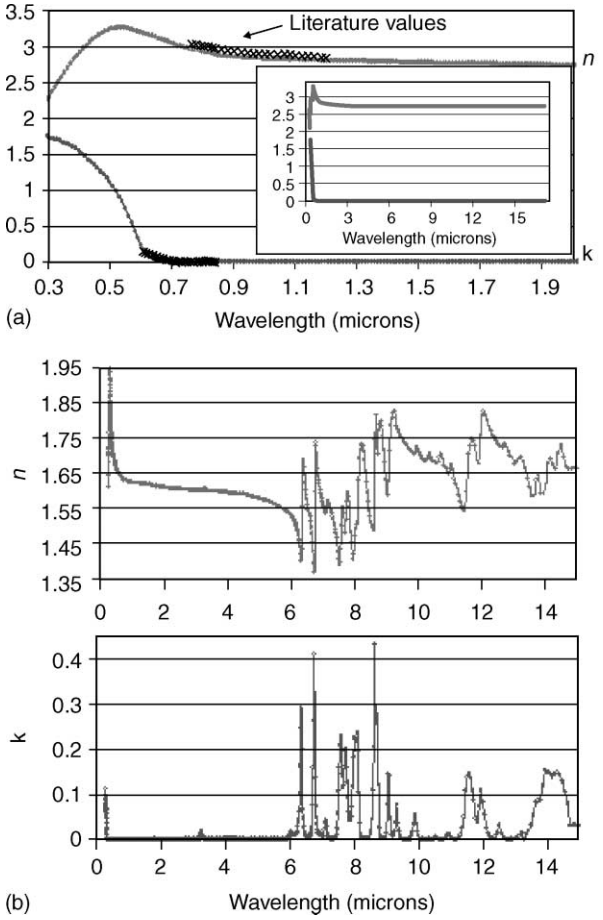

Figure 5 (a) Real part (n – light gray) and imaginary part (k – dark gray) of the refractive index of annealed As_2Se_3. The black crosses correspond to literature values. (b) Real part (n – upper) and imaginary part (k – lower) of the refractive index of PES.

identified, including: high glass transition temperature (T_g), thermoplastic polymers such as poly(ether-sulfone) (PES), poly (ether-imide) (PEI) and members of the chalcogenide glass family, such as arsenic triselenide (As_2Se_3) or arsenic trisulfide. Pairs of these materials will have substantially different refractive indices, as shown in Figure 5, which is a measurement of the real and imaginary indices of refraction of PES and As_2Se_3, obtained using a broadband spectroscopic ellipsometer (SOPRA GES5). They nevertheless exhibit similar thermomechanical properties within a certain thermal processing window.

Adhesion and extensional viscosity in the fluid state are difficult to measure in general, and the measurement of high-temperature surface tension is quite involved. Thus, limited data on these properties are available and it was necessary to empirically identify materials that could be used to draw out mirror-fibers. Various high-index chalcogenide (S, Se, and Te containing) glasses and low-index polymers were

identified as potential candidates based on their optical properties and overlapping thermal softening regimes. Adhesion and viscosity matching were tested by thermal evaporation of a chalcogenide glass layer on top of a polymer film or rod and elongation of the coated substrate at elevated temperatures. The choice of a high-temperature polymer, PES, and a simple chalcogenide glass, As_2Se_3, resulted in excellent thermal co-deformation without film cracking or delamination. Approximate matching of extensional viscosity in this manner was also demonstrated using As_2Se_3 and PEI. The properties, processing, and applications of chalcogenide glasses have been explored extensively elsewhere. One advantage in choosing As_2Se_3 for this application is that not only is it a stable glass, but it is a stoichiometric compound that can be readily deposited in thin films through thermal evaporation or sputtering without dissociation. Additionally, As_2Se_3 is transparent to IR radiation from approximately 0.8 to 17 μm as shown in the ellipsometric data (Figure 5a), and has a refractive index of ~2.8 in the mid-IR. PES is a high-performance, dimensionally stable thermoplastic with a refractive index of ~1.6 and good transparency to EM waves in a range extending from the visible regime into the mid-IR (~5 μm), as shown in Figure 5b.

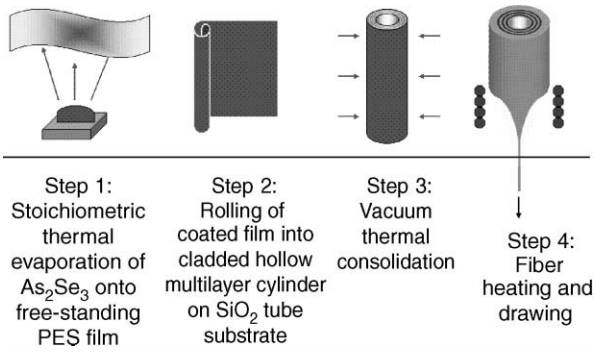

Figure 6 Multilayer preform fabrication sequence.

Preform Construction Process and Fiber Draw

The selected materials were used to construct a multilayer preform rod, which essentially is a macroscale version of the final fiber. In order to fabricate the dielectric mirror fiber preform, an As_2Se_3 film was deposited through thermal evaporation on either side of a free-standing PES film which was then rolled on top of a PES tube substrate, forming a structure having 21 alternating layers of PES and As_2Se_3, as shown in Figure 6.

The resulting multilayer fiber preform was subsequently drawn down using an optical fiber draw tower into hundreds of meters of multilayer fiber with a precisely controlled submicron layer thickness, creating a photonic bandgap in the mid-IR. Fibers of outer diameters varying from 175–500 μm with a typical standard deviation of 10 μm from target, were drawn from the same preform to demonstrate adjustment of the reflectivity spectra through thermal deformation. The spectral position of the photonic bandgap was controlled by the optical monitoring of the outer diameter (OD) of the fiber during draw, which was later verified by reflectivity measurements on single and multiple fibers of different diameters. Scanning electron micrographs (SEMs) of the cross-section of these fibers are depicted in Figure 7.

Bandstructure for Multilayer Fibers for External Reflection Applications

In theoretically predicting the spectral response of these fibers, it is helpful to calculate the photonic

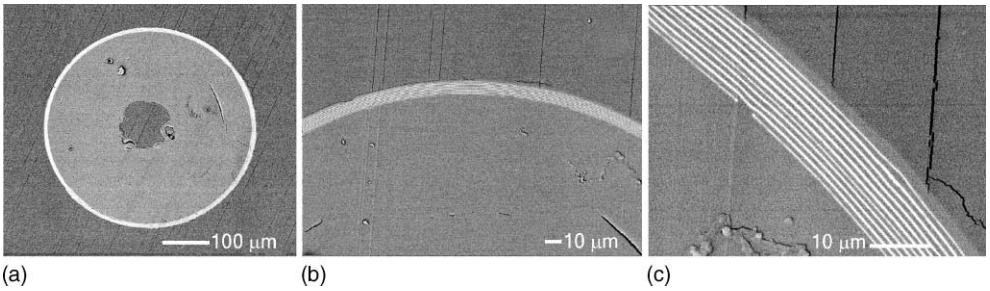

Figure 7 SEM micrographs of 400 μm OD fiber cross-section. The entire fiber is embedded in epoxy. (a) shows the entire fiber cross-section, with mirror structure surrounding the PES core; (b) demonstrates that the majority of the fiber exterior is free of significant defects and that the mirror structure adheres well to the fiber substrate; and (c) reveals the ordering and adhesion within the alternating layers of As_2Se_3 (bright layers) and PES. Stresses developed during sectioning caused some cracks in the mounting epoxy that are deflected at the fiber interface. Fibers from this batch were used in the reflectivity measurements recorded below in Figure 9a. Figure 8 Photonic band diagram for a one-dimensional photonic crystal having a periodic refractive index alternating between 2.8 and 1.55. Gray regions represent propagating modes within the structure, while white regions represent evanescent modes. Hatched regions represent photonic bandgaps where high reflectivity can be expected for external EM waves over an angular range extending from normal to 35° incidence. The lower dark shaded trapezoid represents a region of external omnidirectional reflection.

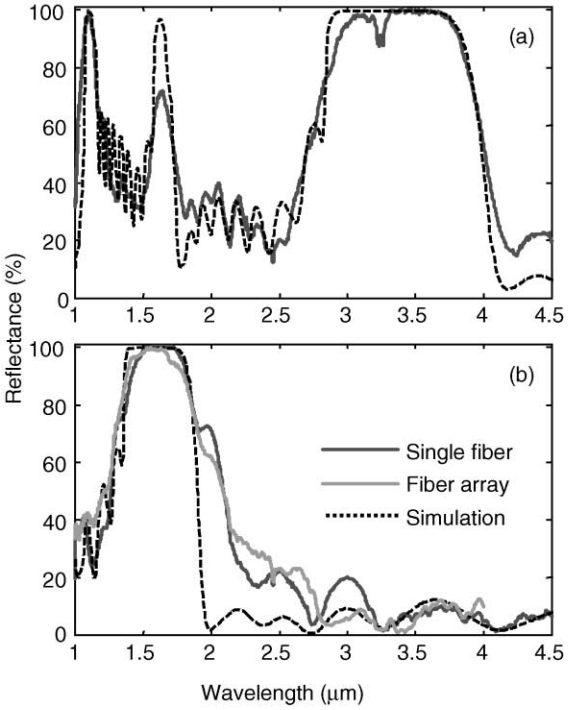

Figure 9 Measured reflectance spectra for 400 μm OD (a) and 200 μm OD (b) dielectric mirror fibers relative to gold-coated fibers of the same diameter. (a) shows a single-fiber reflectivity measurement, while (b) compares single-fiber reflectivity to that measured from a multifiber array. Simulations were performed using the transfer matrix method.

bandstructure that corresponds to an infinite one-dimensional photonic crystal. This allows for the analysis of propagating and evanescent modes in the structure, corresponding to real or imaginary Bloch wave number solutions.

The electric or magnetic field vector is parallel to the mirror layer interfaces for the TE and TM polarized modes, respectively. The parallel wavevector (k_y) is the component of the incident electromagnetic (EM) wavevector that is parallel to the layer interfaces. The phase space accessible from an external ambient medium is contained between the light lines (defined by the glancing-angle condition $\omega = ck_y/n_0$), and the modes between the 35° lines correspond to those sampled experimentally. Axes are normalized to the thickness a of one mirror bilayer (a period consisting of one high- and one low-index layer). Figure 8 depicts the photonic band diagram for an infinite structure having similar periodicity and refractive indices to the mirror structures fabricated here. Three photonic bandgaps are present where high reflectivity is expected within the 0–35° angular range, and the fundamental gap contains a region of external omnidirectional reflectivity.

Optical Characterization of 'Mirror Fibers'

Mirror fiber reflectivity was measured from both single fibers and parallel fiber arrays using a Nicolet/SpectraTech NicPlan Infrared Microscope and Fourier Transform Infrared Spectrometer (Magna 860). The microscope objective (SpectraTech 15×, Reflachromat) used to focus on the fibers had a numerical aperture (NA) of 0.58. This results in a detected cone where the angle of reflection with respect to the surface normal of the structure could vary from normal incidence to ~35°, which is determined by the NA of the microscope objective. As a background reference for the reflection measurements, we used gold-coated PES fibers of matching diameters. Dielectric mirror fibers, drawn to 400 μm OD, exhibited a very strong reflection band centered at 3.4 μm wavelength (Figure 9a). Measured reflectivity spectra agree well with planar-mirror transfer matrix method (TMM) simulations, where the reflectivity was averaged across the aforementioned angular range for both polarization modes. Fibers drawn down to 200 μm OD show a similar strong fundamental reflection band centered near 1.7 μm (Figure 9b). This shifting of the primary photonic bandgap clearly illustrates the precise tuning of the reflectivity spectra over wide frequency ranges through thermal deformation processing. Strong optical signatures are measurable from single fibers as small as 200 μm OD. Fiber array measurements,

simultaneously sampling reflected light from multiple fibers, agree quite well with single-fiber data (Figure 9b).

These reflectivity results are strongly indicative of uniform layer thickness control, good interlayer adhesion, and low interdiffusion through multiple thermal treatments. This was confirmed by SEM inspection of fiber cross-sections (Figure 7). The layer thicknesses observed ($a = 0.90$ μm for the 400 μm fibers; $a = 0.45$ μm for the 200 μm fibers) correspond well to the measured reflectivity spectra. The fibers have a hole in the center, due to the choice of a hollow rod as the preform substrate, which experienced some nonuniform deformation during draw. The rolled-up mirror structure included a double outer layer of PES for mechanical protection, creating a noticeable absorption peak in the reflectivity spectrum at ~3.2 μm (Figure 9a).

A combination of spectral and direct imaging data demonstrates excellent agreement with the photonic band diagram. The measured gap width (range to mid-range ratio) of the fundamental gap for the 400 μm OD fiber is 27%, compared to 29% in the photonic band diagram.

Tunable 'Fabry–Perot' Fibers

The fabrication of fibers surrounded by or lined with alternating layers of materials with a large disparity in their refractive indices, presents interesting opportunities for passive and active optical devices. While a periodic multilayer structure, such as the one reported above, leads to the formation of photonic bandgaps and an associated range of high reflectivity, it is the incorporation of intentional deviations from periodicity, also called 'defects', which allows for the creation of localized electromagnetic modes in the vicinity of the defect. These structures, sometimes called optical cavities, in turn can provide the basis for a large number of interesting passive and active optical devices such as vertical cavity surface emitting lasers (VCSELs), bi-stable switches, tuneable dispersion compensators, tuneable drop filters, etc. Here we report on the fabrication of a fiber surrounded by a Fabry–Perot cavity structure and demonstrate that by application of axial mechanical stress, the spectral position of the resonant Fabry–Perot mode can be reversibly tuned.

Structure and Optical Properties of the Fabry–Perot Fibers

The fabrication technique described above allows for the accurate placement of optical cavities that can encompass the entire or partial fiber circumference. The fibers discussed above are made of As_2Se_3 and PES and have a low index Fabry–Perot cavity (Figure 10).

This structure was achieved by introducing an extra polymer layer in the middle of the periodic multilayer structure of the preform, thus generating a defect mode in the photonic bandgaps of the drawn fibers. The position of the bandgap center is linearly related to the optical thickness of the layers by the Bragg condition. Through accurate outer diameter control afforded by the laser micrometer mounted on the draw tower we have been able to place gaps (Figure 11) at wavelengths ranging from 11 microns to below 1 micron. Such cost-effective tuneable optical filters could lead to applications such as optical

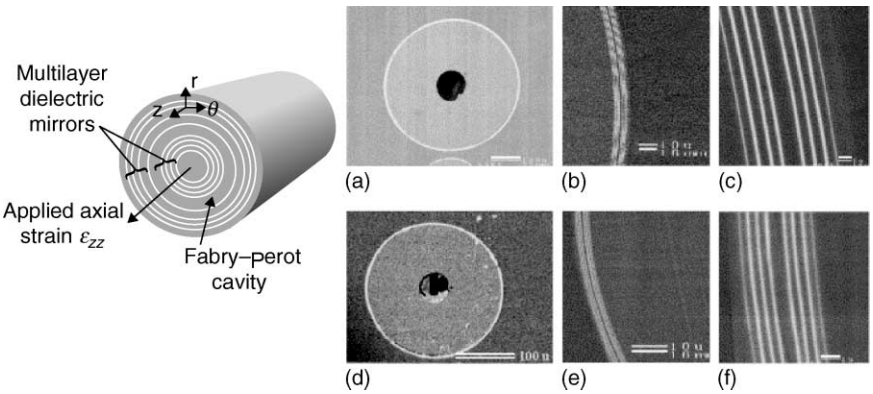

Figure 10 Schematic of the structure of dielectric mirror fibers made of As_2Se_3 (light gray) and PES (dark gray) with low index Fabry–Perot cavity. The local cylindrical coordinate system is represented as well as the applied axial strain ε_{zz}. Typical radii are ~150 μm ± 100 μm. Backscattered SEM micrographs of the cross-sections of a 460 micron diameter fiber (a, b, c) and of a 240 micron diameter fiber (d, e, f) embedded in epoxy and microtomed. (a) and (d) show the entire cross-section of the fibers, (b) and (e) demonstrate long-range layer uniformity, and (c) and (f) reveal the ordering and adhesion of the Fabry–Perot cavity structure. Bar scales have been redrawn for clarity. switches for wavelength-division-multiplexing (WDM) systems and sensors.

The cross-sectional structures of a 240 micron and a 460 micron diameter fiber were observed by an SEM using a backscattered electron detector (Figure 10). The structure is composed of a hollow core polymer rod surrounded by six bilayers of As_2Se_3 and PES, separated in the middle by an extra polymer layer, which forms the Fabry–Perot cavity. An extra polymer layer protects the fiber surface. For the 240 micron (460 micron) diameter fiber, the glass layers are ~135 nm (250 nm) thick, except for the first and the last ones which are half as thick due to the fabrication technique; the polymer layers are ~270 nm (540 nm) thick and the defect layer is ~610 nm (1170 nm) thick.

Reflectivity spectra measurements were performed under a microscope using a (Nicolet SpectraTech NicPlan) Infrared Microscope and Fourier Transform Infrared Spectrometer (Magna 860) with a lens numerical aperture (NA) corresponding to 30 degrees of angular spread. They exhibited a single-mode Fabry–Perot resonant mode at 1.74 and 3.2 μm for the 240 and 460 micron diameter fiber, respectively (Figure 12).

Because of the range of incident angles, the measured quality factor (Q-factor, defined as its spectral position divided by the full width half maximum (FWHM)) was equal to 31. Using the different thicknesses and the real and imaginary part of the refractive index ($n \& k$) of As_2Se_3 and PES carefully measured with a broadband (300 nm to 16 microns) spectroscopic ellipsometer (Sopra GES-5), the reflectivity spectra of these fibers were computed with the TMM by approximating them as a one-dimensional planar stacking. By averaging the calculated spectra over the accessible incident angles

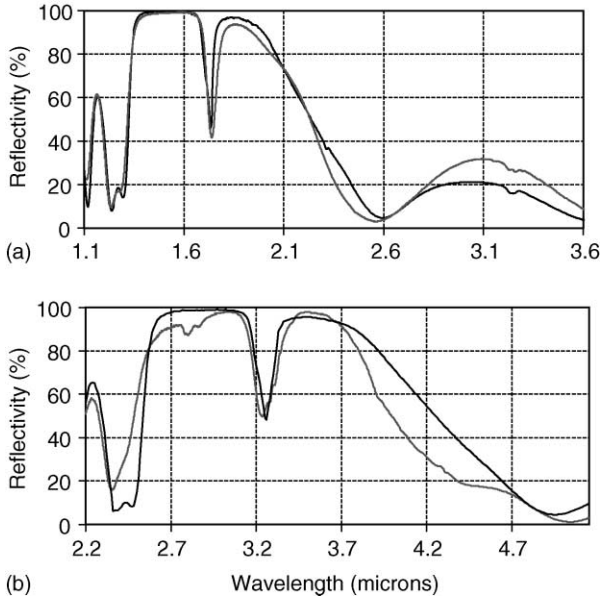

Figure 12 Computed (black lines) and measured (grey lines) reflectivity spectra for the 240 micron (a) and of the 460 micron diameter fibers (b) with Fabry–Perot resonant modes at 1.74 and 3.2 μm, respectively. Reproduced with permission from Benoit G, *et al.* (2003) Static and dynamic properties of optical cavities in photonic bandgap gains. *Advanced Materials* 15: 2053–2056.

and polarizations, we obtained a very good agreement between the simulation and the measurements.

Simulation of the Opto-Mechanical Behavior of the Fabry–Perot Fibers

We focused our analysis on the elastic regime, which ultimately limits the operational range of these fibers. The fiber's Young's modulus (E) can be approximated by modeling this multilayer structure as independent parallel springs under axial (along the z-axis of the fiber) strain assumed to be equal for all the layers, leading to a Young's modulus of 2.64 GPa (using $E_{PES} = 2.4$ GPa for bulk PES and $E_{As_2Se_3} = 15$ GPa reported for 1.5 μm thick films).

Neglecting the possible strain-induced refractive index variation of the materials, the normalized shift of the Fabry–Perot resonant mode can be related to the applied axial strain by calculating the radial stresses σ_{rr} (resulting from the difference between the Poisson ratios of the materials – $\nu_{PES} = 0.45$ and $\nu_{As_2Se_3} = 0.289$ – and the adhesion condition between the layers) and displacements u_r in each layer under axial strain. Starting from the equilibrium equations:

$$\frac{\partial \sigma_{zz}}{\partial z} = 0 \qquad [4]$$

$$\frac{\partial \sigma_{rr}}{\partial r} + \frac{\sigma_{rr} - \sigma_{\theta\theta}}{r} = 0 \Leftrightarrow \frac{d^2 u_r}{d^2 r} + \frac{1}{r}\frac{du_r}{dr} - \frac{u_r}{r^2} = 0 \qquad [5]$$

and using Hooke's law and Lame's equations, we can derive a general expression for u_r and σ_{rr}, with two unknowns A and B per layer:

$$u_r = \frac{A}{r} + Br \qquad [6]$$

$$\sigma_{rr} = -\frac{2GA}{r^2} + 2(\eta + G)B + \lambda\varepsilon_{zz} \qquad [7]$$

where $G = E/[2(1+\nu)]$ is the shear modulus and $\eta = E\nu/[(1+\nu)(1-2\nu)]$ the Lame modulus. The continuity of the displacement and the radial stress at each interface, plus the boundary conditions (σ_{rr} vanishes at free surfaces) can be expressed as a linear system whose unique solution allows us to relate the radial strain in each layer to the applied axial strain as a linear relation $\varepsilon_{rr} = C\varepsilon_{zz}$, where C can be interpreted as an effective Poisson ratio. Finally, taking into account that the Fabry–Perot resonant mode itself is linearly shifted within the bandgap because of the different effective Poisson ratios of the glass and polymer layers, we obtain a linear relation between the normalized shift of the Fabry–Perot resonant mode and the applied axial strain:

$$\frac{\Delta\lambda}{\lambda} = -0.373\varepsilon_{zz} \qquad [8]$$

All the layers (except the outer protective polymer layer) are under tensile radial stress whose maximum (0.22 MPa under 1% axial strain) is located at the interface between the layers and the polymer core where delamination is most likely to occur.

Mechanical Tuning Experiment and Discussion

Measurements were performed on fibers ~30 cm long, which were fixed at one end with epoxy to a load cell (Transducer Techniques MDB-2.5) while the other end was attached with strong tape to a pole mounted on a stepper rotational stage (Newport PR50) (Figure 13). This end of the fiber was also screwed to the pole to further secure it in place.

The diameter of the pole was equal to 2.1 cm, leading to a normalized shift precision below 0.005%. The uncertainty on the Young's modulus, due to the precision of the load cell, was lower than 30 MPa. All the reflectivity spectra were normalized to a background taken with a flat gold mirror. The measurements were realized as far as possible from the fixed ends of the fiber where edge effects are likely to occur. These edge effects result in a reduction of the length of the fiber that deforms uniformly and consequently increase the real strain far from the edges by a factor of 1.14 and 1.15 for the 240 and the 460 micron diameter fiber, respectively (determined experimentally by measuring the position of two reference points on the fiber) compared to the strain calculated from the rotation of the pole. Moreover, to avoid measuring slight variations in the spectral position of the bandgap resulting from outer diameter variations, typically of the order of 4–5 microns over meters of fibers, the measurements were realized at a fixed reference position on the fiber.

By focusing on the fundamental bandgap of the 240 and the 460 micron diameter fiber, we demonstrated the tuning of the Fabry–Perot resonant mode under increasing axial strain (Figure 14).

A drop in the reflectivity of 13% was observed at 1.71 μm (dash line) for the 240 micron diameter fiber when increasing the applied axial strain from 0.23% (light gray) to 1.07% (dark gray). The normalized-shift versus strain curves (Figure 15) appeared to be linear for both fibers up to approximately 0.9% (dash line) with a slope equal to −0.3859 and −0.3843 for the 240 and the 460 micron diameter fiber, respectively, close to the predicted value (−0.373, eqn [8]).

The normalized shift was equal to −0.347% for 0.9% applied axial strain, which seems to be the limit of the elastic regime and corresponds to small applied

loads: 76 and 300 g for the 240 and 460 micron diameter fiber, respectively. Under higher strains, the normalized-shift versus strain curves were no longer linear and the measured loads would start decreasing slightly with time, which could be a sign of delamination between the layers and the polymer core, of plastic deformation and/or of relaxation in the layers. The stress–strain curves also exhibit an elastic regime up to approximately 1% strain with a corresponding Young's modulus equal to 2.59 GPa for the 240 μm OD fiber and to 2.39 GPa for the 460 μm OD fiber. These values are slightly lower than the predicted value, possibly due to relaxation effects in the polymer and the glass layers (for As_2Se_3 and PES, $T_g = 175$ and 220 °C, respectively).

Wavelength-Scalable Hollow Optical Fibers with Large Photonic Bandgaps for CO_2 Laser Transmission

Hollow optical transmission fibers offer the potential to circumvent fundamental limitations associated with conventional index guided fibers and thus have been the subject of active research in recent years. Here we report on the materials selection, design, fabrication, and characterization of extended lengths of hollow optical fiber lined with an interior omnidirectional dielectric mirror. These fibers consist of a hollow air core surrounded by multiple alternating submicron-thick layers of a high-refractive-index glass and a low-index polymer, resulting in large infrared photonic bandgaps. These gaps provide strong confinement of optical energy in the hollow fiber core and lead to light guidance in the fundamental and up to fourth-order gaps. We show that the fiber transmission windows can be scaled over a large wavelength range covering at least 0.75 to 10.6 microns. The utility of our approach is further demonstrated by the design and fabrication of tens of meters of hollow photonic bandgap fibers for 10.6 micron radiation transmission. We demonstrate transmission of carbon dioxide (CO_2) laser light with high power-density through more than 4 meters of hollow fiber and measure the losses to be less than 1.0 dB/m at 10.6 microns. This establishes suppression of fiber waveguide losses by orders of magnitude compared to the intrinsic fiber material losses.

Silica optical fibers have been extremely successful in telecommunications applications, and other types of solid-core fibers have been explored at wavelengths where silica is not transparent. However, all fibers that rely on light propagation principally through a solid material have certain fundamental limitations stemming from nonlinear effects, light absorption by electrons or phonons, material dispersion, and Rayleigh scattering that limit maximum optical transmission power and increase attenuation losses. These limitations have, in turn, motivated the study of a fundamentally different light-guiding methodology: the use of hollow waveguides having highly reflecting walls. Light propagation through air in a hollow fiber eliminates or greatly reduces the problems of nonlinearities, thermal lensing, and end-reflections, facilitating high-power laser guidance and other applications which may be impossible using conventional fibers. Hollow metallic or metallo-dielectric waveguides have been studied fairly extensively and found useful practical application, but their performance has been bounded by the notable losses occurring in metallic reflections at visible and infrared (IR) wavelengths, as well as by the limited length and mechanical flexibility of the fabricated waveguides. Hollow all-dielectric fibers, relying on specular or attenuated total reflection, have also been explored, but high transmission losses have prevented their broad application. More recently, all-dielectric fibers,

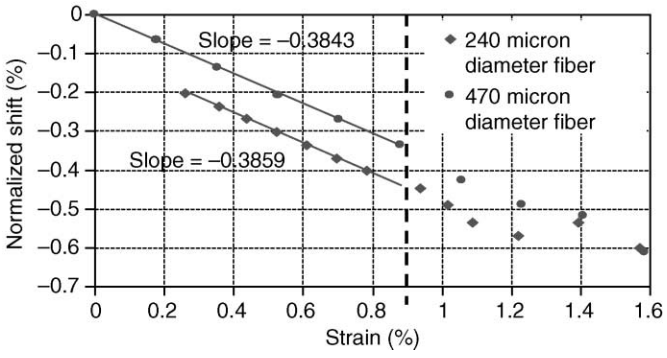

Figure 15 Normalized shift of the Fabry–Perot resonant mode (defined as $\Delta\lambda/\lambda$) versus applied axial strain for the 240 micron (diamonds) and the 460 micron diameter fiber (dots). The curve obtained for the 240 micron diameter fiber is lower because the experimental 0% strain is likely to correspond to a nonzero positive strain, necessary to keep this thinner fiber straight for the measurement (equivalent to a load less than 10 g). Reproduced with permission from Benoit G, *et al.* (2003) Static and dynamic properties of optical cavities in photonic bandgap gains. *Advanced Materials* 15: 2053–2056.

consisting of a periodic array of air holes in silica, have been used to guide light through air using narrow photonic bandgaps. Solid-core, index-guiding versions of these silica photonic crystal fibers have also been explored for interesting and important applications, such as very large core single-mode fibers, nonlinear enhancement and broadband supercontinuum generation, polarization maintenance, and dispersion management. However, the air-guiding capabilities of such waveguides thus far remain inferior to transmission through solid silica, due to various factors such as the difficulties in fabricating long, uniform fibers which must have a high volume fraction of air and many air–hole periods, as well as by the large electromagnetic (EM) penetration depths associated with the small photonic bandgaps achievable in these air–silica structures. In our fiber, the hollow core is surrounded by a solid high-refractive-index-contrast multilayer structure leading to large photonic bandgaps and omnidirectional reflectivity. The pertinent theoretical background and recent analyses indicate that such fibers may be able to achieve ultralow losses and other unique transmission properties. The large photonic bandgaps result in very short EM penetration depths within the layer structure, significantly reducing radiation and absorption losses while increasing robustness. Omnidirectional reflectivity is expected to reduce intermode coupling losses.

To achieve high index contrast in the layered portion of the fiber, we combined a chalcogenide glass with a refractive index of ~2.8 As_2Se_3, and a high-performance polymer with a refractive index of ~1.55 PES. We recently demonstrated that these materials could be thermally co-drawn into precisely layered structures without cracking or delamination, even under large temperature excursions. The same polymer was used as a cladding material, resulting in fibers composed of ~98% polymer by volume (not including the hollow core) and thus combine high optical performance with polymeric processability and mechanical flexibility. We fabricated a variety of fibers by depositing a 5–10 micron thick As_2Se_3 layer through thermal evaporation onto a 25–50 micron thick PES film and the subsequent 'rolling' of that coated film into a hollow multilayer tube called a fiber preform. This hollow macroscopic preform was consolidated by heating under vacuum and cladded with a thick outer layer of PES; the layered preform was then placed in an optical fiber draw tower and drawn down into tens or hundreds of meters of fiber having well-controlled submicron layer thicknesses. The nominal positions of the photonic bandgaps were determined by laser monitoring of the fiber OD during the draw process. Typical standard deviations in the fiber OD were ~1% of the OD. The resulting fibers were designed to have large hollow cores, useful in high-energy transmission.

SEM analysis (Figure 16) reveals that the drawn fibers maintain proportionate layer thickness ratios and that the PES and As_2Se_3 films adhere well during rigorous thermal cycling and elongation. Within the multilayer structure shown in Figure 1, the PES layers (gray) have a thickness of 900 nm, and the As_2Se_3 layers (bright) are 270 nm thick (except for the first and last As_2Se_3 layers, which are 135 nm). Broadband fiber transmission spectra were measured with a Fourier transform infrared (FTIR) spectrometer (Nicolet Magna 860), using a parabolic mirror to couple light into the fiber and an external detector. The results of these measurements are shown in the lower panel of Figure 2 for fibers having two different layer structures. For each spectrum, light is guided at the fundamental and high-order photonic bandgaps. Also shown in the upper panel of Figure 2, is the corresponding photonic band diagram for an infinite periodic multilayer structure calculated using the experimental parameters of our fiber (layer thicknesses and indices). Good agreement is found between the positions of the measured transmission peaks and the calculated bandgaps, corroborated with the SEM-measured layer thicknesses, verifying that transmission is dominated by the photonic bandgap mechanism. In order to demonstrate 'wavelength scalability' (i.e., the control of transmission through the fiber's structural parameters) another fiber was produced, having the same cross-section but with thinner layers. We compared the transmission

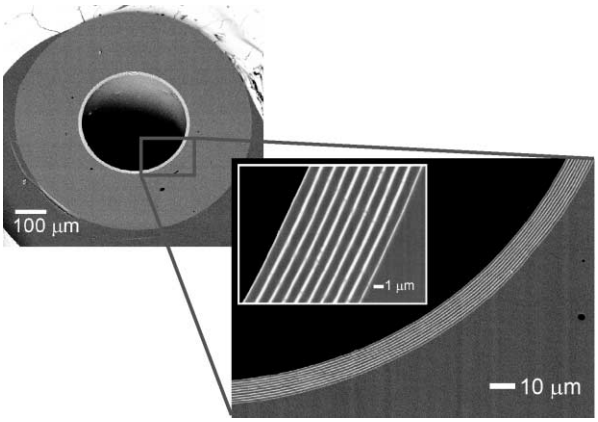

Figure 16 Cross-sectional SEM micrographs at various magnifications of hollow cylindrical multilayer fiber mounted in epoxy. The hollow core appears black, the PES layers and cladding gray, and the As_2Se_3 layers bright white. This fiber has a fundamental photonic bandgap at a wavelength of ~3.55 microns. Reproduced with permission from Temelkuran B, Hart SD, Benoit G, Joannopoulos JD and Fink Y (2002) Wavelength-scalable hollow optical fibres with large photonic bandgaps for CO_2 laser transmission. *Nature* 420: 650–653.

spectra for the original 3.55 micron bandgap fibers to the fiber with the scaled-down layer thicknesses.

Figure 17 shows the shifting of the transmission bands, corresponding to fundamental and high-order photonic bandgaps, from one fiber to the next. The two fibers analyzed in Figure 17 were fabricated from the same fiber preform using different draw-down ratios (fibers with a fundamental bandgap centered near 3.55 microns have an OD of 670 microns; those with a gap at 3.1 microns have an OD of 600 microns). The high-order bandgaps are periodically spaced in frequency, as expected for such a photonic crystal structure.

The wavelength scalability of our fibers was further demonstrated in the fabrication of hollow fibers designed for the transmission of 10.6 micron EM radiation. This not only shows that these structures can be made to guide light at extremely disparate wavelengths, but that specific useful bandgap wavelengths can be accurately targeted during fabrication and fiber drawing. Powerful and efficient CO_2 lasers

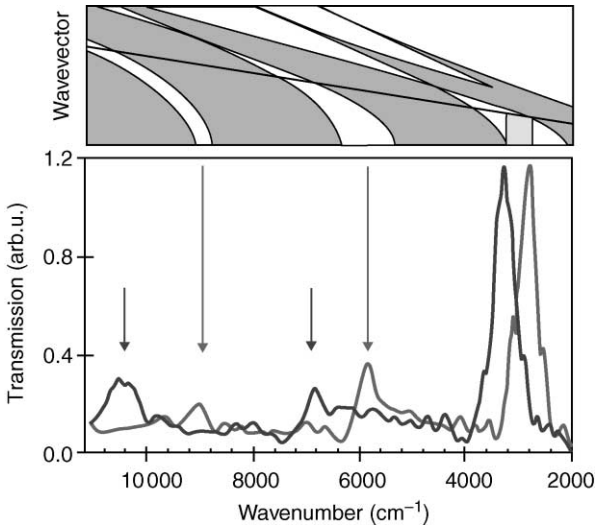

Figure 17 Upper panel: Calculated photonic bandstructure associated with the dielectric mirror lining of the hollow fiber. Modes propagating through air and reflected by the fiber walls lie in the bandgaps (white) and within the light cone defined by the glancing-angle condition (black line). The gray regions represent modes radiating through the mirror. The fundamental bandgap has the widest range-to-mid-range ratio, with a region of omnidirectional reflectivity highlighted in black. Lower panel: Comparison of transmission spectra for two different hollow fibers of ~30 cm length having similar structure but scaled photonic crystal (multilayer) period dimensions. The spectrum in gray is from a fiber with a fundamental photonic bandgap at 3.55 microns; the black spectrum is from a fiber where the corresponding bandgap is at 3.1 microns. High-order bandgaps (indicated by arrows) are periodically spaced in frequency. Reproduced with permission from Temelkuran B, Hart SD, Benoit G, Joannopoulos JD and Fink Y (2002) Wavelength-scalable hollow optical fibres with large photonic bandgaps for CO_2 laser transmission. *Nature* 420: 650–653.

are available that emit at 10.6 microns and are used in such applications as laser surgery and materials processing, but waveguides operating at this wavelength have remained limited in length or loss levels. Using the fabrication techniques outlined above, we produced fibers having hollow core diameters of 700–750 microns and ODs of 1300–1400 microns with a fundamental photonic bandgap spanning the 10–11 micron wavelength regime, centered near 10.6 microns. Figure 5 depicts a typical FTIR transmission spectrum for these fibers, measured using ~30 cm long straight fibers.

In order to quantify the transmission losses in these 10.6 micron bandgap hollow fibers, fiber cutback measurements were performed. This involved the comparison of transmitted intensity through ~4 meters of straight fiber with the intensity of transmission through the same section of fiber cut to shorter lengths (Figure 18 inset). This test was performed on multiple sections of fiber, and the results found to be nearly identical for the different sections tested. The measurements were performed using a 25 watt CO_2 laser (GEM-25, Coherent-DEOS) and high power detectors (Newport 818T-10). The fiber was held straight, fixed at both ends as well as at multiple points in the middle to prevent variations in the input coupling and propagation conditions during fiber cutting. The laser beam was sent through focusing lenses as well as 500 micron diameter pinhole apertures and the input end face of the fiber was coated with a metal film to prevent accidental

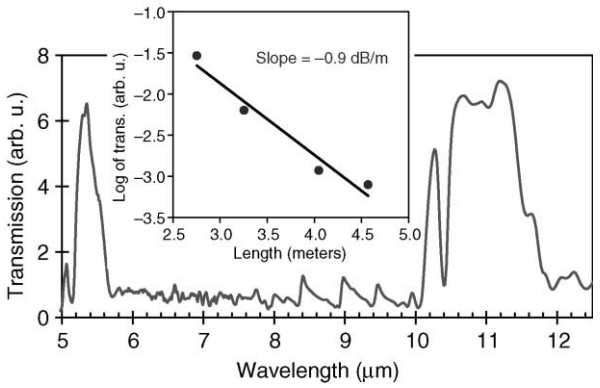

Figure 18 Typical transmission spectrum of hollow fibers designed to transmit CO_2 laser light. The fundamental photonic bandgap is centered near a wavelength of 10.6 microns and the second-order gap is at ~5 microns. Inset: Log of transmitted power (arbitrary units) versus length of fiber (meters). The slope of this graph is the loss in dB/m. The measured fiber has a hollow core diameter of 700 microns. Reproduced with permission from Temelkuran B, Hart SD, Benoit G, Joannopoulos JD and Fink Y (2002) Wavelength-scalable hollow optical fibres with large photonic bandgaps for CO_2 laser transmission. *Nature* 420: 650–653.

laser damage from misalignment. The transmission losses in the fundamental bandgap at 10.6 microns were measured to be 0.95 dB/m, as shown in the inset of Figure 18, with an estimated measurement uncertainty of 0.15 dB/m. These loss measurements are comparable to some of the best reported loss values for other types of waveguides operating at 10.6 microns. A bending analysis for fibers with a bandgap centered at 10.6 microns revealed bending losses below 1.5 dB for 90 degree bends with bending radii from 4–10 cm. We expect that these loss levels could be lowered even further by increasing the number of layers, through optimization of the layer thickness ratios and by creating a cylindrically symmetric multilayer fiber with no inner seam (present here because of the 'rolling' fabrication method). In addition, using a polymer with lower intrinsic losses should greatly improve the transmission characteristics.

One reasonable figure of merit for optical transmission losses through hollow all-dielectric photonic bandgap fibers is to compare the hollow fiber losses to the intrinsic losses of the materials used to make the fiber. As_2Se_3 has been explored as an IR-transmitting material, yet the losses at 10.6 microns reported in the literature are ~10 dB/m for highly purified material, and more typically are greater than 10 dB/m for commercially available materials such as those used in our fabrication. Based on FTIR transmission and spectroscopic ellipsometer measurements that we have performed on PES, the optical losses associated with propagation through solid PES should be greater than 40 000 dB/m at 10.6 microns. This demonstrates that guiding light through air in our hollow bandgap fibers leads to waveguide losses that are orders of magnitude lower than the intrinsic fiber material losses, which has been one of the primary goals of hollow photonic bandgap fiber research. These comparatively low losses are made possible by the very short penetration depths of EM waves in the high refractive index contrast photonic crystal structure, allowing these materials to be used at wavelengths that may have been thought improbable. Another long-standing motivation of infrared fiber research has been the transmission of high-power laser light. As a qualitative demonstration of the potential of these fibers for such applications, both straight and smoothly bent fibers of lengths varying from 0.3–2.5 meters were used to transmit enough CO_2 laser energy to burn holes through paper. The maximum laser power density coupled into our fibers in these trials was approximately 300 W/cm^2, more than sufficient to burn a homogeneous polymer material, including PES. No damage to the fibers was observed when the laser beam was properly coupled into the hollow fiber core. These results indicate the feasibility of using hollow multilayer photonic bandgap fibers as a low-loss wavelength-scalable transmission medium for high-power laser light.

Introduction

Why do ray optics dominate the literature on optical engineering? The major practical reason may be that historically optical engineering has dealt with systems for image forming. These systems transform divergent spherical waves from points in an object, into spherical waves converging to focal points in the image. Thus, the basic operation of an imaging system performed by a lens is changing the radius of curvature of spherical fields. The propagation of spherical waves is modeled well by geometrical optics, so long as truncation by apertures and other high frequency aberrations are not significant. Moreover, the basic merit function in imaging evaluates the appearance of the image point at its correct location by so-called dot diagrams. Evaluation of this merit function requires only a ray bundle representation of the output field. The combination of a ray representation with geometrical optics propagation is called raytracing, which explains the dominance of raytracing in conventional optical engineering. Because the design of illumination systems is also often based on principles of imaging, raytracing remains a suitable technique in that case too. However, systems that perform general light transformations must apply wave-optical engineering techniques, which constitutes a generalization of conventional optical engineering. In this sense it includes the modeling of image-forming systems as a special case.

Modeling Principles

Modeling in wave-optical engineering addresses the propagation of electromagnetic fields through systems as illustrated in Figure 1. The introduction of operators and operands as mathematical tools simplifies a systematic discussion of the modeling concepts. Formally, an electromagnetic field may be expressed by the operand $\mathbf{f} \in \mathsf{F}$ with the set of fields F. The actual form of $\mathbf{f} \in \mathsf{F}$ depends on the physical approach chosen to model electromagnetic fields. For instance, $\mathbf{f} \in \mathsf{F}$ may stand for a ray bundle, a complex amplitude, or a coherence function. The photon source generates a field which acts as the input field $\mathbf{f}$ into the optical system. The quality of the output field $\mathbf{f}_{\text{out}}$ is evaluated with the help of a merit function $\mathbf{\Omega}$. This function may consist of M components which yields:

$$\mathbf{\Omega}(\mathbf{f}_{\text{out}}) = \{\Omega_1(\mathbf{f}_{\text{out}}), \ldots, \Omega_\mu(\mathbf{f}_{\text{out}}), \ldots, \Omega_M(\mathbf{f}_{\text{out}})\} \quad [1]$$

with $\Omega_\mu : \mathsf{F} \rightarrow \mathsf{R}^+$ and $\mu = 1, \ldots, M$. Each component Ω_μ defines a mathematical way to obtain one positive valued quantity for a given $\mathbf{f}_{\text{out}}$. Examples are the rms-value to evaluate the quality of a wavefront, M^2-value to judge the profile of a laser beam, center of gravity of a light distribution, light transformation efficiency, and the value of an overlap integral to determine the coupling efficiency into a fiber. Any property of the output field can be evaluated by an appropriate definition of a function Ω_μ, as long as the demanded field parameters are accessible for the field model in use. However, it should be mentioned, that it is not clear *a priori*, that all quality criteria Ω_μ can be satisfied simultaneously. How the different Ω_μ are related is dependent on the application.

The propagation of the input field through the system is mathematically summarized by the operator equation:

$$\mathbf{f}_{\text{out}} = S(p_\alpha)\mathbf{f}_{\text{in}} \quad [2]$$

with the operator $S : \mathsf{F} \rightarrow \mathsf{F}$. p_α stands for all parameters p_1, p_α, p_{A} which specify the system, for instance position of elements, refractive index, surface profiles, and layer thickness. Obviously a full electromagnetic model of S does not exist for arbitrary systems. The propagation problem eqn [2] is much too complex for a wave-optical solution. However, for a sequential approach the situation is different. If the propagation through a system is performed sequentially through the elements and the homogenous regions, at least approximate wave-optical methods are available to model the propagation S. In a sequential approach, either the transmitted or reflected field is considered per region

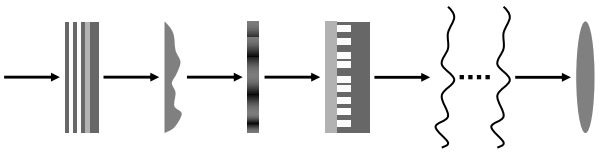

Figure 1 An optical system may include various types of elements to perform the desired optical function. Layered media, free-form surfaces, index-modulated regions, microstructured interfaces, lenses, and other structured media offer the flexibility needed to realize general light transformations. Typically structured media and homogenous regions follow each other.

of the system. Although this is an approximation, it turns out to be very useful in wave-optical engineering. With regard to Figure 2 the sequential approach is mathematically expressed by

$$\mathbf{f}_{\text{out}} = S(p_\alpha)\mathbf{f}_{\text{in}} = \mathcal{P}_J(n_J, \Delta z_J) S_{J-1}(p_{\alpha_{J-1}}) \cdots S_2(p_{\alpha_2}) \times \mathcal{P}_1(n_1, \Delta z_1)\mathbf{f}_{\text{in}} \quad [3]$$

$\mathcal{P}_j(n_j, \Delta z_j)$ expresses the propagation through a homogenous dielectric with refractive index n_j and extent Δz_j. This type of propagation is also called free propagation. Sometimes the term free propagation is restricted to propagation in vacuum; Here it is used more generally. $S_j(p_{\alpha_j})$ models the propagation through an optical component which is specified by the parameters p_{α_j}. Optical engineering needs physical models for the field operand $\mathbf{f}$, the free propagation $\mathcal{P}$, and the propagation S_j through elements. The most fundamental demand in wave-optical engineering is a wave-optical model to express the field $\mathbf{f}$ in homogenous regions. It is common to restrict to harmonic fields. The generalization to more general radiation is often possible by suitable superposition of harmonic fields. This approach assumes linear optical systems as typical in optical engineering. From Maxwell's equations it follows that harmonic fields in homogenous regions are completely specified if two independent field components are determined in one plane z_0 within the region. Therefore, the electromagnetic field operand takes the form:

$$\mathbf{f}(x, y, z_0) = [E_x(x, y, z_0), E_y(x, y, z_0)] \quad [4]$$

with the complex amplitudes E_x and E_y of the x and y components of the electric field vector. Because the knowledge of $\mathbf{f}(x, y, z_0)$ allows the direct calculation of the missing complex amplitudes E_z, H_x, H_y, H_z via Maxwell's equations, the entire electromagnetic harmonic field in a homogenous region is specified by eqn [4].

With respect to the two components of the field operand $\mathbf{f}$ propagation operators S are 2×2-matrices of the form:

$$S = \begin{Bmatrix} S_{xx} & S_{xy} \\ S_{yx} & S_{yy} \end{Bmatrix} \quad [5]$$

In the case of a diagonal matrix, that is $S_{xy} = S_{yx} = 0$, E_x and E_y propagate independently and are considered decoupled channels of the system. If in addition $S_{xx} = S_{yy}$, both channels behave identically, and it is sufficient to model only one channel. This is often referred to as the scalar model. Of course, also in the scalar model the electromagnetic field still consists of two independent components and maintains its vectorial nature.

Numerical implementation of eqn [3] for the field operand of eqn [4] constitutes the backbone of modeling in wave-optical engineering.

Free Propagation

The propagation $\mathcal{P}$ of harmonic fields $\mathbf{f}$ through homogenous regions of a system has a rigorous electromagnetic solution in form of the spectrum of plane waves integral which yields:

$$\begin{aligned} \mathbf{f}(x,y,z \geq z_0) &= \mathcal{P}_{\text{SPW}} \mathbf{f}(x,y,z_0) \\ &= \begin{pmatrix} \mathcal{P}_{\text{SPW}} & 0 \\ 0 & \mathcal{P}_{\text{SPW}} \end{pmatrix} \begin{pmatrix} E_x(x,y,z_0) \\ E_y(x,y,z_0) \end{pmatrix} \\ &= \begin{pmatrix} \mathcal{F}^{-1}([\mathcal{F}E_x(x,y,z_0)]e^{i(k_x x + k_y y + k_z \Delta z)}) \\ \mathcal{F}^{-1}([\mathcal{F}E_y(x,y,z_0)]e^{i(k_x x + k_y y + k_z \Delta z)}) \end{pmatrix} \end{aligned} \quad [6]$$

with the Fourier transform $\mathcal{F}$ and $\Delta z = z - z_0$. The term $\mathcal{F}E(x,y,z_0)$ is called spectrum of planewaves (SPW). The operator matrix is diagonal and $\mathcal{P}_{\text{SPW}} = \mathcal{P}_{xx} = \mathcal{P}_{yy}$, that means the x- and y-components propagate independent of each other according to the same formula in homogenous dielectrics.

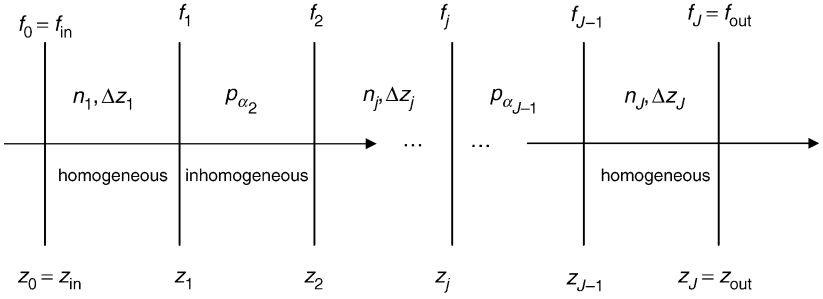

Figure 2 Formally a system may be subdivided into a sequence of homogenous dielectrics like air and inhomogeneous regions which include the elements. We indicate a region by the letter *j*.

In this sense, free propagation is a scalar problem which allows the convenient use of $U(x,y,z)$ instead of two field components for the sake of simpler mathematical expressions.

Equation [6] allows the derivation of other rigorous versions of the free propagation operator $\mathcal{P}_{\mathrm{SPW}}$, for instance Rayleigh's integral formula, which is well-known from diffraction theory. Moreover, eqn [6] leads to important approximate operators for far-field propagation and the propagation of paraxial fields. Propagation of a field into its far field is given by the operator:

$$\begin{aligned} U(r\mathbf{s}) &= \mathcal{P}_{\mathrm{far}} U(x,y,z_0) \\ &= -\mathrm{i}2\pi k s_z [\mathcal{F}U(x,y,z_0)]|_{(ks_x,ks_y)} \frac{\exp(\mathrm{i}kr)}{r} \end{aligned} \quad [7]$$

with the wave number $k = 2\pi n/\lambda$, $r = |\mathbf{r}| = (x^2+y^2+(\Delta z)^2)^{1/2}$, and the direction vector $\mathbf{s} = (s_x, s_y, s_z) = \mathbf{r}/r$. Here, and in what follows, λ denotes the vacuum wavelength. $|_{(ks_x,ks_y)}$ indicates the variables to be inserted into the Fourier transformed field. Though the far-field formula is derived for $r \to \infty$, it is also of great practical value for the propagation of fields generated by nonparaxially emitting sources like laser diodes. Roughly speaking eqn [7] predicts a spherical wave in the far field which is modulated by the spectrum of planewaves of the field in z_0. $\mathcal{P}_{\mathrm{far}}$ propagates from the plane z_0 to the spherical surface with radius r and not to a plane z.

The paraxial approximation of eqn [6] follows if the spectrum of planewaves $\mathcal{F}U(x,y,z_0)$ possesses significant values only for small k_x and k_y, that is if both electric field components propagate approximately along the z-axis. The resulting propagation operator is known as Fresnel's integral formula. In practice, its formulation with the Fourier transform $\mathcal{F}$ is typically more suitable:

$$\begin{aligned} U(x,y,z \geq z_0) &= \mathcal{P}_{\mathrm{paraxial}} U(x,y,z_0) \\ &= \frac{k \exp[\mathrm{i}k\Delta z]}{\mathrm{i}2\pi\Delta z} \exp\left[\frac{\mathrm{i}k(x^2+y^2)}{2\Delta z}\right] \\ &\quad \times \left| \left\{ \mathcal{F}\left(\exp\left[\frac{\mathrm{i}k(x^2+y^2)}{\Delta z}\right] U(x,y,z_0) \right) \right\} \right|_{(x,y)n/\lambda\Delta z} \end{aligned} \quad [8]$$

$|_{(x,y)n/\lambda\Delta z}$ indicates the variables to be inserted after Fourier transform. The far-field approximation of eqn [8] leads to the well-known Fraunhofer diffraction formula.

Equations [6]–[8] provide fundamental operators for the propagation of fields in wave-optical engineering. All integrals are based on Fourier transforms which allows the application of the fast Fourier transform (FFT) in practice. Dependent on the propagation technique, one or two FFTs must be performed. In practice, the sampling of fields is of great concern. Naturally the amount of data should be as small as possible. According to the rigorous propagation operator eqn [6] the (x,y)-coordinate system and therefore the sampling period in z_0 and z are identical, that is, scaling does not occur. As illustrated in Figure 3, that can lead to an enormous amount of data for large propagation distances. For demonstration purpose the field amplitude depicted at the top is chosen. The field window has the size 1 mm × 4 mm. The wavelength λ is 632.8 nm, $n = 1$, and the sampling distance 10 μm. That results in 100 × 400 sampling points. Propagation of this field with the spectrum of planewave operator maintains the size of the field window. The resulting field for a propagation distance $\Delta z = 10$ mm is shown in the middle. Because of diffraction, the field widens. As long as the initial window is large enough to encompass the propagated field, the propagation method works well. At the bottom, the resulting field for $\Delta z = 200$ mm is shown. The field exceeds the size of the window and that leads to numerical errors (aliasing). This can be avoided by embedding the initial field into a window which is large enough with respect to the expected size of the propagated field. As a result, one obtains the

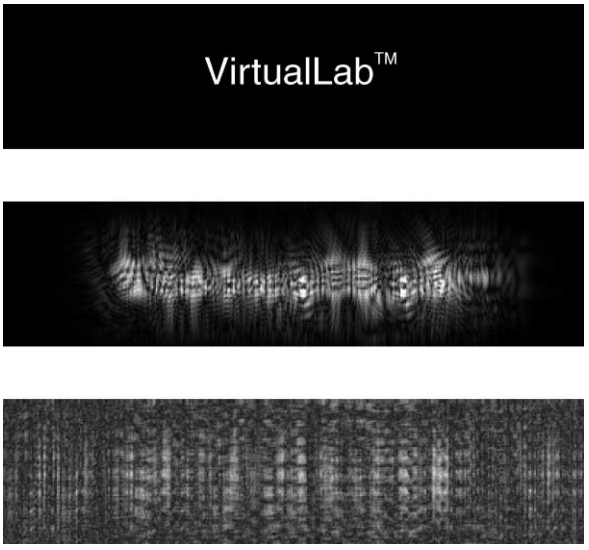

Figure 3 Illustration of numerical properties of the spectrum of plane wave propagation technique. The field amplitude depicted at the top is numerically propagated in free space and the distributions in the middle and the bottom are obtained. The simulations in this and all following figures were performed. The simulations in this and all following figures were performed with the wave-optical engineering software VirtualLab™ from LightTrans GmbH.

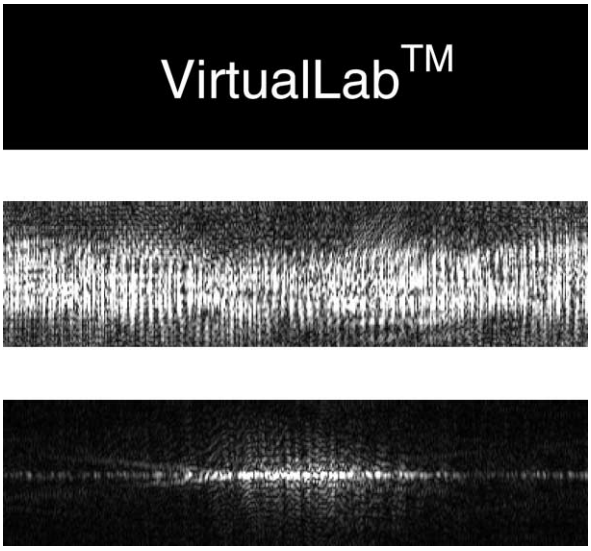

Figure 4 Starting from the same input field and the same distances as in Figure 3 the propagated fields depicted in the middle and the bottom are obtained using the paraxial propagation operator. Because of the inherent scaling the field window sizes are 632.8 μm × 632.8 μm and 12.656 mm × 12.656 mm, respectively. The number of sampling points remains unchanged. Obviously, the field in the middle is too small to encompass the propagated field and numerical errors occur. For the long distance the field size is perfectly matched to the field size obtained by propagation.

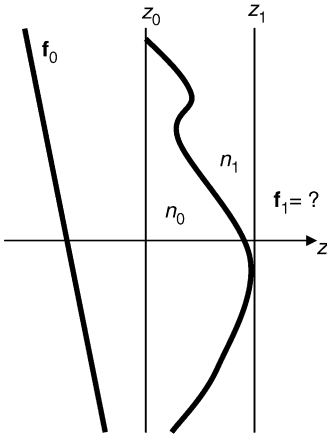

Figure 5 A planewave $\mathbf{f}_0$ propagates through an interface between two homogeneous dielectrics with refractive index n_0 and n_1. The interface is of general shape and therefore a rigorous solution of the propagation problem does not exist. The virtual planes in z_0 and z_1 encompass the interface in a way which minimizes the distance $z_1 - z_0$.

demanded accuracy at cost of increasing data memory requirements and computation time. Thus in practice the SPW propagation operator is particularly suitable for short distances. Fortunately the paraxial propagation operator eqn [6] possesses a complementary behavior. Because of $(x, y)n/\lambda\Delta z$, the (x, y)-coordinate system changes its scaling with the distance. As illustrated in Figure 4, that makes it well suited for large propagation distances but problems occur for small ones. Therefore, all paraxial propagation problems have an efficient numerical solution by a suitable combination of $\mathcal{P}_{\text{paraxial}}$ and $\mathcal{P}_{\text{SPW}}$. In the nonparaxial case the far-field operator eqn [7] often helps to realize a numerically efficient propagation for large distances. However, there are sometimes situations, in which free propagation of nonparaxial fields causes significant numerical problems.

Propagation Through Elements

The propagation of harmonic fields $\mathbf{f}$ through elements is a challenging task. For example, Figure 5 illustrates propagation through smooth or microstructured interfaces between two homogenous media. The field $\mathbf{f}_1(x, y, z_1)$ should be determined if $\mathbf{f}_0(x, y, z_0)$, the shape of the interface, and the refractive indices n_0 and n_1 are known. The reflection mode of operation can be formulated analogously. It is remarkable that this basic problem possesses a rigorous solution only for a few special interface geometries. Of particular importance are the rigorous solutions for plane and periodic interfaces. In the first case, the solution comprizes Snell's law of refraction, the law of reflection, and Fresnel's formulae. Grating theory provides the solution for periodic interfaces. It is possible to use these methods also for nonperiodic interfaces but at the cost of immense computational effort. Thus, they are only practicable for structures with detail no larger than a few wavelengths. For general interfaces, accurate approximate methods are required. One approach is to decompose a general propagation problem into a set of simpler problems that can be solved rigorously. The results are then combined to obtain an approximate solution of the original problem. Two basic concepts for subdividing the general problem are: (i) Decomposition of the incident field into laterally truncated fragments which illuminate elementary fractions of the interface. (ii) Decomposition of the response of the interaction of the incident field with the interface into approximately independent ones related to local interface features. The first technique is referred to as local elementary interface approximation (LEIA) and the second one as local independent response approximation (LIRA). Elementary interfaces of particular importance are plane, periodic, and spherical ones.

The local plane interface approximation (LPIA) is of particular importance in wave-optical engineering. Figure 6 illustrates the basic concept for the example

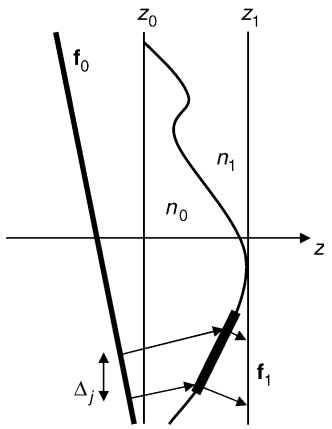

Figure 6 If a lateral fraction of the input field is propagated towards the interface, it is often possible to laterally restrict the major part of the propagated field to a local plane interface. Because of diffraction it is never possible to do that rigorously. Neglecting diffraction in the region between z_0 and z_1 provides a simple model to propagate a section of the incident plane field through the interface. Fresnel's formulae and Snell's law of refraction can then be applied directly to obtain the transmitted plane field, which is propagated to the plane z_1.

of a plane incident field. It has been proven that the approximation of geometrical optics propagation within the regions of the component, here that means between z_0 and z_1, provides results which are surprisingly accurate in numerous situations of practical interest. A full wave-optical version of LPIA is currently under research and development. In general, however, LPIA is applicable if the characteristic lateral extent of the local modulation of the interface is not close to the wavelength. It should be emphasized that LPIA is, as most other approximate propagation techniques, a 2×2 matrix, like eqn [5], with nonvanishing components. That means, for instance, that in general, an E_y-component occurs in z_1 even if $E_y = 0$ in z_0. That is, the two field channels experience crosstalk. A further approximation in geometrical optics LPIA, popular in Fourier optics holography, and diffractive optics is the thin element approximation (TEA). Geometrical optics LPIA leads to TEA if refraction and the local dependence of Fresnel losses at the interface are neglected. Obviously, that is allowed only if all angles involved, including the slope of the interface and the direction of the input field, are small. Therefore, TEA is a paraxial and geometrical optics approximation. Moreover, small local slopes of the interface lead to a restriction to thin elements, which explains the name TEA. It is also referred to as scalar approximation, because the operator matrix becomes diagonal with $S_{\mathrm{TEA}} = S_{xx} = S_{yy}$, that means the two field channels propagate independently according the same formula through the interface. In the thin element only approximation the dependence of the optical path through the element on position (x, y) is considered and mathematically takes the form:

$$\begin{aligned} U(x, y, z_1) &= S_{\mathrm{TEA}}\, U(x, y, z_0) \\ &= c_{\mathrm{Fresnel}}\, U(x, y, z_0) \exp\left[\frac{\mathrm{i}2\pi n_1(z_1 - z_0)}{\lambda}\right] \\ &\quad \times \exp\left[\frac{\mathrm{i}2\pi h(x, y)(n_0 - n_1)}{\lambda}\right] \end{aligned} \qquad [9]$$

with the vacuum wavelength λ. The profile height $h(x, y)$ is expressed as the distance from z_0 to the interface. Propagation through an interface between dielectrics modeled with TEA affects the phase of the incident field proportional to the profile height. The magnitude remains unchanged besides a constant factor c_{Fresnel}, due to Fresnel's equations. If complex valued refractive indices are taken into consideration, absorption results in an amplitude modulation completely analogous to the phase modulation described in eqn [9]. This way it is also possible to address the propagation through apertures and the combination of S_{TEA} with $\mathcal{P}$ leads to the well-known diffraction integrals. In fact, Kirchhoff's boundary conditions of field propagation through a hole in a completely opaque screen can be interpreted as TEA for complex valued refractive indices.

The simple form of the TEA operator allows a straightforward numerical implementation. The field operand and the profile are equidistantly sampled and the resulting field is sampled analogously. That makes the combination of S_{TEA} with numerical implementations of the free propagation operators $\mathcal{P}$ easy. As soon as refraction is considered in geometrical optics LPIA, the equidistant sampling of the output field is destroyed which enforces additional interpolation effort before a free propagation by fast Fourier transforms can be implemented, because fast numerical Fourier transform algorithms require an equidistant sampling.

In wave-optical engineering the combination of geometrical optics LPIA with a wave-optical field model is mandatory. In this context it is instructive to mention, that its combination with a ray-bundle representation of the incident electromagnetic field leads to raytracing through the interface, that is it reduces to the basic technique in conventional optical engineering.

Similar to LPIA it is possible to consider linear gratings as elementary local interface and the local linear grating approximation (LLGA) results. It is of special concern for all types of diffractive elements, for which the interface can locally considered

periodically. An important example is given for diffractive lenses in the outer zones of high numerical aperture lenses. In the center and for low numerical aperture TEA is appropriate for propagating through diffractive lenses.

Design Principles

The design problem in wave-optical engineering can be stated as follows: specify system parameters p_α in a way that ensures for a given input field $\mathbf{f}_{\text{in}}$ an output field $\mathbf{f}_{\text{out}}$ which satisfies the quality criteria defined by the merit functions Ω_μ. In addition, one may demand a system which is most simple, particularly cheap, or various other system properties of concern in practice.

Design constitutes an optimization problem. Restrictions to the system parameters and the merit function sets design constraints as well as design freedoms.

System parameters can be restricted, for instance, by the materials available, the maximum size of a system, and types of element profiles. Within these limits the system parameters are chosen freely during optimization to achieve the optical function.

The merit functions determines which parameters of the output field are important and should be emphasized, for instance the intensity distribution. All output fields, whose parameters satisfy the constraints satisfy the design problem. In most applications, not all field parameters are constrained. For instance, in laser materials processing or illumination applications, the merit function is related to energy quantities and then the phase of the output field can be used as a free parameter distribution. Moreover, the output field is typically not constrained in the entire output plane, but only in so-called signal regions, which introduces freedom of amplitude outside the signal regions. Hence, dependent on the application, there exist field parameters that can be chosen partly or completely free during design.

Successful design strategies use the freedoms to improve the matrix function. It is often not clear a priori, if a solution does exist. Then the field constraints are satisfied as good as possible in terms of the merit function.

In imaging systems, typical system parameters include, for instance, distances, refractive indices, curvature of lenses, and parameters to specify aspherical surfaces. For high-end lens systems, the resulting number of parameters can be large, but they are still small enough to utilize parameter optimization algorithms if the designer starts with a reasonable initial guess. In wave-optical engineering, the number of system parameters can become huge due to the generalized nature of the structures, which typically prevents the use of system parameter optimization techniques. For example, the profile of diffractive elements is typically specified by 10^4–10^6 parameters. Thus a direct optimization of the system parameters, which requires the evaluation of $S(p_\alpha)$ (see eqn [3]) after any change of system parameters p_α, is not realistic.

Instead of optimizing the system parameters directly, which is referred to as design in the structural embodiment of the system, a technique wellknown from Fourier optics and diffractive optics can be generalized for wave-optical engineering. It does not start with structure related element parameters but replaces all or at least some of the operators $S_j(p_{\alpha_j})$ of eqn [3] by mathematical operators $\mathcal{T}_j(t_{\tau_j})$. t_τ denotes the parameters of $\mathcal{T}$. The propagation operator through a system expressed in this functional embodiment has the form:

$$\begin{aligned}\mathbf{f}_{\text{out}} &= S_{\text{functional}}\mathbf{f}_{\text{in}} \\ &= \mathcal{P}_J(n_J, \Delta z_J)\mathcal{T}_{J-1}(t_{\tau_{J-1}})\cdots\mathcal{T}_2(t_{\tau_2}) \\ &\quad \times \mathcal{P}_1(n_1, \Delta z_1)\mathbf{f}_{\text{in}}\end{aligned} \qquad [10]$$

if all propagations through elements are expressed in functional form. A very important example of a functional operator $\mathcal{T}$ is given by a simple multiplication of both field components with identical or different complex functions $t(x, y)$, that is:

$$\mathcal{T}_t(t_\tau)\mathbf{f}_{\text{in}} = \begin{pmatrix} t_{xx}(x, y) & 0 \\ 0 & t_{yy}(x, y) \end{pmatrix}\mathbf{f}_{\text{in}}(x, y) \qquad [11]$$

The values of both $t(x, y)$ form the parameters t_τ of $\mathcal{T}$. The functions $t(x, y)$ are also called ideal transmission functions of elements. Of special interest are phase-only transmission functions $t(x, y) = \exp[i\tau(x, y)]$ (see discussion below). If $t(x, y) = t_{xx}(x, y) = t_{yy}(x, y)$, the design is simplified. Fortunately, in most actual applications this assumption is valid.

Designing in the functional embodiment requires the evaluation of $S_{\text{functional}}$ instead of S of eqn [3], which reduces the numerical complexity enormously. That improves the likelihood for developing efficient design algorithms to optimize the distances Δz_j, the refractive indices n_j, and parameters t_{τ_j}.

The design in the functional embodiment does not deliver the structure parameters of elements but only parameters t_τ of the operator $\mathcal{T}$ which gives information about how a field should be changed at the position z where $\mathcal{T}$ takes effect. Thus, in a next design step, elements must be obtained which cause the required effect. This so-called structure design

step is also generally challenging because it requires the solution of an inverse propagation problem through interfaces. For a further discussion the most important $\mathcal{T}$, that is the transmission type operator of eqn [11], is considered. For the sake of simplicity $t(x, y) = t_{xx}(x, y) = t_{yy}(x, y)$ is assumed. Then, a solution which uses geometrical optics LPIA in combination with phase-only transmissions is known in the form of a recursive structure design strategy. In its paraxial approximation, that is TEA, the solution becomes very simple. For a transmission $t(x, y) = \exp[i\tau(x, y)]$, obtained from a functional design, an element with a surface profile:

$$h(x, y) = \frac{\lambda\tau(x, y)}{2\pi(n_{\text{element}} - n_{\text{free}})} \qquad [12]$$

results from eqn [9]. The refractive index of the element is denoted by n_{element} and the homogenous region behind the element has the index n_{free}, eqn [12] constitutes a direct relationship between the phase values of the transmission function and the profile $h(x, y)$. This structure design technique is accurate for all paraxial situations. However, it is also a reasonable method for nonparaxial structure design since it provides an initial profile for further optimization. Obviously it is applicable for phase-only transmission functions only. That underlines the importance of this type of functional operator for the design in the functional embodiment. Often the fabrication of profiles is done with lithographic techniques which result in surface reliefs with a few discrete height levels, that means the profile $h(x, y)$ is quantized. According to eqn [12] a quantization of $h(x, y)$ directly leads to quantized phase values $\tau(x, y)$. This quantization must be taken into account when designing $\tau(x, y)$. An example should serve to discuss further aspects of structure design according to eqn [9]. A fundamental transmission in various applications is the phase of a spherical wave and its paraxial version, the quadratic phase. An example of a spherical phase $\tau(x, y)$ is shown in Figure 7 where the 2π-modularity of the exponential function is taken into account – as normal for phase data which has been obtained by numerical calculations. Inserting this phase into eqn [9] leads to the profile of a diffractive lens. Because of the use of inverse TEA for structure design it works as demanded for moderate numerical apertures and starts to suffer from aberrations for large numerical apertures because of electromagnetic effects in the very outer zones. It is also possible to unwrap the phase before inserting it into eqn [9]. Then a smooth surface, that is a refractive spherical lens, results. It is well-known that a spherical lens works accurately in the paraxial domain and suffers from aberrations for moderate and large numerical apertures, which are more severe than for the diffractive lens. The use of inverse geometrical optics LPIA as a structure design technique is not restricted to the paraxial domain and therefore it leads to a suitable aspherical surface in order to ensure a spherical phase transmission for larger numerical apertures too. This is illustrated in Figure 8. The lens example shows another advantage of the two-step design method, which consists of the design in the functional embodiment prior to the one in the structural form of the element. In the functional

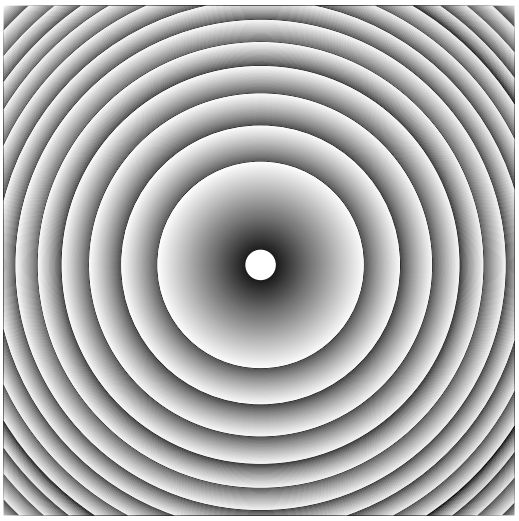

Figure 7 The phase of a spherical phase in the 2π-modulo representation. This phase can be unwrapped which leads to a smooth spherical phase which varies from 0 to various 2π. The noisy edges are due to the use of a cartesian coordinate system.

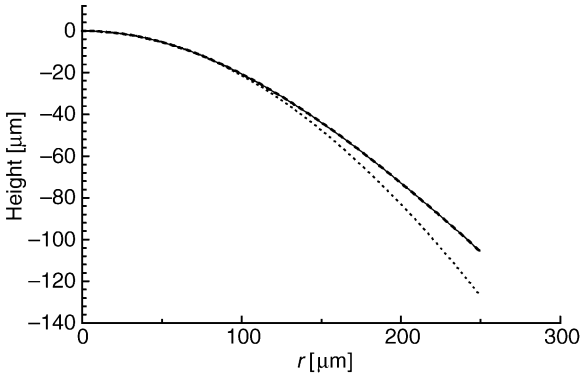

Figure 8 Application of the thin lens approximation for structure design leads to a spherical surface for a spherical phase-only transmission. The corresponding surface is depicted by the dotted line. If geometrical optics LPIA is used for structure design, an aspherical surface is obtained as required. The aspherical surface is depicted by the solid line. The height of the surfaces are shown as function of the radius *r*. Naturally the difference between TEA and geometrical optics LPIA occurs for larger *r* only.

form the transmission is obtained. It is not necessary to decide about the use of a diffractive or a refractive element in an early stage of the design. Moreover, it provides the designer with insight into selecting optical elements to achieve the function. If the phase-only transmission can be unwrapped, a refractive as well as a diffractive element can be used. An optical engineer has the freedom to decide about the suitable choice taking fabrication, size, costs, and other additional constraints into account. However, as soon as the phase-only transmission includes so-called vortices, unwrapping is not possible and diffractive optics is mandatory. An example of a vortex is shown in Figure 9. It turns out that vortices are more likely to appear in wave-optical engineering the less image-like the optical function is (see also last section). It is important to note, that functional design assumes a diagonal operator matrix, that is, it excludes crosstalk of the two field channels. Transferring the system into a structural form may violate this assumption because of vectorial effects in the nonparaxial domain. For instance, geometrical optics LPIA in general does not correspond to a diagonal operator. Therefore, it is necessary to analyze the final system for $\mathbf{f}_{\text{in}}$ – even in the case of linear polarized light – using more accurate propagation techniques than S_{TEA} if it is not ensured that the paraxial approximation is accurate enough.

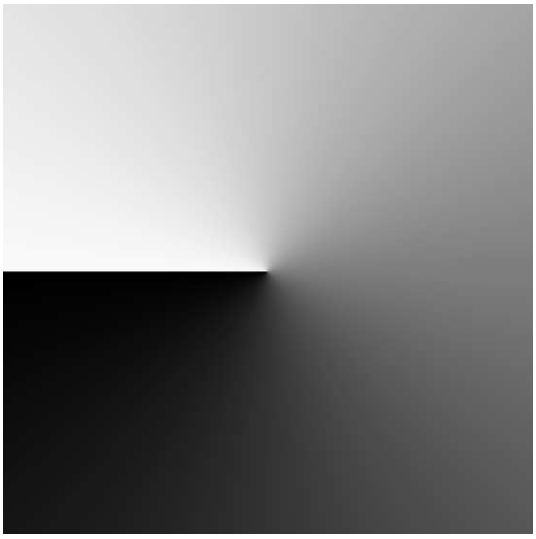

Figure 9 Illustration of a single vortex of charge one. The phase varies from 0 to 2π. Because of the vortex, this phase is not unwrappable, that means a smooth phase function cannot be obtained. The transition in the phase function requires a microstructure in the profile of the element, which generates this phase-only transmission.

The so-called thin lens, or ideal lens, in conventional optical engineering constitutes a special case of the two-step design strategy. In the first design step, distances and lens focal lengths are determined, without taking into account the actual shape of a lens. In the second step lenses, or even lens systems, are inserted according to the position and the focal length specified in the first step. Thus, wave-optical engineering extends our understanding by broadening established methods in optical engineering.

Fundamental Systems

A smart approach to design minimizes the number of elements required to achieve a desired light transformation. Thus, it is logical to try a functional design with a system of the form:

$$\begin{aligned} U_{\text{out}}(x,y) &= S_{\text{functional}}\, U_{\text{in}}(x,y) \\ &= \mathcal{P}(n_{\text{free}}, \Delta z_{\text{out}}) \exp[\mathrm{i}\tau(x,y)] \\ &\quad \times \mathcal{P}(n_{\text{free}}, \Delta z_{\text{in}}) U_{\text{in}}(x,y) \end{aligned} \qquad [13]$$

which is illustrated in Figure 10. One phase-only transmission, properly placed between the input and the output plane, should realize the desired transformation of the function. Scalar terminology is used, because both components are decoupled in the functional embodiment.

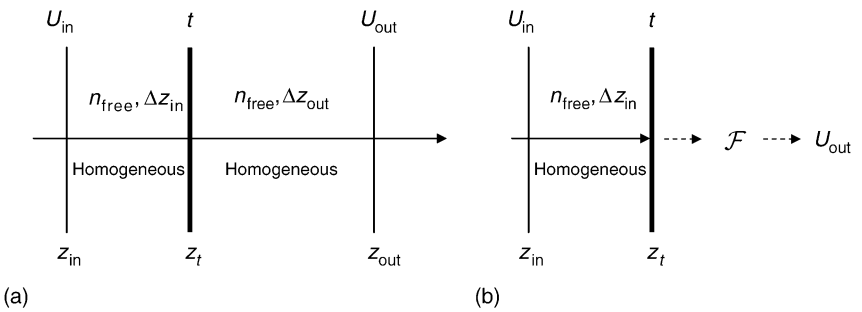

Figure 10 A basic system for light transformation can be described functionally by two propagations through homogeneous dielectrics with refractive index n_{free} and one phase-only transmission function. (b) If the second propagation is replaced by an operation in functional form, here the Fourier transform, the setup shown on the right side results.

If the output field is completely specified by the merit function, for instance: if the complex amplitude of a laser beam should be transformed into another one, the so-called amplitude matching strategy is a very powerful technique to solve the design problem stated by eqn [13]. In amplitude matching one determines the Distances Δz_{in} and Δz_{out} such that the inverse propagated U_{out} and the forward propagated U_{in} possess identical magnitudes. If such distances exist, the transformation can be realized using a phase-only transmission in the plane z_t. The phase simply follows from the ratio of the propagated fields. If no distances exist where amplitude matching occurs, the design problem has no solution and at least one more transmission function must be introduced.

As mentioned above, in numerous applications the output field is not specified completely. In particular, phase is often a free parameter. Then, an even simpler system approach than the one suggested by eqn [13], often leads to reasonable solution. Instead of $\mathcal{P}(n_{\text{free}}, \Delta z_{\text{out}})$, a Fourier transform is assumed, then if,

$$\begin{aligned} U_{\text{out}}(k_x, k_y) &= S_{\text{functional}} U_{\text{in}}(x, y) \\ &= \mathcal{F}\{\exp[\mathrm{i}\tau(x, y)]\mathcal{P}(n_{\text{free}}, \Delta z_{\text{in}}) U_{\text{in}}(x, y)\} \end{aligned} \qquad [14]$$

The output field is expressed in k-coordinates as long as the system is discussed in functional form. For a functional design the distance Δz_{in} is of no concern, however it must be chosen together with the structure design as discussed below. Thus, in functional design, one concentrates only on the design of the transmission function. The iterative Fourier transform algorithm (IFTA), an extremely powerful algorithm, has been developed to accomplish this design. Its principle is illustrated in Figure 11. The algorithm sequentially applies constraints on the transmission and in the Fourier plane. Properly controlled, the algorithm converges to a Fourier pair for which the transmission plane constraint is satisfied completely and the Fourier domain constraint is satisfied as accurately as required by the merit function. The initial distribution is of enormous importance for a successful transmission design. Typically the initial distribution is defined in the Fourier plane as shown in Figure 11. A field $U_{\text{sig}}(k_x, k_y)$ is chosen, which satisfies the merit function. It is called the signal field. Because of design freedoms such as phase, typically there exists a set of signal fields F_{sig}. If phase freedom is available, any field with the desired amplitude and an arbitrary phase is an element of F_{sig} and can be used as initial distribution of the IFTA. Dependent on the application, the choice of the phase is of fundamental concern. In the following we assume

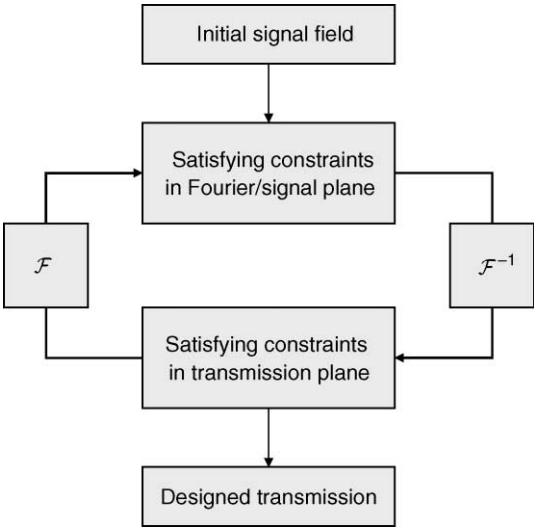

Figure 11 Illustration of the basic principle of the iterative Fourier transform algorithm (IFTA). By a sequential satisfaction of constraints in the signal and the transmission plane, the design in the functional embodiment can be accomplished. If both constraints are satisfied accurate enough, the IFTA is terminated with a final satisfaction of the transmission plane constraints. The depicted IFTA version can be generalized by replacing $\mathcal{F}$ by $\mathcal{P}$ or any S.

phase freedom is available, but IFTA is also useful if this is not the case.

It is helpful to distinguish between two types of signal fields. If amplitudes for only a finite number of discrete k-values, (i.e., angles or directions), need to be determined, the transmission acts as a diffractive beamsplitter. In all other cases more general light transformations are concerned.

The constraints in the transmission plane follow from the structure design. In most cases the structure design is done by TEA according to eqn [12]. Then, phase-only transmissions are required. Typically the fabrication of the corresponding element profile demands a phase quantization in addition. Both constraints have been intensively investigated for the IFTA.

As mentioned above, practically signal fields are always restricted to one or more signal regions of finite extent. For example, a detector has finite extent. Outside of these regions the signal may be unrestricted or only partially restricted. This freedom in amplitude outside the signal regions is fundamental for a successful design of phase-only transmissions. It has been shown, that the only phase-only function whose Fourier transform exists over a finite area is a linear phase. The transform of all other phase-only functions contribute energy outside of the signal regions. In other words, the use of amplitude freedom is mandatory. Energy losses due to stray light outside

the signal region cannot be avoided. As a result, it is not possible to generate the desired response with 100% efficiency. For any given signal field U_{sig} an upper bound $\eta_{bound}(U_{sig})$ of the achievable efficiency $\eta(U_{sig})$ of light transformation with a phase-only transmission has been derived, that is $\eta(U_{sig}) \leq \eta_{bound}(U_{sig})$. The equal sign is only valid for the special case of a linear phase transmission, for which the signal field consists of one k-direction only. Then $\eta_{bound}(U_{sig}) = \eta(U_{sig}) = 1$ is obtained. After structure design for a linear phase-only transmission with TEA, a so-called blazed grating results. If TEA is a sufficient approximation one concludes that a blazed grating has a theoretical efficiency of 100%. For all other signals the theoretical efficiency is smaller than 100%. Moreover, the upper bound is a function of U_{sig} and thus also of its phase. Therefore, in a first step of a transmission design it is recommendable to perform a phase synthesis which maximizes the upper bound. This first design step delivers information about achieveable efficiency and a suitable initial signal field for the IFTA.

If fabrication requires phase quantization, amplitude freedom can be used to separate quantization noise from the signal regions. Unfortunately this reduces the achievable efficiency even more. If the phase to be quantized is homogenously distributed, the upper bound for a phase-only transmission quantized to Q equidistant phase levels is given by:

$$\eta_{bound}(U_{sig}, Q) = \mathrm{sinc}^2\left[\frac{1}{Q}\right]\eta_{bound}(U_{sig}) \qquad [15]$$

For the special case of linear phase, the well-known formula $\eta(Q) = \mathrm{sinc}^2[1/Q]$ follows. The values of $\mathrm{sinc}^2[1/Q]$ and therefore of quantized blazed gratings in the paraxial approximation are 0.405, 0.812, 0.950, 0.987, and 0.997 for $Q = 2$, 4, 8, 16, and 32, respectively. This result does not mean that, for example, a diffractive beamsplitter with a splitting ratio $1 : M_{beams}$ and 16 height levels will provide ~99% efficiency. According to eqn [15], the theoretical values are smaller and depend on M_{beams} because $\eta_{bound}(U_{sig})$ depends via U_{sig} on M_{beams}. If fabrication processes and the inherent imperfections are taken into consideration, the values decrease even more. As a rule of thumb, it is possible to claim that efficiencies larger than 90% are always challenging to obtain. With sophisticated design and fabrication techniques, efficiencies larger than 80% are reasonable.

Up to now, we have discussed only the importance of the signal field phase to efficiency. But the phase of the initial signal field has another extremely important effect on the result of the transmission design. From mapping-type considerations, a smooth initial signal field phase can be constructed in order to realize a light transformation. An example is illustrated in Figure 12. It shows the central part of the phase of the transmission function which transforms a Gaussian input beam into a flat-top line beam. Because of the smooth signal phase also the transmission phase is smooth and therefore unwrappable. This approach is typical for a so-called beam shaping design. It requires a well-defined input beam and high accuracy in adjustment of the beam shaping optics to obtain the output field with good quality. If, instead of a smooth initial phase, a random one is applied, the situation illustrated in Figure 13 (left) is achieved. Here the phase of the transmission looks random, which is typical for beamsplitter and diffuser. Because such phase functions possess numerous vortices, they do not allow an unwrapping. Thus, diffractive elements are the logical result of structure design. An example is shown in Figure 13 (right).

Figure 14 shows how light from a laser diode passes through the diffuser element of Figure 13 (right). The radiation is transformed into an intensity pattern that depicts the 'skyline' of Jena. Although globally the intensity possesses the requested shape, a closer look shows that the intensity distribution is speckled. However, in numerous applications this is not a problem so long as the size of the speckles is well adapted to the resolution of the detector.

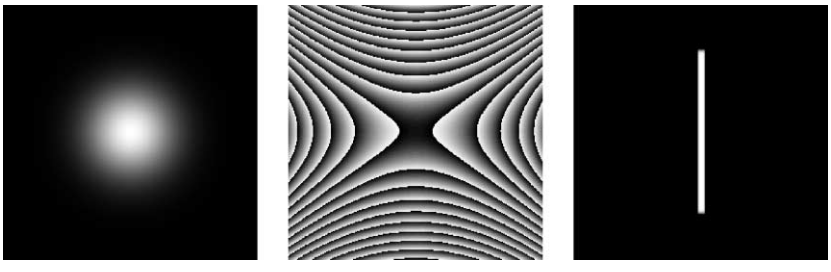

Figure 12 The input beam on the left propagates through the transmission function the central part of the phase of which is shown in the middle and in the signal plane the amplitude shown on the right results. This Gaussian-to-line transformation is a typical beam shaping design task.

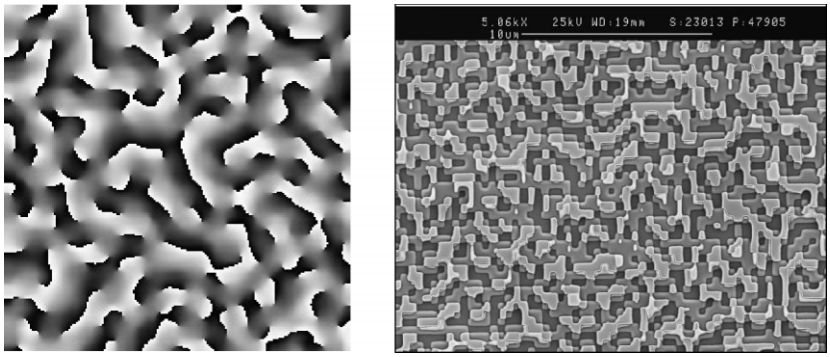

Figure 13 A typical phase distribution of a transmission (left) which results from design with IFTA for a random initial signal field phase. Numerous vortexes prevent its unwrapping. Therefore, structure design leads to diffractive elements. Then, a quantization of the phase is demanded in most cases. An example is shown on the right-handed side. It depicts a portion of a four level diffuser which results in the output field shown in **Figure 14**. The pixel size is 400 nm and the corresponding element was designed and fabricated in a cooperation of LightTrans GmbH and the Institute of Applied Physics at the University of Jena.

This technique is called diffuser-type light transformation. The appearance of the global intensity distribution is robust against variations in the input beam and thus is well-suited also for partial coherent illumination, for example radiation from an excimer laser and LED. In that case, even the appearance of speckles is reduced or vanishes completely. The mapping-type and the diffuser-type approach to choose the initial signal phase constitute two extreme cases of a great variety to control basic aspects of light transformation using different initial phases.

After choosing a suitable initial signal field $U_{\text{sig}}(k_x, k_y)$ the IFTA typically performs well and a transmission function is obtained, which leads to $|U_{\text{out}}(k_x, k_y)|^2 \propto |U_{\text{sig}}(k_x, k_y)|^2$ in the signal region with minimum error. In the next step the structural design must be performed. The structure of the element is calculated via eqn [12].

Besides designing structure to produce the desired transmission function one needs to realize optically the Fourier transformation. Placing the observation plane in the far field behind the element is the most straightforward way to achieve this. However, field Fourier transformation can also be realized by lenses as shown in **Figure 15**. From simple geometric considerations using paraxial approximation one obtains:

$$\alpha = \frac{2\pi n_{\text{free}}}{\lambda f_{\text{e}}} \qquad [16]$$

Each system produces a Fourier transform that is scaled specially by α, where the output field is considered in a dielectric with refractive index n_{free}. The effective focal length f_{e} is equal to the focal length of the lens if the element is placed in front of the lens (see top of **Figure 15**), the distance of the element to the lens is of no concern for the resulting intensity,

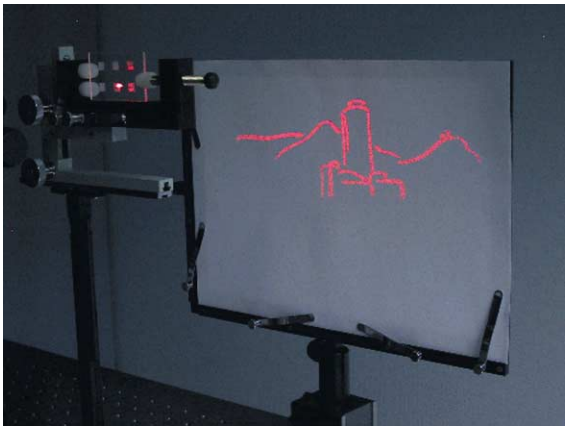

Figure 14 Optical demonstration of the use of a diffuser (see in Figure (right)) transforming a laser diode beam into an intensity displaying the 'skyline' of Jena. No additional optical element is needed! Stray light appears but is laterally separated from the desired signal and thus it is easy to be filtered.

however it is recommended to minimize the distance between element and lens for elements with deflection angles close to the paraxial limit. That avoids light losses due to truncation by the lens aperture. If the focal length itself is chosen as the distance of the element to the lens, a so-called $2f$-setup results, which generate, in addition to the correct magnitude, the correct phase of the Fourier transformation in the focal plane. If an alternative distance to the lens is used, an additional quadratic phase occurs in the focal plane. If the element is placed behind the lens (see middle row of **Figure 15**), f_{e} is the distance between element and focal plane. This setup provides some freedom in adjusting the output scaling. On the other hand, it requires an accurate adjustment of position to obtain a specific scaling. This is not required for the first setup. In order to obtain a specific

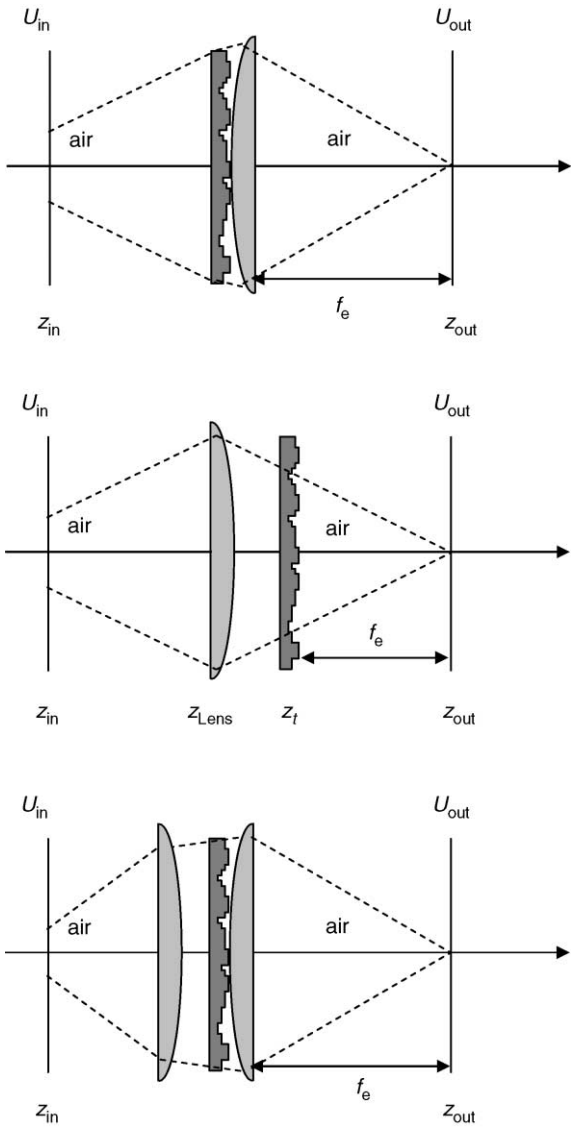

Figure 15 Three setups to realize a Fourier transformation for a beam shaping or diffuser/splitter element, which deflects the light only in a paraxial way. In all cases the output is obtained in the focal plane of the lens.

scaling of the output field $U_{out}(\alpha x, \alpha y)$, the effective focal length and the size of $U_{sig}(k_x, k_y)$ in the k-space must be chosen properly according to eqn [16]. In addition to the size of the output field, its resolution is also of fundamental importance. According to eqn [14] and the convolution theorem the output field is given by

$$U_{out}(k_x, k_y) = \mathcal{F}\ \exp[i\tau(x, y)] * \mathcal{F}\mathcal{P}(\Delta z_{in}) U_{in}(x, y) \quad [17]$$

where $*$ denotes the convolution. For a constant transmission function one would obtain the focus of the input beam. In functional embodiment that is $\mathcal{F}\mathcal{P}(\Delta z_{in}) U_{in}(x, y)$ only. In the structural form, the focus of the beam must be calculated by propagating the input field through the system without the transmission function. The Fourier transformed transmission function, that is $\mathcal{F}\ \exp[i\tau(x, y)]$, is convolved with this beam focus in order to obtain the resulting output field. In beamsplitting that means a replication of the beam. In general the output field can be understood as being composed of numerous replicated beam foci which are overlapping. That makes plausible that the size of the focus of the input beam limits the resolution of the whole output field. The size of the focus is determined by the basic beam focusing lens system and not by the diffractive or refractive element. In conclusion, a highly resolved output field requires a focusing optic with high numerical aperture. For examples, it is not possible to obtain a flat-top beam profile from a Gaussian beam where focus has the same size as the flat-top should have. The steeper the sidewalls of the flat-top profile, the smaller must be the focal spot without the beam shaping element. The choice of a suitable numerical aperture of the lens system must be done before the transmission design is performed because it also determines the extent of the transmission function. The distance Δz_{in} must be chosen in such a way that ensures that the propagated input field illuminates the whole aperture of the system.

If a high numerical aperture on the output side is required to achieve a high resolution, the setup in the middle of Figure 15 should be avoided and the first setup is preferable. Otherwise the element would be illuminated by a highly nonparaxial field which violates the structure design with TEA. With the same argument, but now on the input side, an input field with high divergence should be at least partly collimated to achieve a paraxial illumination of the element. Then, the setup at the bottom of Figure 15 results.

For nonparaxial light transformation, that means the output field is large and hence the transformation requires nonparaxial deflection of the input field; the described transmission and structure design is still useful to obtain an initial design for a further optimization by wave-optical modeling techniques.

Though a Fourier approach to obtain general light transformations seems rather restricted, it covers a broad field of applications. The combination of suitable beam optics with the refractive free-form or diffractive element can be very simple (see optical setup of Figure 14) or very complex. That mainly depends on the resolution and size of the demanded output field as it is well known from imaging systems.

Each design should be finalized with a complete wave-optical analysis, typically including adjustment and fabrication error tolerancing, to achieve a full

understanding of the optical properties of the system. After this final investigation it is ready for fabrication and application providing a further innovation through optics and photonics on the base of wave-optical engineering.

Introduction

Optical communications systems have grown explosively in terms of the capacity that can be transmitted over a single optical fiber. This trend has been fueled by two complementary techniques, those being the increase in data-rate-per-channel coupled with the increase in the total number of parallel wavelength channels. However, there are many considerations as to the total number of wavelength-division-multiplexed (WDM) channels that can be accommodated in a system, including cost, information spectral efficiency, nonlinear effects, and component wavelength selectivity.

Dispersion is one of the critical roadblocks to increasing the transmission capacity of optical fiber. The dispersive effect in an optical fiber has several ingredients, including intermodal dispersion in a multimode fiber, waveguide dispersion, material dispersion, and chromatic dispersion. In particular, chromatic dispersion is one of the critical effects in a single mode fiber (SMF), resulting in a temporal spreading of an optical bit as it propagates along the fiber. At data rates ≤ 2.5 Gbit/s, the effects of chromatic dispersion are not particularly troublesome. For data rates ≥ 10 Gbit/s, however, transmission can be tricky and the chromatic dispersion-induced degrading effects must be dealt with in some way, perhaps by compensation. Furthermore, the effects of chromatic dispersion rise quite rapidly as the bit rate increases – when the bit rate increases by a factor of four, the effects of chromatic dispersion increase by a factor of 16! This article will only deal with the management of chromatic dispersion in single mode fiber.

One of the critical limitations of optical fiber communications comes from chromatic dispersion, which results in a pulse broadening as it propagates along the fiber. This occurs as photons of different frequencies (created by the spreading effect of data modulation) travel at different speeds, due to the frequency-dependent refractive index of the fiber core. Compounding the problems cause by chromatic dispersion is the fact that as bit rates rise, chromatic dispersion effects rise quadratically with respect to the increase in the bit rate. One can eliminate these effects using fiber with zero chromatic dispersion, known as dispersion shifted fiber (DSF). However, with zero dispersion, all channels in a wavelength-division-multiplexed (WDM) system travel at the same speed, in-phase, and a number of deleterious nonlinear effects such as cross-phase modulation (XPM) and four-wave mixing (FWM) result. Thus, in WDM systems, some amount of chromatic dispersion is necessary to keep channels out-of-phase, and as such chromatic dispersion compensation is required. Any real fiber link may also suffer from 'dispersion slope' effects, in which a slightly different dispersion value is produced in each WDM channel. This means that while one may be able to compensate one channel exactly, other channels may progressively accumulate increasing amounts of dispersion, which can severely limit the ultimate length of the optical link and the wavelength range that can be used in a WDM system. This article will address the concepts of chromatic dispersion and dispersion slope management followed by some examples highlighting the need for tunability to enable robust optical WDM systems in dynamic environments. Some dispersion monitoring techniques are then discussed and examples given.

Chromatic Dispersion in Optical Fiber Communication Systems

In any medium (other than vacuum) and in any waveguide structure (other than ideal infinite free space), different electromagnetic frequencies travel at different speeds. This is the essence of chromatic dispersion. As the real fiber-optic world is rather distant from the ideal concepts of both vacuum and infinite free space, dispersion will always be a concern when one is dealing with the propagation of electromagnetic radiation through fiber. The velocity in fiber of a single monochromatic wavelength is constant. However, data modulation causes a broadening of the spectrum of even the most monochromatic laser pulse. Thus, all modulated data have a nonzero spectral width which spans several wavelengths, and the different spectral components of modulated data travel at different speeds. In particular, for digital data intensity modulated on an optical carrier, chromatic

dispersion leads to pulse broadening – which in turn leads to chromatic dispersion limiting the maximum data rate that can be transmitted through optical fiber (see Figure 1).

Considering that the chromatic dispersion in optical fibers is due to the frequency-dependent nature of the propagation characteristics, for both the material (the refractive index of glass) and the waveguide structure, the speed of light of a particular wavelength λ will be expressed as follows, using a Taylor series expansion of the value of the refractive index as a function of the wavelength:

$$v(\lambda) = \frac{c_0}{n(\lambda)} = \frac{c_0}{n_0(\lambda_0) + \frac{\partial n}{\partial \lambda}\delta\lambda + \frac{\partial^2 n}{\partial \lambda^2}(\delta\lambda)^2} \qquad [1]$$

Here, c_0 is the speed of light in vacuum, λ_0 is a reference wavelength, and the terms in $\partial n/\partial\lambda$ and $\partial^2 n/\partial\lambda^2$ are associated with the chromatic dispersion and the dispersion slope (i.e., the variation of the chromatic dispersion with wavelength), respectively. Transmission fiber has positive dispersion, i.e. longer wavelengths result in longer propagation delays. The units of chromatic dispersion are picoseconds per nanometer per kilometer, meaning that shorter time pulses, wider frequency spread due to data modulation, and longer fiber lengths will each contribute linearly to temporal dispersion. Higher data rates inherently have both shorter pulses and wider frequency spreads. Therefore, as network speed increases, the impact of chromatic dispersion rises precipitously as the square of the increase in data rate. The quadratic increase with the data rate is a result of two effects, each with a linear contribution. On one hand, a doubling of the data rate makes the spectrum twice as wide, doubling the effect of dispersion. On the other hand, the same doubling of the data rate makes the data pulses only half as long (hence twice as sensitive to dispersion). The combination of a wider signal spectrum and a shorter pulse width is what leads to the overall quadratic impact. Moreover, the data modulation format used can significantly affect the sensitivity of a system to chromatic dispersion. For example, the common nonreturn-to-zero (NRZ) data format, in which the optical power stays high throughout the entire time slot of a '1' bit, is more robust to chromatic dispersion than is the return-to-zero (RZ) format, in which the optical power stays high in only part of the time slot of a '1' bit. This difference is due to the fact that RZ data have a much wider channel frequency spectrum compared to NRZ data, thus incurring more chromatic dispersion. However, in a real WDM system, the RZ format increases the maximum allowable transmission distance by virtue of its reduced duty cycle (compared to the NRZ format), making it less susceptible to fiber nonlinearities as can be seen in Figure 2.

A rule for the maximum distance over which data can be transmitted is to consider a broadening of the pulse equal to the bit period. For a bit period B, a dispersion value D and a spectral width $\Delta\lambda$, the dispersion-limited distance is given by

$$L_D = \frac{1}{D \cdot B \cdot \Delta\lambda} = \frac{1}{D \cdot B \cdot (cB)} \propto \frac{1}{B^2} \qquad [2]$$

(see Figure 3). For example, for single mode fiber, $D = 17$ ps/nm/km, so for 10 Gbit/s data the distance is $L_D = 52$ km. In fact, a more exact calculation

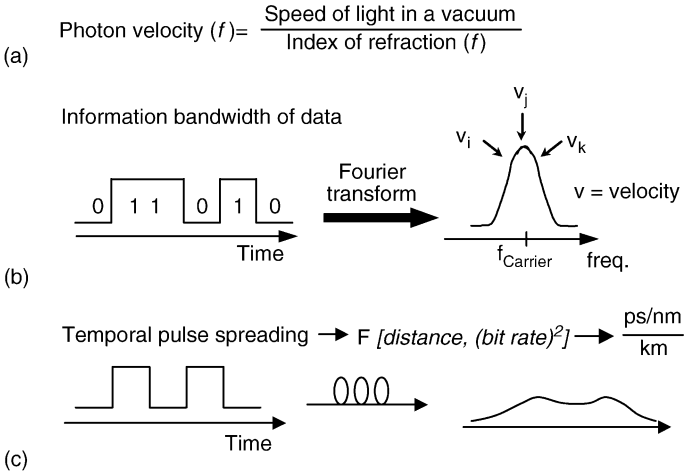

Figure 1 The origin of chromatic dispersion in data transmission. (a) Chromatic dispersion is caused by the frequency-dependent refractive index in fiber. (b) The nonzero spectral width due to data modulation. (c) Dispersion leads to pulse broadening, proportional to the transmission distance and the data rate.

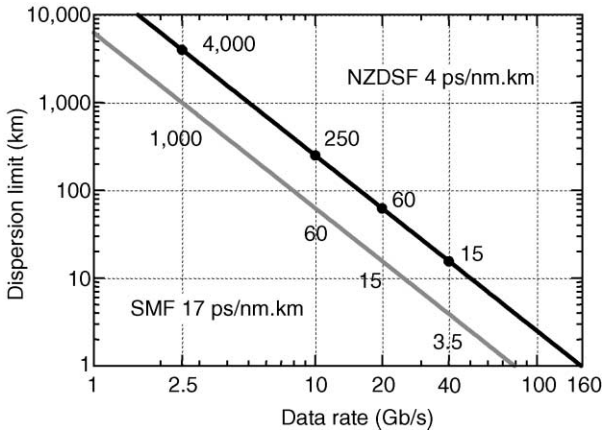

Figure 3 Transmission distance limitations due to uncompensated dispersion in SMF as a function of data rate for intensity modulated optical signals. (Reproduced with permission from Garrett LD (2001) Invited Short Course, *Optical Fiber Communication Conference*.)

shows that for 60 km, the dispersion induced power penalty is less than 1 dB (see Figure 4). The power penalty for uncompensated dispersion rises exponentially with transmission distance, and thus to maintain good signal quality, dispersion compensation is required.

Chromatic Dispersion Management

Optical Nonlinearities as Factors to be Considered in Dispersion Compensation

Even though it is possible to manufacture fiber with zero dispersion, it is not practical to use such fiber for WDM transmission, due to large penalties induced by fiber nonlinearities. Most nonlinear effects originate from the nonlinear refractive index of fiber, which is

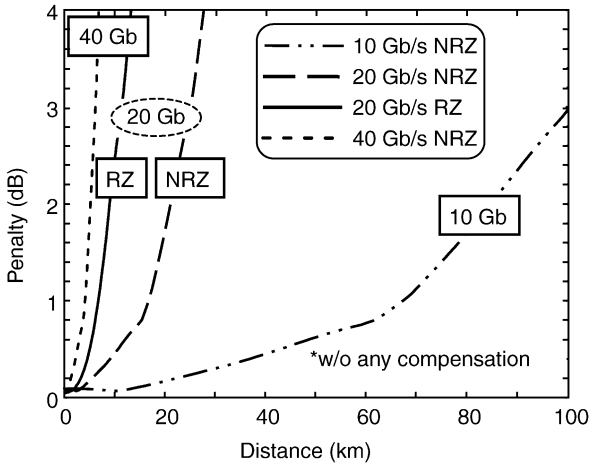

Figure 4 Power penalties due to uncompensated dispersion in single mode fiber (SMF) as a function of distance and data rate. (Reproduced with permission from Garrett LD (2001) Invited Short Course, *Optical Fiber Communication Conference*.)

not only dependent on the frequency of light but also on the intensity (optical power), and is related to the optical power as:

$$\bar{n}(f, P) = n(f) + n_2 \frac{P}{A_{\text{eff}}} \qquad [3]$$

where $n(f)$ is the linear part of the refractive index, P is the optical power inside the fiber, and n_2 is the nonlinear-index coefficient for silica fibers. The typical value of n_2 is 2.6×10^{-20} m^2/W. This number takes into account the averaging of the polarization states of the light as it travels in the fiber. The intensity dependence of the refractive index gives rise to three major nonlinear effects.

Self-phase modulation (SPM)

A million photons 'see' a different glass than does a single photon, and a photon traveling along with many other photons will slow down. SPM occurs because of the varying intensity profile of an optical pulse on a single WDM channel. This intensity profile causes a refractive index profile and, thus, a photon speed differential. The resulting phase change for light propagating in an optical fiber is expressed as:

$$\Phi_{\text{NL}} = \gamma P L_{\text{eff}} \qquad [4]$$

where the quantities γ and L_{eff} are defined as:

$$\gamma = \frac{2\pi n_2}{\lambda A_{\text{eff}}} \quad \text{and} \quad L_{\text{eff}} = \frac{1 - e^{-\alpha L}}{\alpha} \qquad [5]$$

where A_{eff} is the effective mode area of the fiber and α is the fiber attenuation loss. L_{eff} is the effective nonlinear length of the fiber that accounts for fiber loss, and γ is the nonlinear coefficient measured

in rad/km/W. A typical range of values for γ is between 10–30 rad/km/W. Although the nonlinear coefficient is small, the long transmission lengths and high optical powers, that have been made possible by the use of optical amplifiers, can cause a large enough nonlinear phase change to play a significant role in state-of-the-art lightwave systems.

Cross-phase modulation (XPM)

When considering many WDM channels co-propagating in a fiber, photons from channels 2 through N can distort the index profile that is experienced by channel 1. The photons from the other channels 'chirp' the signal frequencies on channel 1, which will interact with fiber chromatic dispersion and cause temporal distortion. This effect is called cross-phase modulation. In a two-channel system, the frequency chirp in channel 1, due to power fluctuation within both channels, is given by

$$\Delta B = \frac{d\Phi_{NL}}{dt} = \gamma L_{eff}\frac{dP_1}{dt} + 2\gamma L_{eff}\frac{dP_2}{dt} \qquad [6]$$

where, dP_1/dt and dP_2/dt are the time derivatives of the pulse powers of channels 1 and 2, respectively. The first term on the right-hand side of the above equation is due to SPM, and the second term is due to XPM. Note that the XPM-induced chirp term is double that of the SPM-induced chirp term. As such, XPM can impose a much greater limitation on WDM systems than can SPM, especially in systems with many WDM channels.

Four-wave-mixing (FWM)

The optical intensity propagating through the fiber is related to the electric field intensity squared. In a WDM system, the total electric field is the sum of the electric fields of each individual channel. When squaring the sum of different fields, products emerge that are beat terms at various sum and difference frequencies to the original signals. Figure 5 depicts that if a WDM channel exists at one of the four-wave-mixing beat-term frequencies, then the beat term will interfere coherently with this other WDM channel and potentially destroy the data.

Dispersion Maps

While zero-dispersion fiber is not a good idea, a large value of the accumulated dispersion at the end of a fiber link is also undesirable. An ideal solution is to have a 'dispersion map,' alternating sections of positive and negative dispersion as can be seen in Figure 6. This is a very powerful concept: at each point along the fiber the dispersion has some nonzero value, eliminating FWM and XPM, but the total dispersion at the end of the fiber link is zero, so that no pulse broadening is induced (Table 1). The most advanced systems require periodic dispersion compensation, as well as pre- and post-compensation (before and after the transmission fiber).

The addition of negative dispersion to a standard fiber link has been traditionally known as 'dispersion compensation,' however, the term 'dispersion management' is more appropriate. SMF has positive dispersion, but some new varieties of nonzero dispersion-shifted fiber (NZDSF) come in both positive and negative dispersion varieties. Some examples are shown in Figure 7. Reverse dispersion fiber is also now available, with a large dispersion

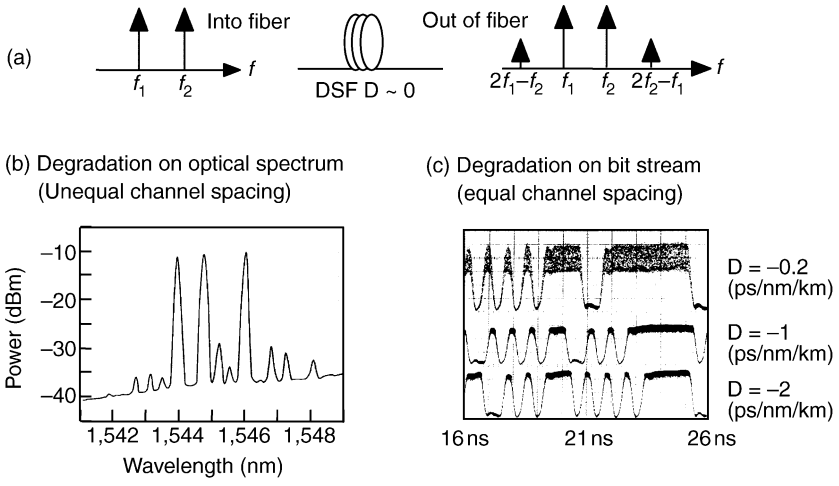

Figure 5 (a) and (b) FWM induces new spectral components via nonlinear mixing of two wavelength signals. (c) The signal degradation due to FWM products falling on a third data channel can be reduced by even small amounts of dispersion. (Reproduced with permission from Tkach RW, Chraplyvy AR, Forghieri F, Gnauck AH and Derosier RM (1995) Four-photon mixing and high-speed WDM systems. *Journal of Photon Technology* 13(5): 841–849.)

comparable to that of SMF, but with the opposite sign. When such flexibility is available in choosing both the magnitude and sign of the dispersion of the fiber in a link, dispersion-managed systems can be fully optimized to the desired dispersion map using a combination of fiber and dispersion compensation devices (see Figure 8).

Dispersion is a linear process, so first-order dispersion maps can be understood as linear systems. However, the effects of nonlinearities cannot be ignored, especially in WDM systems, with many tens of channels, where the launch power may be very high. In particular, in systems deploying dispersion compensating fiber (DCF), the large nonlinear coefficient of the DCF can dramatically affect the dispersion map.

Corrections to Linear Dispersion Maps

Chromatic dispersion is a necessity in WDM systems, to minimize the effects of fiber nonlinearities. A chromatic dispersion value as small as a few ps/nm/km is usually sufficient to make XPM and FWM negligible. To mitigate the effects of nonlinearities but maintain small amounts of chromatic dispersion, NZDSF is commercially available. Due to these nonlinear effects, chromatic dispersion must be managed, rather than eliminated.

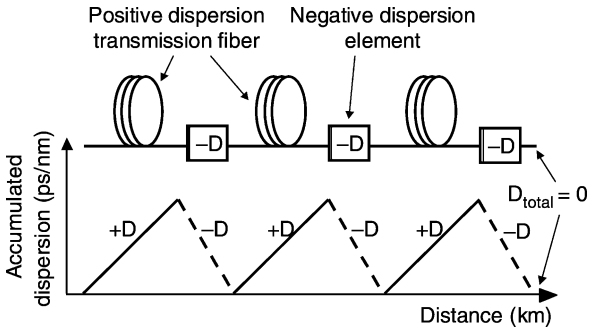

Figure 6 Dispersion map of a basic dispersion managed system. Positive dispersion transmission fiber alternates with negative dispersion compensation elements such that the total dispersion is zero end-to-end.

If a dispersion-management system was perfectly linear, it would be irrelevant whether the dispersion along a path is small or large, as long as the overall dispersion is compensated to zero (end to end). Thus, in a linear system the performance should be similar, regardless of whether the transmission fiber is SMF, and dispersion compensation modules are deployed every 60 km, or the transmission fiber is NZDSF (with approximately a quarter of the dispersion value of SMF) and dispersion compensation modules are deployed every 240 km. In real life, optical nonlinearities are very important, and recent results seem to favor the use of large, SMF-like, dispersion values in the transmission path and correspondingly high dispersion compensation devices. A recent study of performance versus channel spacing showed that the capacity of SMF could be more than four times that of NZDSF. This is because the nonlinear coefficients are much higher in NZDSF than in SMF, and for dense WDM the channel interactions become a limiting factor. A critical conclusion is that not all dispersion compensation maps are created equal: a simple calculation of the dispersion compensation, to cancel the overall dispersion value, does not lead to optimal dispersion map designs.

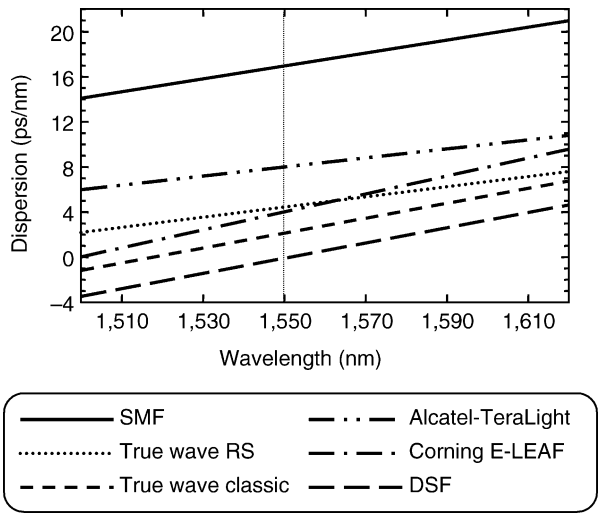

Figure 7 Chromatic dispersion characteristics of various commercially available types of transmission fiber.

Table 1 Commercially available fibers and their characteristics

	Dispersion @ 1,550 nm [ps/nm/km]	*Dispersion slope [ps/nm^2/km]*	*Attenuation [dB]*	*Mode field diameter [μm]*	*PMD [ps/km$^{0.5}$]*
SMF	18	0.08	≤0.25	11	≤0.5
Tera Light	8.0	0.058	≤0.2	9.2	≤0.04
TW-RS	4.4	0.043	≤0.25	8.4	≤0.03

Standard DCF	−90	−0.22	≤0.5	5.2	≤0.08

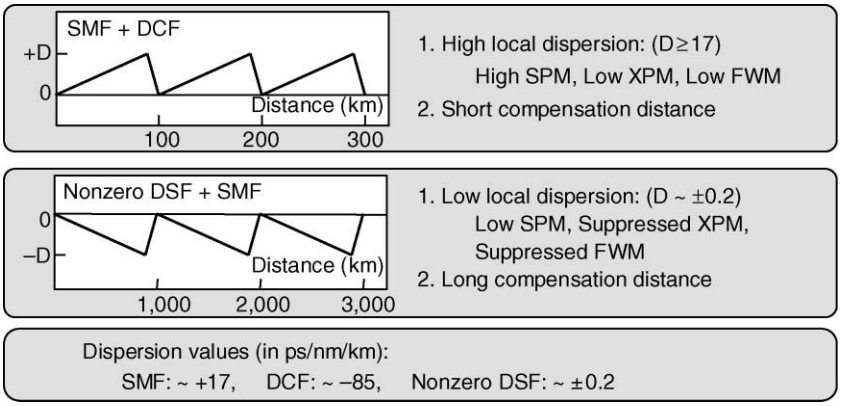

Figure 8 Various dispersion maps for SMF-DCF and NZDSF-SMF.

Additionally, several solutions have been shown to be either resistant to dispersion, or have been shown to rely on dispersion itself for transmission. Such solutions include chirped pulses (where prechirping emphasizes the spectrum of the pulses so that dispersion does not broaden them too much), dispersion assisted transmission (where an initial phase modulation tailored to the transmission distance leads to full-scale amplitude modulation at the receiver end due to the dispersion), and various modulation formats robust to chromatic dispersion and nonlinearities.

Dispersion Management Solutions

Fixed Dispersion Compensation

From a systems point of view, there are several requirements for a dispersion compensating module: low loss, low optical nonlinearity, broadband (or multichannel) operation, small footprint, low weight, low power consumption, and clearly low cost. It is unfortunate that the first dispersion compensation modules, based on DCF only, met two of these requirements: broadband operation and low power consumption. On the other hand, several solutions have emerged that can complement or even replace these first-generation compensators.

Dispersion compensating fiber (DCF)

One of the first dispersion compensation techniques was to deploy specially designed sections of fiber with negative chromatic dispersion. The technology for DCF emerged in the 1980s and has developed dramatically since the advent of optical amplifiers in 1990. DCF is the most widely deployed dispersion compensator, providing broadband operation and stable dispersion characteristics, and the lack of a dynamic, tunable DCF solution has not reduced its popularity.

As can be seen in Figure 9, the core of the average dispersion compensating fiber is much smaller than that of standard SMF, and beams with longer wavelengths experience relatively large changes in mode size (due to the waveguide structure) leading to greater propagation through the cladding of the fiber, where the speed of light is greater than that of the core. This leads to a large negative dispersion value. Additional cladding layers can lead to improved DCF designs that can include negative dispersion slope to counteract the positive dispersion slope of standard SMF.

In spite of its many advantages, DCF has a number of drawbacks. First, it is limited to a fixed compensation value. In addition, DCF has a weakly guiding structure and has a much smaller core cross-section, 19 μm^2, compared to the 85 μm^2 of SMF. This leads to higher nonlinearity, higher splice losses, as well as higher bending losses. Last, the length of DCF required to compensate for SMF dispersion is rather long, about one-fifth of the length of the transmission fiber for which it is compensating. Thus DCF modules induce loss, and are relatively bulky and heavy. The bulk is partly due to the mass of fiber, but also due to the resin used to hold the fiber securely in place. One other contribution to the size of the module is the higher bend loss associated with the refractive index profile of DCF; this limits the radius of the DCF loop to 6–8 inches, compared to the minimum bend radius of 2 inches for SMF.

Traditionally, DCF-based dispersion compensation modules are usually located at amplifier sites. This serves several purposes. First, amplifier sites offer relatively easy access to the fiber, without requiring any digging or unbraiding of the cable. Second, DCF has high loss (usually at least double that of standard SMF), so a gain stage is required

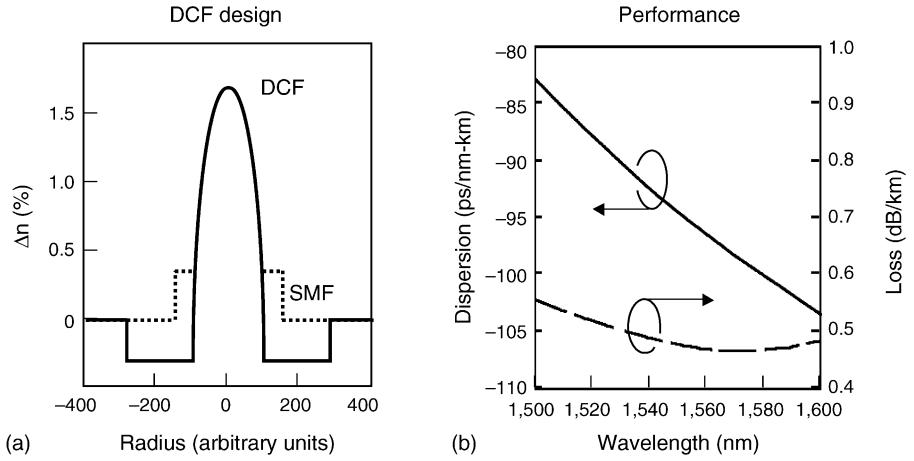

Figure 9 Typical DCF (a) refractive index profile and (b) dispersion and loss as a function of wavelength. Δn is defined as refractive index variation relative to the cladding.

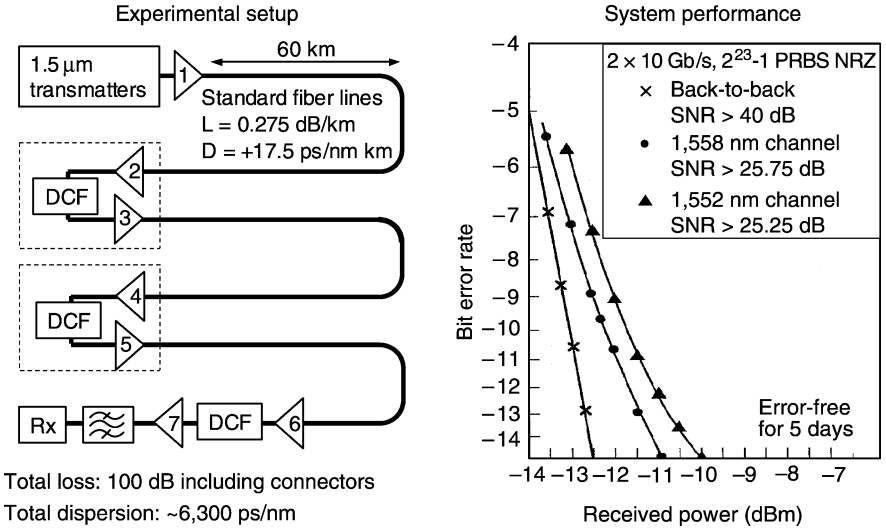

Figure 10 System demonstration of dispersion compensation using DCF. (Reproduced with permission from Park YK, Yeates PD, Delavaux J-MP, *et al.* (1995) A field demonstration of 20-Gb/s capacity transmission over 360 km of installed standard (non-DSF) fiber. *Photon. Technol. Lett.* 7(7): 816–818.)

before the DCF module to avoid excessively low signal levels. DCF has a cross-section four times smaller then SMF, hence a higher nonlinearity, which limits the maximum launch power into a DCF module. The compromise is to place the DCF in the mid-section of a two-section EDFA. This way, the first stage provides pre-DCF gain, but not to a power level that would generate excessive nonlinear effects in the DCF. The second stage amplifies the dispersion compensated signal to a power level suitable for transmission though the fiber link. This launch power level is typically much higher than could be transmitted through DCF without generating large nonlinear effects. Many newer dispersion compensation devices have better performance than DCF, in particular lower loss and lower nonlinearities. For this reason, they may not have to be deployed at the mid-section of an amplifier. Figure 10 shows the real demonstration results using the DCF.

Chirped fiber Bragg gratings

Fiber Bragg gratings have emerged as major components for dispersion compensation because of their low loss, small footprint, and low optical nonlinearity. Bragg gratings are sections of single-mode fiber in which the refractive index of the core is modulated in a periodic fashion, as a function of the spatial coordinate along the length of the fiber. When the spatial periodicity of the modulation matches what is known as a Bragg condition with respect to the wavelength of light propagating through the grating,

the periodic structure acts like a mirror, reflecting the optical radiation that is traveling through the core of the fiber. An optical circulator is traditionally used to separate the reflected output beam from the input beam.

When the periodicity of the grating is varied along its length, the result is a chirped grating which can be used to compensate for chromatic dispersion. The chirp is understood as the rate of change of the spatial frequency as a function of position along the grating. In chirped gratings the Bragg matching condition for different wavelengths occurs at different positions along the grating length. Thus, the roundtrip delay of each wavelength can be tailored by designing the chirp profile appropriately. Figure 11 compares the chirped FBG with uniform FBG. In a data pulse that has been distorted by dispersion, different frequency components arrive with different amounts of relative delay. By tailoring the chirp profile such that the frequency components see a relative delay which is the inverse of the delay of the transmission fiber, the pulse can be compressed back. The dispersion of the grating is the slope of the time delay as a function of wavelength, which is related to the chirp.

The main drawback of Bragg gratings is that the amplitude profile and the phase profile as a function of wavelength have some amount of ripple. Ideally, the amplitude profile of the grating should have a flat (or rounded) top in the passband, and the phase profile should be linear (for linearly chirped gratings) or polynomial (for nonlinearly chirped gratings). The grating ripple is the deviation from the ideal profile shape. Considerable effort has been expended on reducing the ripple. While early gratings were plagued by more than 100 ps of ripple, published results have shown vast improvement to values close to ± 3 ps.

Higher order mode dispersion compensation fiber

One of the challenges of designing standard DCF is that high negative dispersion is hard to achieve unless the cross-section of the fiber is small (which leads to high nonlinearity and high loss). One way to reduce both the loss and the nonlinearity is to use a higher-order mode (HOM) fiber (LP_{11} or LP_{02} near cutoff instead of the LP_{01} mode in the transmission fiber).

Such a device requires a good-quality mode converter between LP_{01} and LP_{02} to interface between the SMF and HOM fiber. HOM fiber has a dispersion per unit length greater than six times that of DCF. Thus, to compensate for a given transmission length in SMF, the length of HOM fiber required is only one sixth the length of DCF. Thus, even though losses and nonlinearity per unit length are larger for HOM fiber than for DCF, they are smaller overall, because of the shorter HOM fiber length. As an added bonus, the dispersion can be tuned slightly by changing the cutoff wavelength of LP_{02} (via temperature tuning). A soon to be released HOM fiber-based commercial dispersion compensation module is not tunable, but can fully compensate for dispersion slope.

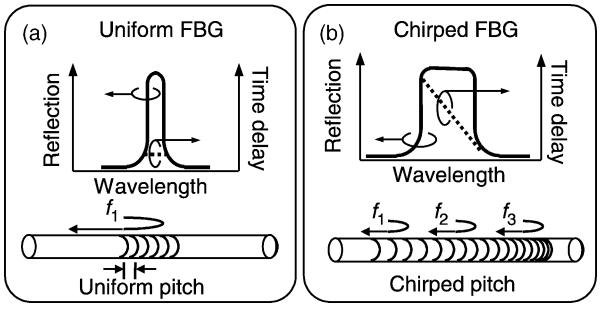

Figure 11 Uniform and chirped FBGs. (a) A grating with uniform pitch has a narrow reflection spectrum and a flat time delay as a function of wavelength. (b) A chirped FBG has a wider bandwidth, a varying time delay and a longer grating length.

Tunable Dispersion Compensation

The need for tunability

In a perfect world, all fiber links would have a known, discrete, and unchanging value of chromatic dispersion. Network operators would then deploy fixed dispersion compensators periodically along every fiber link to exactly match the fiber dispersion. Unfortunately, several vexing issues may necessitate that dispersion compensators are tunability, that they have the ability to adjust the amount of dispersion to match system requirements.

First, there is the most basic business issue of inventory management. Network operators typically do not know the exact length of a deployed fiber link nor its chromatic dispersion value. Moreover, fiber plants periodically undergo upgrades and maintenance, leaving new and nonexact lengths of fiber behind. Therefore, operators would need to keep in stock a large number of different compensator models, and even then the compensation would only be approximate. Second, we must consider the sheer difficulty of 40 Gbit/s signals. The tolerable threshold for accumulated dispersion for a 40 Gbit/s data channel is 16 times smaller than at 10 Gbit/s. If the compensation value does not exactly match the fiber to within a few percent of the required dispersion value, then the communication link will not work. Tunability is considered a key enabler for this bit rate (see Figures 12 and 13). Third, the accumulated dispersion changes slightly with temperature, which begins to be an issue for 40 Gbit/s systems and 10 Gbit/s ultra long-haul systems. In fiber, the zero-dispersion wavelength changes with temperature at a

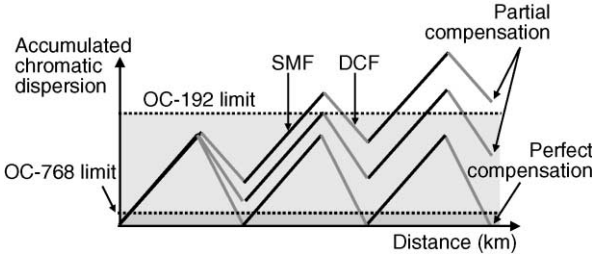

Figure 12 The need for tunability. The tolerance of OC-768 systems to chromatic dispersion is 16 times lower than that of OC-192 systems. Approximate compensation by fixed in-line dispersion compensators for a single channel may lead to rapid accumulation of unacceptable levels of residual chromatic dispersion.

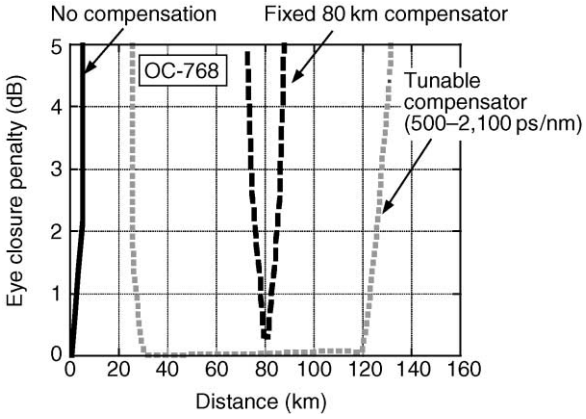

Figure 13 Tunable dispersion compensation at OC-768 (40 Gb/s) is essential for achieving a comfortable range of acceptable transmission distances (80 km for tunable, only ~4 km for fixed compensation).

typical rate of 0.03 nm/°C. It can been shown that a not-uncommon 50 °C variation along a 1,000 km 40 Gbit/s link can produce significant degradation (see Figure 14). Fourth, we are experiencing the dawn of reconfigurable optical networking. In such systems, the network path, and therefore the accumulated fiber dispersion, can change. It is important to note that even if the fiber spans are compensated span-by-span, the pervasive use of compensation at the transmitter and receiver suggests that optimization and tunability based on path will still be needed.

Other issues that increase the need for tunability include: (i) laser and (de)mux wavelength drifts for which a data channel no longer resides on the flat-top portion of a filter, thereby producing a chirp on the signal that interacts with the fiber's chromatic dispersion; (ii) changes in signal power that change both the link's nonlinearity and the optimal system dispersion map; and (iii) small differences that exist in transmitter-induced signal chirp.

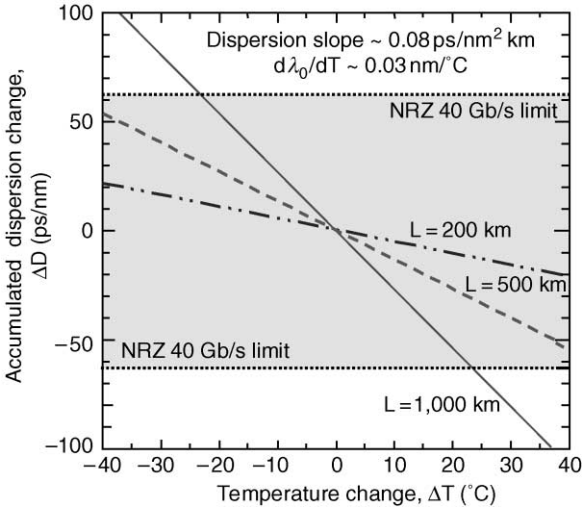

Figure 14 Accumulated dispersion changes as a function of the link length and temperature fluctuation along the fiber link.

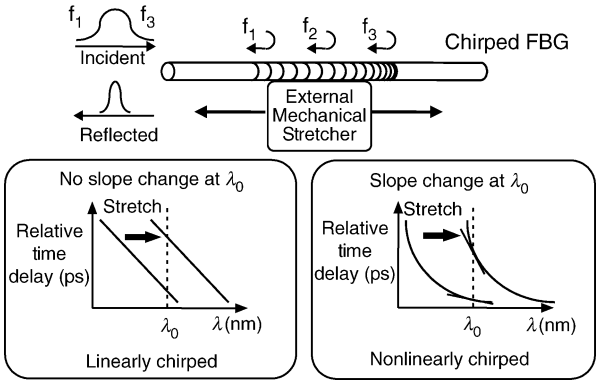

Figure 15 Tuning results for both linearly and nonlinearly chirped FBGs using uniform stretching elements. The slope of the dispersion curve at a given wavelength λ_0 is constant when the linearly chirped grating is stretched, but changes as the nonlinearly chirped grating is stretched.

Approaches to tunable dispersion compensation

A host of techniques for tunable dispersion compensation have been proposed in recent years. Some of these ideas are just interesting research ideas, but several have strong potential to become viable technologies.

Fiber gratings offer the inherent advantages of fiber compatibility, low loss, and low cost. If a FBG has a refractive-index periodicity that varies nonlinearly along the length of the fiber, it will produce a time delay that also varies nonlinearly with wavelength (see Figure 15). Herein lies the key to tunability. When a linearly chirped grating is stretched uniformly by a single mechanical element, the time delay curve is shifted towards longer wavelengths, but the slope of the ps-vs.-nm curve remains constant at all wavelengths within the passband. When a

nonlinearly-chirped grating is stretched, the time delay curve is shifted toward longer wavelengths, but the slope of the ps-vs.-nm curve at a specific channel wavelength changes continuously. Ultimately, tunable dispersion compensators should accommodate multichannel operation. Several WDM channels can be accommodated by a single chirped FBG in one of two ways: fabricating a much longer (i.e., meters-length) grating, or using a sampling function when writing the grating, thereby creating many replicas of transfer function of the FBG in the wavelength domain (see Figure 16).

One free-space-based tunable dispersion compensation device is the virtually imaged phased array (VIPA), based on the dispersion of a Fabry–Perot interferometer. The design requires several lenses, a movable mirror (for tunability), and a glass plate with a thin film layer of tapered reflectivity for good mode matching. Light incident on the glass plate undergoes several reflections inside the plate. As a result, the beam is imaged at several virtual locations, with a spatial distribution that is wavelength-dependent.

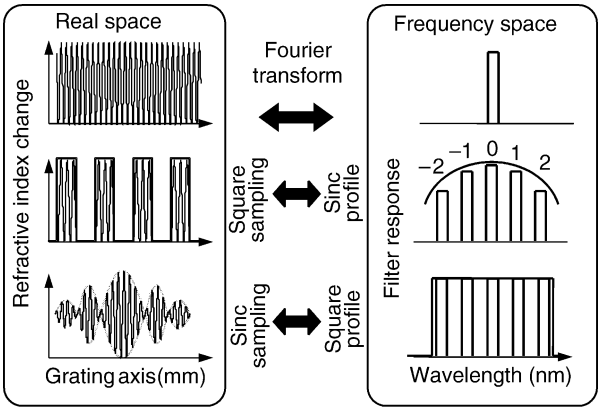

Figure 16 The concept of 'sampled' FBGs, where a superstructure is written on top of the grating that produces a Fourier transform in the frequency domain, leading to multiple grating passbands.

Several devices used for dispersion compensation can be integrated on a chip, using either an optical chip media (semiconductor-based laser or amplifier medium) or an electronic chip. One such technology is the micro-ring resonator, a device that, when used in a structure similar to that of an all-pass filter (see Figure 17), can be used for dispersion compensation on a chip-scale. Although these technologies are not yet ready for deployment as dispersion compensators, they have been used in other applications and have the potential to offer very high performance at low cost.

As the ultimate optical dispersion compensation devices, photonic bandgap fibers (holey fibers) are an interesting class in themselves (see Figure 18). These are fibers with a hollow structure, with holes engineered to achieve a particular functionality. Instead of being drawn from a solid preform, holey fibers are drawn from a group of capillary tubes fused together. This way, the dispersion, dispersion slope, the nonlinear coefficients could in principle all be precisely designed and controlled, up to very small or very large values, well outside the range of those of the solid fiber.

Lett.* 11(6): 674–676.)

Dispersion Slope Mismatch

Transmission fiber, especially fiber with dispersion compensation built in, may suffer from a dispersion slope in which a slightly different dispersion value is produced for each WDM channel (see Figure 19). Even though the compensator would be able to cancel the dispersion of the fiber at the design wavelength, there will be residual dispersion left at the other wavelength channels unless the compensator can match the slope of the dispersion curve of the fiber as well. Some solutions for dispersion slope compensation are described in this section.

First, DCF, with negative dispersion slope, is a prime candidate for deployment as a dispersion slope compensator even though it cannot easily be made tunable. By designing the DCF with the same ratio of dispersion to dispersion slope as that of a real fiber link, new types of DCF can be used to compensate for both dispersion and dispersion slope, much like DCF is used for dispersion compensation today. DCF's popularity, wideband functionality, and stable dispersion characteristics make this a particularly attractive solution. Designing the DCF to match the dispersion characteristics of the transmission fiber is the critical engineering challenge in this slope compensation scheme. Second, third-order nonlinearly chirped FBG can act as a tunable dispersion slope compensator. A simple modification of the nonlinearly chirped FBG allows tuning of the compensated dispersion slope value via stretching the grating. The grating is prepared such that the time delay as a function of wavelength has a cubic profile that covers several WDM channels over a continuous bandwidth of many nanometers. Since the resulting dispersion curve is quadratic over the grating bandwidth, the dispersion slope experienced by the WDM channels can be tuned by stretching the grating using a single mechanical element (see Figure 20). Third, combining the VIPA, with either a 3D mirror or diffraction grating, can also provide tunable free-space dispersion slope compensation. Slope tuning is achieved by dynamically controlling the MEMS-based 3D mirror or the diffraction grating. Fourthly, using an FBG with many spaced thin-film heater sections can also enable tunable dispersion slope. Each heater can be individually electrically controlled, allowing the time delay profile of the grating to be dynamically tuned via changing the temperature along the length of the grating. Advanced applications of this technique can allow alterations to the entire time delay profile of the grating, providing a truly flexible dispersion and dispersion slope compensation mechanism.

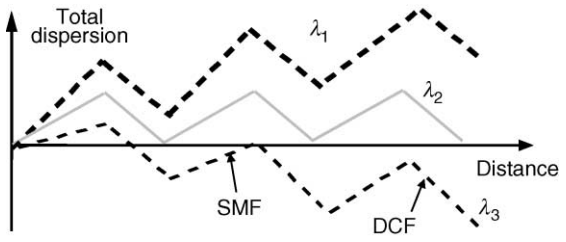

Figure 19 The chromatic dispersion slope mismatch caused by the different slopes of transmission fiber (SMF or NZDSF) and DCF.

Chromatic Dispersion Monitoring

Another important issue related to dispersion management is dispersion monitoring techniques. In a reconfigurable system, it is necessary to reconfigure

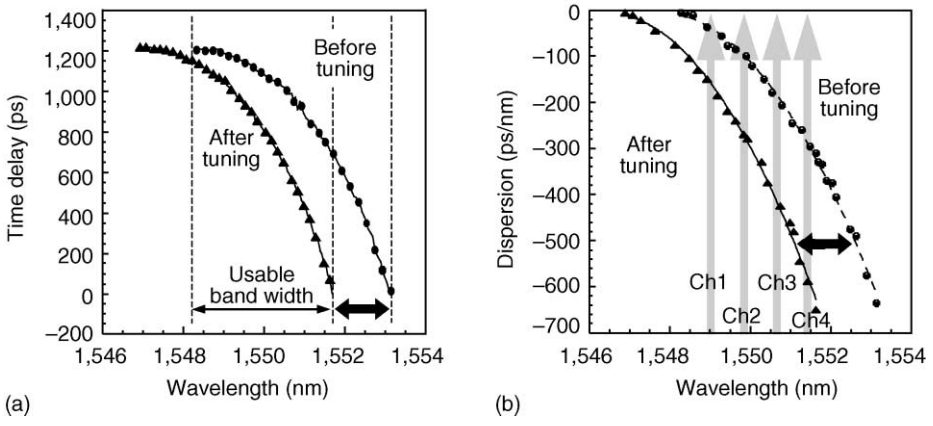

Figure 20 Tunable dispersion slope compensation using a third-order nonlinearly chirped FBG. (a) Cubic time delay curves of the grating, and (b) quadratic dispersion curves showing the change in dispersion in each channel before and after tuning. (Reproduced with permission from Song YW, Motoghian SMR, Starodubov D, *et al.* (2002) Tunable dispersion slope compensation for WDM systems using a non-channelized third-order-chirped FBG. *Optical Fiber Communication Conference* 2002. Paper ThAA4.)

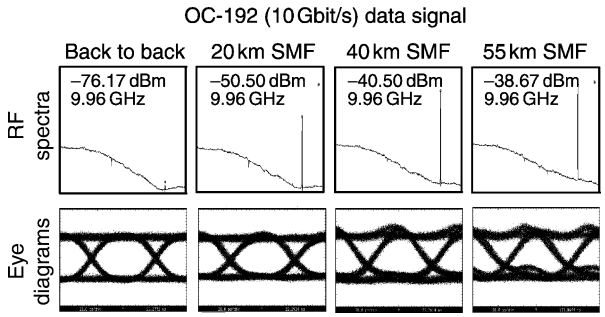
any tunable chromatic dispersion compensation modules on the fly as the network changes. An in-line chromatic dispersion monitor can quickly measure the required dispersion compensation value while data are still being transmitted through the optical link. This is very different from the more traditional chromatic dispersion measurement techniques where dark fiber is used and the measurement is done off-line over many hours (or days).

Chromatic dispersion monitoring is most often done at the receiving end, where the Q-factor of the received data or some other means is employed to assess the accumulated dispersion. Existing techniques that can monitor dispersion in-line, fast, and with relatively low cost include: (i) general performance monitoring using the bit-error rate (BER) or eye opening, but this approach cannot differentiate among different degrading effects; (ii) detecting the intensity modulation induced by phase modulation at the transmitter; (iii) extracting the bit-rate frequency component (clock) from photo-detected data and monitoring its RF power (see Figure 21); (iv) inserting a subcarrier at the transmitter and subsequently monitoring the subcarrier power degradation; (v) extracting several frequency components from the optical data using very narrow-band optical filters and detecting the optical phase; (vi) dithering the optical-carrier frequency at the transmitter and measuring the resultant phase modulation of the clock extracted at receiver with an additional phase-locked loop; and (vii) using an optical filter to select the upper and lower vestigial sideband (VSB) signals in transmitted optical data and determine the relative group delay caused by dispersion (see Figure 22).



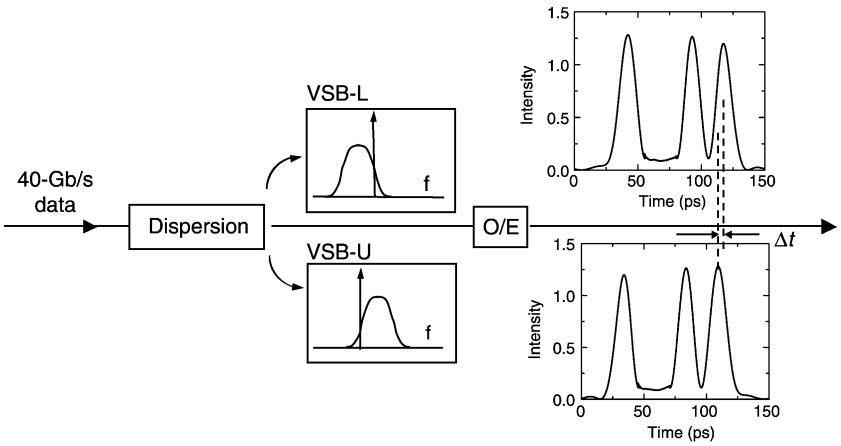


Figure 21 Clock regenerating effect due to chromatic dispersion for NRZ data. As the amount of residual dispersion increases, so does the amount of power at the clock frequency. This power can be used to monitor the amount of uncompensated chromatic dispersion. (Reproduced with permission from Pan Z, Yu Q, Xie Y, *et al.* (2001) Chromatic dispersion monitoring and automated compensation for NRZ and RZ data using clock regeneration and fading without adding signalling. *Optical Fiber Communication Conference 2001.* Paper WH5.)

Conclusion

Chromatic dispersion is a phenomenon with profound implications for optical fiber communications systems. It has negative effects, broadening data pulses, but it also helps reduce the effects of fiber nonlinearities. For this reason, managing dispersion, rather than trying to eliminate it altogether, is the key. Fixed dispersion components are suitable for point-to-point OC-192 systems. Tunable dispersion components are essential for dispersion management in reconfigurable and OC-768 systems. These dispersion compensation elements must have low loss, low nonlinearity, and must be cost effective.

Clock phase shift = $2\pi \times R_b \times$ (Time delay) = f(dispersion)

Figure 22 Chromatic dispersion monitoring using the time delay (Δt) between two VSB signals, which is a function of chromatic dispersion. (Reproduced with permission from Yu Q, Yan L-S, Pan Z and Willner AE (2002) Chromatic dispersion monitor for WDM systems using vestigial-sideband optical filtering. *Optical Fiber Communication Conference 2002.* Paper WE3.)

Although several technologies have emerged that meet some or all of the above requirements, no technology is a clear winner. The trend is towards tunable devices, or even actively self-tunable compensators, and such devices will allow system designers to cope with the shrinking system margins and with the emerging rapidly reconfigurable optical networks.

List of Units and Nomenclature

Chromatic dispersion	The time-domain pulse broadening in an optical fiber caused by the frequency dependence of the refractive index. This results in photons at different frequencies traveling at different speeds [ps/nm/km].
Chromatic dispersion slope	Different wavelengths have different amounts of dispersion values in an optical fiber [ps/nm^2/km].
Conventional single mode fiber (SMF)	Fiber that transmits only a single optical mode by virtue of a very small core diameter relative to the cladding. Provides lowest loss in the 1,550 nm region and has zero dispersion at 1,300 nm.
Cross-phase modulation (XPM)	A nonlinear Kerr effect in which a signal undergoes a nonlinear phase shift induced by a copropagating signal at a different wavelength in a WDM system.
Dispersion compensating fiber (DCF)	Optical fiber that has both a large negative dispersion and dispersion slope around 1,550 nm.
Fiber Bragg gratings (FBGs)	A small section of optical fiber in which there is a periodic change of refractive index along the core of the fiber. An FBG acts as a wavelength-selective mirror, reflecting only specific wavelengths (Bragg wavelengths) and passing others.
Four-wave mixing (FWM)	A nonlinear Kerr effect in which two or more signal wavelengths interact to generate a new wavelength.
Kerr effect	Nonlinear effect in which the refractive index of optical fiber varies as a function of the intensity of light within the fiber core.
Modulation	The process of encoding digital data onto an optical signal so it can be transmitted through an optical network.
Nonlinear effects	Describes the nonlinear responses of a dielectric to intense electromagnetic fields. One such effect is the intensity dependence of the refractive index of an optical fiber (Kerr effect).
Nonzero dispersion-shifted fiber (NZDSF)	Optical fiber that has a small amount of dispersion in the 1,550 nm region in order to reduce deleterious nonlinear effects.
Polarization mode dispersion (PMD)	Dispersion resulting from the fact that different light polarizations within the fiber core will travel at different speeds through the optical fiber [ps/km$^{0.5}$].
Self-phase modulation (SPM)	A nonlinear Kerr effect in which a signal undergoes a self-induced phase shift during propagation in optical fiber.
Wavelength division multiplexing (WDM)	Transmitting many different wavelengths down the same optical fiber at the same time in order to increase the amount of information that can be carried.

Introduction

This article is a brief review of display technology being used today. It emphasizes some of the optical aspects of displays. The details of the basic construction of the display devices are also discussed to aid in understanding. The displays covered are the CRT, VFD, FED, PDP, LED, OLED, LCD-AMLCD, transmissive and transflective LCDs.

Definition of a Display

A display can be defined as an object which transfers information to the viewer and/or an output unit that gives a visual representation of data.

Optical Characteristics of a Display

A display has (in general) the optical characteristics of luminance, reflectivity, contrast ratio, color, surface gloss, resolution, and image sharpness (sometimes called small area contrast). Measurement methods can be obtained from the EIA (Electronics Industries Alliance), JT-31 (Optical Characteristics of Display Devices), SAE (Society of Automotive Engineers and ISO Standards) and VESA Standards, to name a few.

Luminance

The luminance of a display is its light output and is given in units of candela/square meter or cd/m^2 (in the English system fL). Luminance is measured using a photometer, photometer/colorimeter, or spectroradiometer.

Illuminance

The illuminance is the light incident on the surface being measured. Its units are Lumen per m^2 or Lux (and in the English system Ft.cd). This is measured using illuminance meters.

Reflectivity

The reflectivity for CRTs (cathode ray tubes) is measured with incident light at 45 degrees (in some cases for LCDs, a smaller 30 degree angle is used). The reflected light from the surface is measured with a detector normal to (perpendicular to) the surface. Devices such as 'tube face reflectivity' (TFR) can be used to measure this parameter and it is published in the EIA-JT-31 measurement methods. Other similar methods are used for flat panel displays.

Color

Although color perception is different for different individuals, standard responses to color stimuli have been developed and we can measure the color of different objects and display images. Color can be measured with such equipment as a colorimeter or spectroradiometer. The output data are given in various color systems. Color systems, such as the 1931 CIE (Commission International de I'Eclairage) Color System (x, y), the 1960 CIE (u, v) or 1976 CIE (u', v') color coordinates are all used. All these color systems can be converted to each other by simple mathematical relations and these conversions are usually available to the user in the data output. The choice of the color space/system is dependent on application but the system in most general use for displays is the 1976 CIE (u', v'). This color system has become more widely used because equally perceived color differences in this color system are at almost equal distances in this color space. In reality, the quest for a system with equal distances equating to equal color differences can be achieved through a complicated matrix approach in which the constants used in the matrix vary from point to point in the color space.

Gloss

Gloss is a measure of surface reflectivity under Snell's Law criteria (equal incidence and reflection angles). The measurement angles of 20, 45, 60, and 85 degrees are used to measure the gloss of common surfaces. Display glass surface measurements tend to use the 60 degree gloss angle. The surface of a display can be made rougher to scatter incident light away from the viewer or it can be optically coated to reduce the reflected light to achieve improved viewing. Some times both methods are used. Reduced gloss surfaces also are involved with the reduction in surface glare. The level of increased roughness of the surface affects the user's ability to see detail.

Contrast Ratio

When people talk about contrast they generally mean 'contrast ratio'. The contrast ratio (CR) of an area on a display is a unitless parameter and is defined as the excited luminance (L_e) divided by

the unexcited luminance (L_u). The excited luminance (L_e) equals the glass transmission (T) times some excited internal luminance (L_{ei}) and for simplicity, L_u equals T times an internal zero ambient unexcited luminance light level of (L_{ui}). Factors, such as internal scattered light in LCDs and scattered electrons and scattered light in CRTs, give a nonzero un-excited luminance L_u.

When dealing with the CR, the effect of ambient illumination A contributes to the numerator and the denominator. Thus, when the ambient illumination is increased, it lowers the contrast ratio. In a simple case where the ambient illumination is reflected from the surface of the display whose reflectivity is ρ, the contrast ratio is given below:

$$\mathrm{CR} = (L_e + A\rho)/(L_u + A\rho) \quad [1]$$

For the case of the reflectivity of a phosphor screen (reflectance R) coated panel with a glass transmission (T), the reflectivity to first approximation is

$$\rho = cRT^2 \quad [2]$$

where c is a constant.

So we see that changes in contrast can come about through changing the display's glass panel transmission. For example, if the L_e of the white field of a CRT was 100 fL with a 90% panel glass (along with $R = 0.5$) and had a L_u of 2 fL, then the zero ambient contrast would be 50. However, with an ambient illumination of 50 Ftcd the contrast would be 4.76. Now, when we use a 50% transmission panel glass at the ambient illumination of 50 Ft.cd the CR is increased to approximately 8.39. Equations [1] and [2] show how to calculate the contrast. It should be noted that decreased panel glass transmission or the use of 'dark glass' increases contrast because the reflectivity is a 'T squared' effect and the luminance L is a function 'T'. There are second-order effects involved with the reduction of reflected light and unexcited luminance which make the equations more complicated. These second-order effects will not be covered as they are beyond the basic discussion of this article.

In comparing display CR, one must compare the displays at the same ambient illumination. Additionally, you will find that a number of flat panel display advertising reports will report the CR at zero ambient illumination. As we have shown, these CR values are the highest ones for the display. The CR for emissive displays tends to be constant over a wide range of viewing angles, whereas the contrast ratio for liquid crystal displays (LCDs) is more variable over large-angle viewing. Recent new electrode position developments, such as the 'in-plane switching' technology for active matrix liquid crystal displays (AMLCDs) has gone a long way to reduce this reduced angle-of-view effect in that type of LCD display.

Figure 1 shows how a viewer in a sport utility vehicle (SUV) would see the changes in contrast with viewing angle for two types of twisted nematic LCDs (TN-LCDs). One of the TN LCDs does not

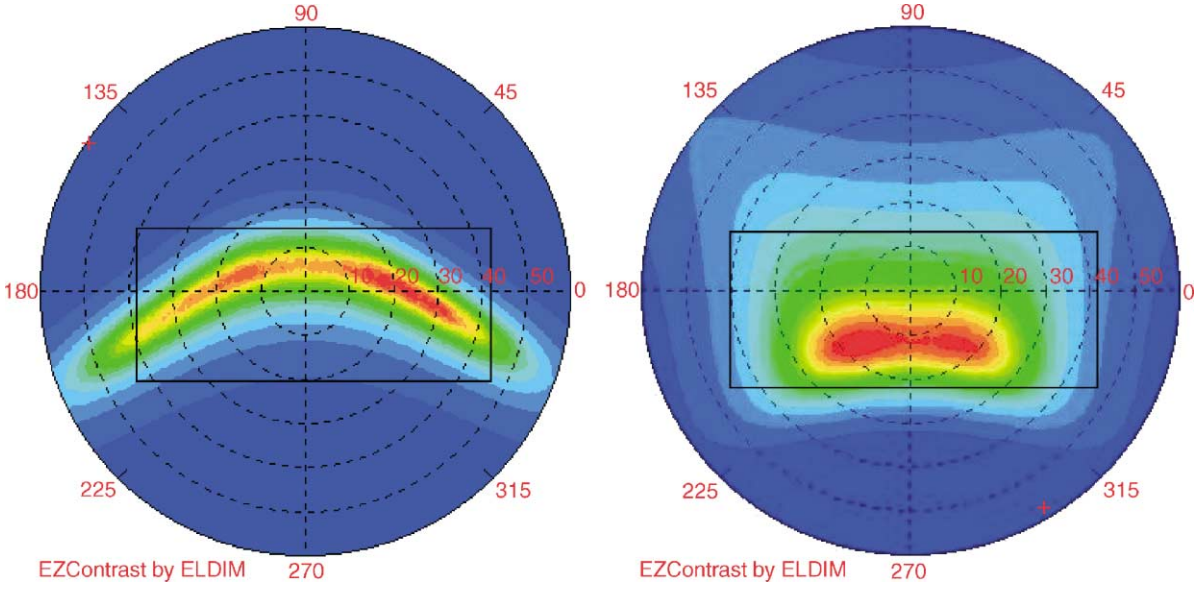

Figure 1 A typical rectangular viewing envelope for a mid-size SUV vehicle superimposed on LCD iso-contrast plots. Left is standard TN LCD. Right, is film-compensated TN LCD. have the film compensation and the other does. For relative contrast appraisal, the red areas show the highest contrast regions and the blue the lowest. It is obvious that different technologies can give significant changes in viewed contrast.

Phosphor Aging

The fall off of luminance as the phosphor screen is bombarded with the electron beam is called phosphor aging. This effect is due to two main factors: (i) the thermal quenching of the phosphor luminescence (which is reversible); and (ii) a nonreversible aging due to damage to the screen components (such as phosphor, binder, and aluminum coating). It has been found that the aging (when we are using an electron beam) is a function of the number of electrons bombarding the screen. Aging models help us to understand and predict the amount of aging a tube will show after a fixed amount of time. The first aging model in 1951 was on ion bombardment and showed that:

$$I = I_0/(1 + AN) \quad [3]$$

where I_0 is the initial luminance before aging, and I is the final luminance.

In 1961 a similar (one parameter) Model $I = I_0/(1 + CN)$ was used by Pfhanl, where C is the aging constant to half luminance and N is the number of coulombs. In 1981, a two-component model for low current aging was presented, where:

$$I = I_0/(1 + N(B/Q^D)) \quad [4]$$

Here we have two constants B and D, and Q is the cumulated charge in number of coulombs. When $D = 0$ then the equation given above goes to the Pfhanl case.

Later, in 1996 the three-parameter model was described and in 1997 the Gaussian beam aging model was described.

Ambient Illumination and Reflection

To see the information shown on a display, the information must be spatially detected by the human eye over the reflected ambient illumination (such as room and sunlight). The ambient illumination is generally from localized or diffuse sources. As we have seen previously, the effect of diffuse illumination can be reduced through the use of neutral density filters. But, when we are dealing with very high ambient light such as that entering the canopy of a fighter aircraft then, the monochromatic information from the display can be viewed using selective spectral filters. However, for the usual computer monitor, the 'specular reflection' (Snell's Law type of reflection) off the front of the display is due to a localized external light source. This reflection is reduced by methods such as anti-glare (AG) and anti-reflecting (AR) surfaces applied to the front surface of the display. A flat versus curved front surface of the display can also be a glare reduction technique. Surface roughness is used in AG surfaces to scatter a portion of the specular light away from the viewer. Surface roughness can be achieved through surface abrading, surface plastic coating, surface silicate coating, and surface acid etching to name a few methods. AR surfaces use optical interference techniques to reduce the reflected light to the viewer. In some cases, both methods are applied to a display surface. Surface gloss of the display is usually measured with a gloss meter in 60 degree gloss values but 20, 45, and 80 degree angles are also used. Resolution is measured in line pairs/mm or pixels/mm and image sharpness is associated with modulation transfer function (MTF) measurements. We should note here that resolution and image sharpness are not the same thing. High resolution is equated with the high frequency limit of the MTF measurement. Since the reduction in specular reflection through the use of surface roughness can affect the image sharpness, we see that a system of trade-offs can be developed to optimize a display for a given viewing environment. AR coatings improve glare reduction without scattering and thus give higher-resolution capability to the displays but this is usually obtained at a higher price then the AG coatings.

Types of Displays

Displays can be divided into two types; emissive and nonemissive. By emissive we mean that the display surface gives off light. In the nonemissive, the display or a small portion of the display acts as a shutter or spatial filter which also can be reflective in nature. In this nonemissive mode, the display can pass light from a source in back of or in front of the shutter (or both, as we shall see later).

Table of Emissive and Nonemissive Displays

Thus from Table 1 we see that under the title of emissive displays we have the cathode ray tube (CRT), projection CRT, vacuum fluorescent display (VFD), field emissive display (FED), electroluminescent (EL) display, light emitting diode (LED), organic light emitting diode (OLED), and plasma. These devices, which are in the realm of emissive displays, use certain types of emissive materials called

Table 1 Table of emissive and nonemissive displays

PLASMA	

lumophors (or phosphors). The lumophors are called cathodoluminescent, photoluminescent, and electroluminescent, depending whether the excitation action was due to the interaction of the phosphor with cathode rays, photons, or low-voltage electrons. Cathodoluminescent lumophors are used in cathode ray tubes (CRTs – television tubes, monitor tubes, projection CRTs), (VFDs), and (FEDs).

EL displays can use inorganic lumophors (phosphors) or organic lumophors such as those used in OLEDs. Under photoluminescence displays, we have 'plasma displays' (plasma TV), IR-up conversion, and fluorescent lamps. In plasma displays, the excitation of the plasma in a localized region gives rise to UV photons which strike the phosphor screen in that region. In IR-up conversion, IR photons are absorbed in such a way that two IR photons can excite an electron with twice the energy of one IR photon. This then allows the use of IR lasers to create displays through the excitation of these up-conversion phosphors. In fluorescent lamps, the UV created by the excitation of Hg or Xe, strikes the special lamp phosphors (coated on the inside of the glass envelope), which become luminescent.

Under the heading of shutters we can consider LCDs which consist of AMLCDs, super twisted nematic liquid crystal displays (STN LCDs) and bistable LCDs. Another shutter type is the liquid crystal on silicon (LCOS) display and the movable digital mirror display (DMD), and the digital light processing (DLP) projecting engines. Another spatial display type is both normal and dynamic inks. A dynamic ink can be a 'polarizable' ink display in which a two shade (light/dark) ink sphere element can rotate under the presence of an electric field to show the light or dark side. Although they are very interesting, we will not cover ink displays in this article.

The shutter action is also used in some projection TV sets (or projectors) in which the LCD either transmits or reflects (such as LCOS) the light from an arc lamp. The DMD movable mirrors reflect the digital information to the lens system and the unwanted rays are reflected away from the lens to a black light capture area.

The Cathode Ray Tube (CRT)

The CRT is a display which has been in use for over 100 years (the Braun CRT tube was developed in 1898). The CRT uses a phosphor screen which is bombarded by energetic electrons and emits visible light radiation. The single electron gun CRT was used for years in early monochrome television sets and monochrome computer displays. Monochrome green, amber, and white phosphors have been used in monitor tubes. Some color selectivity can be obtained with the single electron gun using the following three methods; (i) voltage penetration phosphors, (ii) current sensitive phosphors and (iii) beam index methods. In a CRT, the penetration of the electron beam follows Hans Bethe's energy loss equation for electron penetration in solids and thus is a function of the electron energy or CRT voltage.

Hans Bethe's energy loss equation is:

$$dE/dx = -2\Pi e^4 (N_e/E)\ln(\alpha E/I) \qquad [5]$$

where: E = energy of the incident electron; x = depth of material; N_e = density of atomic electrons; I = mean excitation energy; and α = a constant.

In the voltage penetration tube, a cascaded screen is used to give a color change when the electron voltage is increased. For example, if a cascade screen is made from a green phosphor layer placed on top of the red phosphor layer then the electrons strike the green phosphor first. Then with increased voltage, the electrons pass through the top phosphor and excite the bottom red phosphor. In the current sensitive color tube, the phosphor screen is composed of (for example) red and green phosphor whose luminance versus current curves are different. In these cases, we are referring to the linearity of the change in luminescence from the phosphor as a result of a change in electron beam current. The red phosphor (generally a rare earth oxide) is a linear phosphor, whereas the green is nonlinear. Changing the current thus can change the color of the display. In the beam index tube, a UV (or secondary electron emitters have also been used) emitting index layer is put along side a red, green, or blue triad (for example, between the blue and the red phosphor stripes). The scanning electron beam, through the use of a UV sensor (or secondary electron detector) mounted in the rear portion of the tube and the scanning electronics, can determine the location of the red, green, and blue phosphors. The electron beam can then excite only the individual phosphor areas of interest. With this tube, generally, the

electron beam is at a low current to give a small enough cross-section to only excite one color and thus has limited application.

Another application of the monochrome is the projection CRT system. Here, three tubes for red, green, and blue are used to project an image on a viewing screen. The terminology is such that, when the CRTs are in the back of the screen and the viewer in front of the screen, it is called a 'rear' projection set and if the CRTs and the viewer are in front of the screen it is a 'front' projection set. The principle here is that, either using one CRT tube at a time or by a superposition two or three of the CRTs, the color of the displayed image will be within the color gamut defined by the primary colors.

The Color CRT

The more ubiquitous method of obtaining a color display is the device called the shadow mask CRT (and the similar Trinitron CRT). This color CRT is designed in such a manner that through the use of an aperture mask, (seen in **Figure 1**) the electrons from the red electron gun strike the red phosphor and likewise electrons from the green and blue electron guns strike the green and blue phosphors. The combination allows the viewer to see a color image. This color separation action is seen in **Figure 2**. Although **Figure 2** shows a delta tri-color design, there are also in-line systems in which the mask consists of an array of slots which are somewhat rectangular in nature. In this array, many slots can be on a line, or a mask made can be made of a series of wires as used in the Trinitron design.

The disadvantage of the shadow mask technique is that the mask can capture as much as 80% of the electrons from the electron guns. This yields lower screen luminance and lower contrast due to scattered electrons. As the screen size gets larger from 19 inches to 36 inches or more, additional temperature compensation methods must be used to reduce the effects of mask heating. A number of methods to control the shift of the electron beam on the phosphor as the mask heats up have been developed. Initially, axially positioned bimetal springs were used on masks to compensate for the heating effect. Then lighter masks were used with corner lock suspension systems. Another method is using mask materials with lower coefficients of expansion such as INVAR.

Contrast in color CRTs has been improved by first applying a carbon coating between the panel glass and the phosphor screen. This requires additional process steps which form 'windows' in the carbon coating (matrix) through which the excited phosphor is seen. The use of pigmented phosphors also helped to reduce the reflectivity of the phosphor/matrix screen.

The phosphors used in the shadow mask color CRT are the red Y_2O_2S:Eu or, in some cases, the Y_2O_3:Eu phosphor. The green phosphor is ZnS:Cu and the blue phosphor is ZnS:Ag.

The CRT seen in **Figure 3** shows the new high-definition television-type (HDTV) tube with the 16×9 aspect ratio as contrasted with the older 4×3 aspect ratio (screen width $\times$ height).

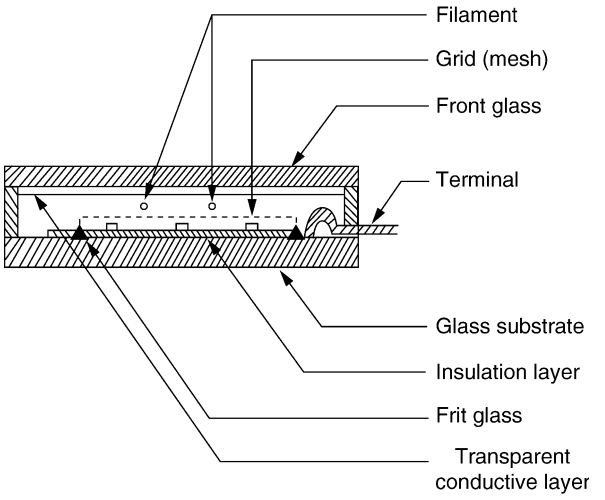

Figure 4 The cross-section of a vacuum fluorescent display assembly.

The Vacuum Fluorescent Display (VFD)

The VFD can be thought of as a low-voltage CRT. Just as in the CRT, electrons from a cathode are controlled by a grid which allows them to be accelerated and strike the phosphor screen anode. However, the electrons in a CRT can be accelerated with a voltage of 30 000 V, whereas the VFD accelerates the electrons with voltages of 12 to 40 V.

In the operation of the VFD, electrons are emitted by the filament. The filament is a very thin tungsten wire coated with a tri-carbonate oxide (barium, strontium, and calcium carbonates) which are the same constituents of the CRT oxide cathode. The filament is held between a filament support and an anchor which applies tension to the filament wire. A current is passed through the filament to achieve a temperature to ~600 °C. At that temperature, thermonic emission occurs. Between the filament and the phosphor elements is a stainless steel mesh grid. By the application of a positive or negative voltage on this grid, electrons can either be cut off or accelerated to the phosphor on the anode. The anode can be a conductor such as graphite, coated with a phosphor layer such as ZnO:Zn (zinc oxide). This is a low-voltage cathodoluminescent phosphor which emits a green color with an emission maxima of about 505 nm. Other phosphors are also used to obtain red, orange, and blue (Figure 4).

In addition to the filament, grid and anode, the VFD is a vacuum device (like the CRT) and contains a getter to assist achieving and maintaining a good vacuum and an internal transparent conductive coating to protect the display from external electrostatic fields. The VFD display is used frequently in the auto industry and aging of the phosphor is very small, achieving 100 000 hrs to half of the initial luminance.

VFD units have been made with phosphor elements on either side of the filament. This gives rise to a 3D effect. Graphic and fixed segment VFDs have been made for multimedia products and 16 × 16 graphics for Kanji and other characters.

Experimentally, 2D VFD arrays have been made similar to the FEDs covered in the next section.

Field Emissive Displays (FEDs)

The FED is similar to the CRT and the VFD in that electrons from a source bombard a phosphor screen. In both the CRT and the VFD thermionic electrons are used. However, in the FED the electrons arise from field emission. Field emission devices create electrons though quantum mechanical tunneling from the emitter surface into the vacuum by the action of a large electrical field. This process is governed by the Fowler–Nordheim equation. This equation takes the form:

$$J = A(\beta V)^2/\Phi \exp(-B\Phi^{3/2}/\beta V) \qquad [6]$$

where, J is the electron current density; V is the applied voltage; Φ is the work function of the emitting tip; A & B are constants; and β is the field enhancement factor.

The emitters can be of the Molybdenum Spindt type and also the polydiamond or diamond-like carbon (DLC) coated emitters. We have the field enhancement with a sharp tip and reduced work function with the DLC. There has been renewed interest in FEDs, with the development of the 'carbon nanotube' as an electron field emitting source. The carbon nanotube is a fullerene material, which is a distinct form of carbon. This 'bucky ball'-like

material is cylindrical instead of spherical in nature, has great strength, and high conductivity.

There are two types of FEDs, a low-voltage (LVFED) and a high-voltage (HVFED). The HVFED uses an aluminum film over the phosphor to protect the phosphor screen from aging. The HVFED can use the high voltage (2–10 KV) electrons to bombard the aluminized screen and it can use the more efficient, somewhat standard CRT phosphors ZnS:Cu green, ZnS:Ag Blue, and Y_2O_3:Eu red. The LVFED (12–200 V) cannot use the standard CRT phosphors but uses the low-voltage phosphor such as the ZnO:Zn green phosphor. This does not use an aluminum layer, since about 2 KV is needed to penetrate the Al layer. The commonly used CRT red phosphor Y_2O_2S:Eu was found unsuitable for HVFED use due to release of the sulfur during electron bombardment.

Figure 5 shows that for this basic FED structure, the electrons from the Spindt emitter are controlled by the voltages of the anode, control electrode and emitter electrode.

Plasma Displays

Earlier plasma displays, made using excited Ne gas with the characteristic amber glow required no phosphor and were used in the printing industry. Present plasma displays used for television and information signs are photoluminescent displays. As shown in Figure 6, the excitation of the plasma gas made of elements such as He, Ne, Ar, and Xe give rise to a glow discharge and the creation of vacuum ultraviolet photons that strike the screen and cause it to luminesce. In construction, the display is similar to the FED in that it is a matrix addressed device. It has been described in literature that the similarity goes even further with the need for anode and cathode surfaces, a means of evacuating and a perimeter seal. There are two types of plasma displays, DC and AC. The AC design appears to be the more successful. Typical PDP phosphors for the triad are (Y,Gd)BO_3:Eu for the red, Zn_2SiO_4:Mn for the green, and $BaMgAl_{10}O_{17}$:Eu (called BAM for short) for the blue. Figure 6 below shows the basic structure of an AC plasma display. One phosphor element is shown with barrier ribs and address and scan electrodes. The discharge of the plasma takes place in the region of the phosphor and excites the photoluminescent phosphor, which is shaped (in this example) along the side of the barrier ribs and over the address electrode.

Electroluminescence

Electroluminescence was first seen in the 1930s by Destriau. EL is the generation of (nonthermal) light by use of an electric field. High electric field EL units emit light through the impact of high energy electrons in luminescent centers in a semi-conducting material. The electric field can be alternating current (AC) or direct current (DC). Powder phosphor AC EL displays appear to be one of the successful inorganic EL display methods. Because of their rugged nature, alternating current electroluminescence ACEL displays have been used in trucks, tractors and the M1 Abrams Tank. Thick-film EL panels are also used in some vehicle displays as back lights for LCDs. These light panels are free from mercury and are more environmentally friendly.

Inorganic LED Displays

Light-emitting diodes are being used as backlights for LCD displays, replacing some of the fluorescent light backlighting methods. They are also used in indicator lights. Large displays have been made of LEDs. Using a matrix array row and column connectors,

we can digitally select a given color LED and pattern in an LED array and generate a color image. Similar methods were carried out many years ago using incandescent lights. However, now they are bright and fast reacting. LEDs operate by semiconductor P–N junction rules and the flow of electrons and holes under forward bias operation give rise to junction light emission. Materials such as GaP:Zn,O are used to create a red LED with an emission maxima wavelength of 699 nm.

Red, green, and blue-UV/blue LEDs are now available, with an increasing demand for white LEDs. Two methods are used to produce a white LED. One method is to use a blue LED with the front of the LED coated with a green photoluminescent phosphor. If the phosphor is thin enough, the blue light penetrates the screen and excites the green to give a blue/green white. Another method is to use a blue LED and coat it with a white photoluminescent phosphor.

Organic LEDs

The basic process of light generation in OLEDs is the formation of a P–N junction. Electrons injected from the N-type material and holes from the P-type material recombine at the junction and light is generated. There are presently two competing methods to fabricate an OLED. The first developed by Kodak in 1987 is the small molecule molecular weight material approach. In OLED operation, the electron hole pair recombine to form excitons (on the average one singlet and three triplet excitons are formed for every four electron hole pairs). The light for the Kodak OLED is from the recombination of singlet excitons and the energy transferred to the fluorescent dye. The terminology is such that we have small molecule-OLEDs (sm-OLEDs) and polymer-OLED (PLED). In later developments, the sm-OLED device structure was reported to have three layers. The first is the hole transport layer (hole transport) enhancing layer copper phthalocyanine (CuPc), a layer NPB (60 nm), the light emitting aluminum tris-8-hydroxyquinolate Alq layer (75 nm), and electron transport layer. The electron transport layer is in contact with the three layer structure. The top electrode is a low work function material, such as MgAg (75–200 nm thick) called an electron injection layer and topped with a transparent indium tin oxide (ITO) layer for transparent OLEDS. All of these coatings are applied in a vacuum chamber.

In the phosphorescent material method, the light emission is from the triplet excitons through the use of phosphorescent dyes and the polymer-based devices. The common base material is a polyphenylene-vinylene PPV and other polymers such as polyfluorene have been used. The construction of the phosphorescent OLED is similar in that the ITO is also used as a starting substrate but the hole transport layer is applied by spin casting from solution. Spin casting is also used for the electron transfer material. After drying (removal of solvents) a calcium cathode material is applied. A contrast of 3000/1 has been achieved (for a military type application) using a green OLED with an AR coated circular polarizer and at an ambient light level of 500 lux, and a 6/1 contrast ratio has been achieved with an ambient illumination of 50 000 lux and an output of 370 cd/m^2. Additionally, OLEDs can be made on flexible (F) substrates and are called FOLEDs. The use of a transparent (T) cathode gives rise to a top emission OLED or a TOLED.

The first OLED display used in auto products was developed by Pioneer and used in a radio display and the Ford Motor Company has shown a White OLED display in one of their 'Concept Cars'. This display allows them to have a reconfigurable instrument

panel (IP) and is made up of a number of 5 inch × 8 inch displays across the instrument panel (Figure 7).

The POLED as seen in Figure 8 is now being used by Philips Mobile Systems in a rear view car mirror, as seen below. It is the display from a video camera looking at the rear of a car to see any obstacles to backing up safely.

Thin Film EL (TFEL) Displays

A simple type of TFEL display is the color by white structure shown below. In this case, the color is generated using a white phosphor and red, green, and blue optical filters. To make this ACEL display function properly, insulators are used on either side of the phosphor. In Figure 9, the ITO conducting stripes (depicted) horizontally on the top and vertically on the bottom, give the means of addressing each color pixel. The white phosphor, for example, is a ZnS:Mn, SrS:Ce blend which gives a white electroluminescence.

Other phosphors such as ZnS:Mn can be used but its yellow luminescence requires the use of a green and red filter and only two metal electrodes on the bottom to give a two-color display. Better red green color separation can be achieved through the use of a $Zn_{1-x}Mg_xS$:Mn and ZnS:Mn phosphor mix. New EL blue phosphor developments have allowed larger color gamuts to be achieved.

One of the important characteristics of the alternating current thin-film electroluminescence (ACTFEL) is that it has an operating temperature range from −40 °C to 85 °C which is key for automotive use. It has a viewing angle of 160 degrees with a life of more than 50 000 hours. Active matrix (active addressed) AMEL structures allow fast

response and moving graphic displays. These have found application in 'heads up displays' (HUD) for the military and medical industries and in consumer goods such as portable computers, pagers, cell phones, and 3D gaming.

The Active Matrix LCD

The active matrix liquid crystal display (AMLCD) device consists of a series of liquid crystal cells or windows whose characteristics can be controlled by an applied voltage to pass or restrict the passage of light through the windows via the external polarizers and the polarizing action of the LCD cells. These displays are used in laptop and tabletop computers, TVs, and for automotive displays (for driving information and entertainment). Figure 10 shows some present applications for AMLCDs in the automobile.

When the simple LCD is used without a transistor matrix, it is termed a passive display rather than an active one. Figure 11 below shows how a simple LCD cell operates.

The action shown in this figure is the twisted alignment nature of the liquid crystal material. When the polarizer on the left has its high transmission axis horizontal and the polarizer on the right of this cell has perpendicular alignment then the light from the backlight (f) is passed through the crossed polarizers. However, when voltage is applied to the cell, the liquid crystal is no longer twisted and the crossed polarizers prevent the light from going though the cell to the viewer. If the polarizers were not crossed but the polarization transmission axis was in the same direction in both polarizers, then the opposite effect would occur.

In order to show a color image, the LCD is designed to have three or more cells clustered per color pixel. The following (Figure 12) is the transmission profiles of each of these red, green, and blue filters.

The backlight used is a fluorescent lamp with a white phosphor (made up of red, green, and blue photoluminescent phosphors). Figure 13 shows what would happen if only the blue phosphor was used and also shows the superposition of the mercury lines that penetrate the phosphor and contribute to the final spectral energy distribution.

Reflective LCD

For applications where there is suitable external light to view the display, no internal light source is used.

This reflective LCD consists of a polarizer and retarder plates stacked on the front side of the cell. The cell with spacers contains the liquid crystal material and on the bottom of the cell is located a reflecting surface. It has been found that a dimpled reflecting surface makes a diffuse reflecting surface (Figure 14).

Transflective LCD

The importance of the transflective device is that it has better contrast under high ambient illumination than the standard transmission back lighted LCD and fair contrast for low ambient illumination.

The construction of this device consists of front and rear circular polarizers, back light, reflective elements, and novel filters. The back light is in the rear of the display. However, like the reflective LCD, internal reflectors are used on each pixel. The filters are designed spatially to be more transmissive for the reflective light than for the back light. Additionally the cell gap for the reflective light is smaller then the transmitted light region because the reflected light passes the cell twice whereas the transmitted light passes the cell once. This type of device seen in Figure 15, is finding uses in the auto industry and where the LCD is needed for both low and high ambient light levels.

Conclusions

In this brief review of displays we have tried to cover many different types of displays. The reader will in time find that there are many other variations on the displays discussed. The object is to give the reader an up-to-date review of the topics involved with displays and the various types of display in use today. By its nature it is a broad approach.

Introduction

In this article we examine how the process of electromagnetically induced transparency (EIT) can be used to increase the efficiency of non-linear optical frequency mixing schemes. We illustrate the basic ideas by concentrating upon the enhancement of resonant four-wave mixing schemes in atomic gases. To start we introduce the quantum interference phenomenon that gives rise to EIT. The calculation of EIT effects in a three-level atomic medium using a density matrix approach is presented. Next we examine the modified susceptibilities that result and that can be used to describe nonlinear mixing, and show how large enhancements in nonlinear conversion efficiency can result. Specific examples are briefly discussed along with a further discussion of the novel aspects of refractive index and pulse propagation modifications that result from EIT. The potential benefits to nonlinear optics of electromagnetically induced transparency are discussed. In an article of this nature it is not possible to credit all of the important contributions to this field, but we include a bibliography for further reading indicating some of the seminal contributions.

Electromagnetically induced transparency is the term applied to the process by which an otherwise opaque medium can be rendered transparent through laser-induced quantum mechanical interference processes. The linear susceptibility is substantially modified by EIT. Absorption is cancelled due to destructive interference between excitation pathways. The dispersion of the medium is likewise modified such that where there is no absorption the refractive index is unity and there can be a large value of normal dispersion leading to low values of group velocity. In contrast to the linear susceptibility the nonlinear susceptibility involving these same resonant laser fields will undergo constructive rather than destructive interference. This leads to a strong enhancement in nonlinear frequency mixing. For a normally transparent medium the nonlinear optical couplings will be small unless large-amplitude fields are applied. The most important consequence of EIT, in contrast to the usual case when a medium is transparent, is that the dispersion is not vanishing and the nonlinear couplings can be very large.

To understand how this comes about we must consider the system illustrated in Figure 1a where because of the resonant condition satisfied for the applied fields the atom can be simplified to just three-levels. The important parameters in this model system are that state $|2\rangle$ is metastable and has a dipole-allowed coupling to state $|3\rangle$. The coupling between states $|1\rangle$ and $|3\rangle$ is also dipole-allowed

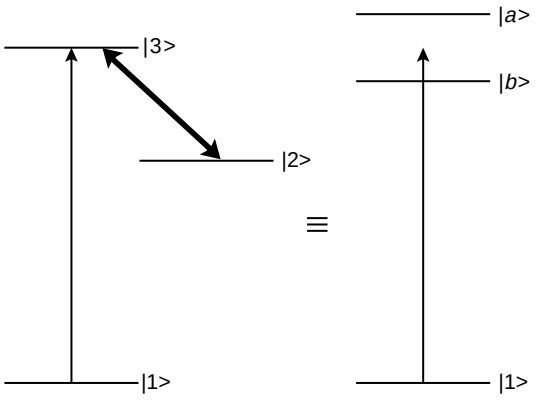

Figure 1 A three-level atomic system coupled to laser fields in the lambda configuration is shown on the left-hand side. In the limit of a strong coupling field this is equivalent to the dressed states $|a\rangle$ and $|b\rangle$ coupled to the ground state by the probe field alone as shown on the right-hand side.

and as a consequence state |3> can decay radiatively to either |1> or |2>. Let a coupling field be applied resonantly to the |2> − |3> transition, which may be cw or pulsed but should in the latter case be transform-limited. We define the Rabi coupling as $\Omega_{23} = \frac{\mu_{23}E}{\hbar}$ where E is the laser electric field amplitude and μ_{23} is the dipole moment of the transition. The Rabi frequency needs to be larger than the inhomogeneous broadening of the sample. A second field, the probe, typically of much lower intensity, is then applied in resonance with the |1> − |3> transition. If the condition $\Omega_{23} \gg \Omega_{13}$ is satisfied then it is convenient to replace the bare atomic states |2> and |3> with the dressed states (see Figure 1b):

$$|a> = \frac{1}{\sqrt{2}}[|2> + |3>] \qquad [1a]$$

$$|b> = \frac{1}{\sqrt{2}}[|2> - |3>] \qquad [1b]$$

Transitions from state |1> induced by the probe field to this pair of near-resonant dressed states are subject to exact cancellation at resonance if |2> is perfectly metastable. This is because the only contribution to the excitation amplitude comes from the matrix elements $<1|\mathbf{r}\cdot\mathbf{E}|3>$ as the |1> − |2> transition is dipole forbidden. The contributions from the equally detuned states |a> and |b> thus enter into the overall amplitude with opposite signs and equal magnitude as can be seen by inspection of eqns [1a] and [1b]. This leads to cancellation of the absorption amplitude. This type of absorption cancellation is well known and closely related to the so-called *dark states*.

Theoretical Treatment of EIT in a Three-Level Medium

It was realized by several workers in the 1970s that laser-induced interference effects could lead to a cancellation of absorption at certain frequencies. To gain a more quantitative understanding of the effects of the coupling field upon the optical properties of a dense ensemble of three-level atoms we require a treatment that computes the optical susceptibility of the medium. A treatment originally carried out by Harris *et al.* for a Λ scheme similar to that illustrated in Figure 1 was the first to derive the modified susceptibilities that will be discussed below. In that treatment the state amplitudes in the three-level atom were solved in the steady-state limit and from these the linear and nonlinear susceptibilities (see below) are then derived. In what follows we adopt a density matrix treatment as employed by various workers. This readily allows the inclusion of dephasing as well as population decay terms. The critical parameters in this system are the strengths of the fields (described in terms of the Rabi couplings), the detuning of the fields from resonance $\Delta\omega_{13} = \omega_{13} - \omega_P$ and $\Delta\omega_{23} = \omega_{23} - \omega_C$ (see Figure 2), the radiative decays from |3> to |1> and |2>, γ_c and γ_d and from |2> − |1> γ_a (although the latter is anticipated to be smaller). Extension to other configurations of the three states, such as a V or ladder scheme is implicit within this general treatment.

Figure 2 illustrates the system considered. This treatment will also address the nonlinear response in a four-wave mixing scheme completed by the two-photon resonant coupling applied between state |1> and |2>.

We write the interaction Hamiltonian as:

$$H = H_0 + V \qquad [2]$$

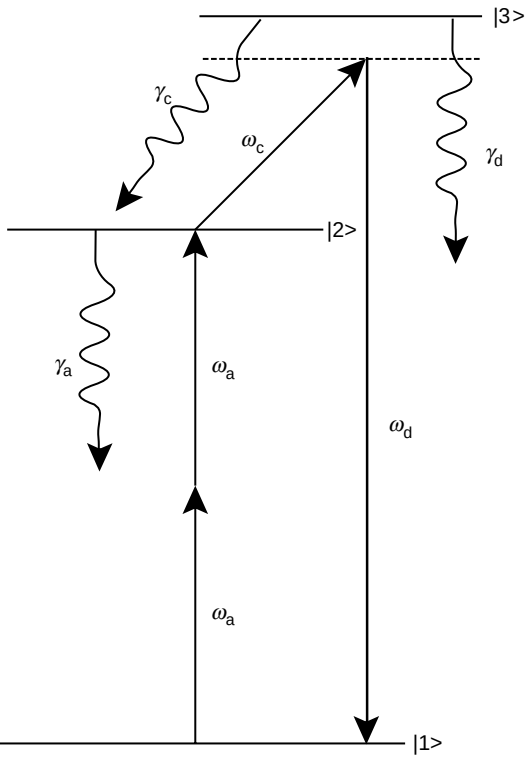

Figure 2 A four-wave mixing scheme incorporating the three-level lambda system in which electromagnetically induced transparency has been created for the generated field ω_d by the coupling field ω_c. The decay rates γ_i from the three atomic levels are also shown. For a full explanation of this system see text.

where H_0 is the unperturbed Hamiltonian of the system and is written as

$$H_0 = \hbar\omega_1|1\rangle\langle 1| + \hbar\omega_2|2\rangle\langle 2| + \hbar\omega_3|3\rangle\langle 3| \quad [3]$$

and V is the interaction Hamiltonian and can be expressed

$$\begin{aligned} V = {} & \hbar\Omega_a e^{-i\omega_a t}|2\rangle\langle 1| + \hbar\Omega_c e^{-i\omega_c t}|2\rangle\langle 3| \\ & + \hbar\Omega_d e^{-i\omega_d t}|3\rangle\langle 1| + c.c \end{aligned} \quad [4]$$

Note that the Rabi frequencies in the equation can be described as $\hbar\Omega_{ij} = \mu_{ij}|E(\omega_{ij})|$, where μ_{ij} is the dipole moment of the transition between states |i> and |j>, the Rabi frequency Ω_a is a two-photon Rabi frequency that characterizes the coupling between the laser field *a* and the atom for this two-photon transition. We have assumed for simplicity that $\omega_a = \omega_b = \omega_{12}/2$.

Assuming all the fields lie close to the resonance, the rotating wave approximation can be applied to the interaction picture and the interaction Hamiltonian V^I is given as

$$\begin{aligned} V^I = {} & \hbar\Omega_a e^{i\Delta_a t}|2\rangle\langle 1| + \hbar\Omega_c e^{i\Delta_c t}|2\rangle\langle 3| \\ & + \hbar\Omega_d e^{i\Delta_d t}|3\rangle\langle 1| + c.c \end{aligned} \quad [5]$$

where Δ_a, Δ_c and Δ_d refer the detunings of the fields and can be written as:

$$\begin{aligned} \Delta_a &= \omega_{12} = 2\omega_a \\ \Delta_c &= \omega_{32} - \omega_c \\ \Delta_d &= \omega_{13} - \omega_d \end{aligned} \quad [6]$$

For the evaluation of the density matrix with this interaction V^I, the Schrödinger equation can be restated in terms of the density matrix components. This form is called the Liouville equation and can be written as:

$$\hbar\frac{\partial}{\partial t}\varrho_{ij}(t) = -i\sum_k H_{ik}(t)\varrho_{ij}(t) + i\sum_k \varrho_{ij}(t)H_{ik}(t) + \Gamma_{ij} \quad [7]$$

where Γ_{ij} represents phenomenologically added decay terms (i.e. spontaneous decays, collisional broadening, etc.). This formalism leads to a set of nine differential equations for nine different density matrix elements that describe the three-level system.

To remove the optical frequency oscillations, a coordinate transform is needed and to incorporate the relevant oscillatory detuning terms into the off-diagonal elements we make the substitution:

$$\begin{aligned} \tilde{\varrho}_{12} &= \varrho_{12}e^{-i\Delta_a t} \\ \tilde{\varrho}_{23} &= \varrho_{23}e^{-i\Delta_c t} \\ \tilde{\varrho}_{31} &= \varrho_{31}e^{-i\Delta_d t} \end{aligned} \quad [8]$$

This operation conveniently eliminates the time dependencies in the rate equations and the equations of motion for the density matrix are given by:

$$\begin{aligned} \frac{\partial}{\partial t}\varrho_{11} &= i\frac{1}{2}\Omega_a\tilde{\varrho}_{12} + i\frac{1}{2}\Omega_d\tilde{\varrho}_{13} - i\frac{1}{2}\Omega_a^*\tilde{\varrho}_{21} \\ &\quad - i\frac{1}{2}\Omega_d^*\tilde{\varrho}_{31} + \Gamma_{11} \\ \frac{\partial}{\partial t}\varrho_{22} &= i\frac{1}{2}\Omega_c^*\tilde{\varrho}_{23} + i\frac{1}{2}\Omega_a^*\tilde{\varrho}_{21} - i\frac{1}{2}\Omega_c\tilde{\varrho}_{32} \\ &\quad - i\frac{1}{2}\Omega_a\tilde{\varrho}_{12} + \Gamma_{22} \\ \frac{\partial}{\partial t}\varrho_{33} &= i\frac{1}{2}\Omega_c^*\tilde{\varrho}_{23} - i\frac{1}{2}\Omega_d^*\tilde{\varrho}_{31} + i\frac{1}{2}\Omega_d\tilde{\varrho}_{13} \\ &\quad - i\frac{1}{2}\Omega_c\tilde{\varrho}_{32} + \Gamma_{33} \\ \frac{\partial}{\partial t}\varrho_{23} &= i\frac{1}{2}\Omega_c\tilde{\varrho}_{22} - i\frac{1}{2}\Omega_c\tilde{\varrho}_{33} - i\Delta_a\tilde{\varrho}_{23} \\ &\quad + i\frac{1}{2}\Omega_d\tilde{\varrho}_{21} - i\frac{1}{2}\Omega_a\tilde{\varrho}_{13} + \Gamma_{23} \\ \frac{\partial}{\partial t}\varrho_{21} &= i\Omega_a\tilde{\varrho}_{22} + i\Omega_a\tilde{\varrho}_{33} + i\Omega_d\tilde{\varrho}_{23} - i\Delta_c\tilde{\varrho}_{21} \\ &\quad - i\frac{1}{2}\Omega_c\tilde{\varrho}_{31} - i\frac{1}{2}\Omega_a\tilde{\varrho}_{31} + \Gamma_{21} \\ \frac{\partial}{\partial t}\varrho_{31} &= i\frac{1}{2}\Omega_d\tilde{\varrho}_{22} + i\Omega_d\tilde{\varrho}_{33} + i\Omega_d\tilde{\varrho}_{23} - i\Delta_c\tilde{\varrho}_{21} \\ &\quad - i\frac{1}{2}\Omega_c\tilde{\varrho}_{31} - i\frac{1}{2}\Omega_a\tilde{\varrho}_{31} + \Gamma_{31} \end{aligned} \quad [9]$$

Using the set of equations above and the relation $\tilde{\varrho}_{ij} = \tilde{\varrho}_{ij}^*$ we obtain equations for $\tilde{\varrho}_{12}$, $\tilde{\varrho}_{32}$, and $\tilde{\varrho}_{13}$. For the incoherent population relaxation the decays can be written:

$$\begin{aligned} \Gamma_{11} &= \gamma_a\varrho_{22} + \gamma_d\varrho_{33} \\ \Gamma_{22} &= -\gamma_a\varrho_{22} + \gamma_c\varrho_{33} \\ \Gamma_{33} &= -(\gamma_c + \gamma_d)\varrho_{33} \end{aligned} \quad [10]$$

and for the coherence damping:

$$\begin{aligned} \Gamma_{21} &= -\left\{\frac{1}{2}[\gamma_a + \gamma_c] + \gamma_{21}^{col}\right\}\varrho_{21} \\ \Gamma_{23} &= -\left\{\frac{1}{2}[\gamma_a + \gamma_c + \gamma_d] + \gamma_{23}^{col}\right\}\varrho_{23} \\ \Gamma_{31} &= -\left\{\frac{1}{2}[\gamma_d + \gamma_c] + \gamma_{31}^{col}\right\}\varrho_{31} \end{aligned} \quad [11]$$

where γ_{ij}^{col} represents collisional dephasing terms which may be present.

This system of equations can be solved by various analytical or numerical methods to give the individual density matrix elements. Analytical solutions are possible if we can assume for instance that $\Omega_c \gg \Omega_a$, Ω_d and that there are continuous-wave fields so a steady-state treatment is valid. For pulsed fields or in the case where the generated field may be significant numerical solutions are in general required.

We are specifically interested in the optical response to a probe field at ω_d (close to resonance with the $|1> - |3>$ transition) that is governed by the magnitude of the coherence ϱ_{13}. We find ϱ_{13} making the assumption that only the coupling field is strong, i.e., that $\Omega_c \gg \Omega_a, \Omega_d$ holds. From this quantity the macroscopic polarization is obtained from which the susceptibility can be computed. The macroscopic polarization P at the transition frequency ω_{13} can be related to the microscopic coherence ϱ_{13} via the expression:

$$P_{13} = N\mu_{13}\varrho_{13} \qquad [12]$$

where N is the number of equivalent atoms in the ground state within the medium, and μ_{13} is the dipole matrix element associated with the transition. In this way real and imaginary parts of the linear susceptibility χ at frequency ω can be directly related to ϱ_{13} via the macroscopic polarization since the latter can be defined as:

$$P_{13}(\omega) = \varepsilon_0 \chi(\omega) E \qquad [13]$$

where E is the electric field amplitude at frequency ω_d. The linear susceptibility (real and imaginary parts) is given by the following expressions:

$$\mathrm{Re}\chi_D^{(1)}(-\omega_d,\omega_d) = \frac{|\mu_{13}|^2 N}{\varepsilon_0 \hbar} \times \left[\frac{-4\Delta_{21}(|\Omega_2|^2 - 4\Delta_{21}\Delta_{32}) + 4\Delta_{31}\gamma_a^2}{4\Delta_{31}\Delta_{21} - \gamma_d\gamma_a - |\Omega_2|^2)^2 + 4(\gamma_d\Delta_{21} + \gamma_a\Delta_{31})^2} \right] \qquad [14]$$

$$\mathrm{Im}\chi_D^{(1)}(-\omega_d,\omega_d) = \frac{|\mu_{13}|^2 N}{\varepsilon_0 \hbar} \times \left[\frac{8\Delta_{21}^2\gamma_d + 2\gamma_a(|\Omega_2|^2 + \gamma_d\gamma_a)}{(4\Delta_{31}\Delta_{21} - \gamma_d\gamma_a - |\Omega_2|^2)^2 + 4(\gamma_d\Delta_{21} + \gamma_a\Delta_{31})^2} \right] \qquad [15]$$

We now consider the additional two-photon resonant field ω_a. This leads to a four-wave mixing process that generates a field at ω_d (i.e., the probe frequency). The nonlinear susceptibility that describes the coupling of the fields in a four-wave mixing process is given by the expression:

$$\chi_D^{(3)}(-\omega_d,\omega_a,\omega_a,\omega_c) = \frac{\mu_{23}\mu_{13}N}{6\varepsilon_0\hbar^3((\Delta_{21} - j\gamma_a/2)(\Delta_{31} - j\gamma_d/2) - (|\Omega_c|^2/4))^*} \times \sum_i \mu_{i1}\mu_{i3}\left(\frac{1}{\omega_i - \omega_a} + \frac{1}{\omega_i - \omega_b}\right)$$

Nonlinear Optical Processes

The dependence of the susceptibilities upon the detuning is plotted in Figure 3. In this plot the effects of inhomogeneous (Doppler) broadening are

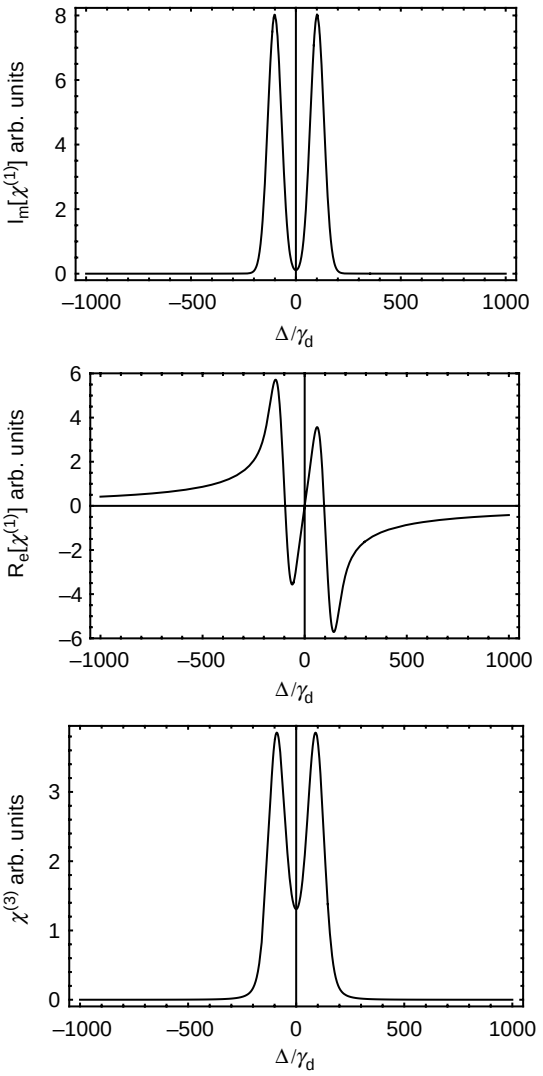

Figure 3 Electromagnetically induced transparency is shown in the case of significant Doppler broadening. The Doppler averaged values of the imaginary $\mathrm{Im}[\chi^{(1)}]$ and real $\mathrm{Re}[\chi^{(1)}]$ parts of the linear susceptibility and the nonlinear susceptibility $\chi^{(3)}$ are plotted in the three frames. The Doppler width is taken to be $20\gamma_d$, $\Omega_c = 100\gamma_d$ and $\gamma_d = 50\gamma_a$, $\gamma_c = 0$.

also incorporated by computing the susceptibilities over the inhomogeneous profile (see below for more details).

By inspection of eqn [14] we see that the absorptive loss at the minimum of $\mathrm{Im}[\chi^{(1)}]$ varies as γ_a/Ω_c^2. This dependence is a consequence of the interference discussed above. In the absence of interference (i.e., just simply Autler–Townes splitting) the minimum loss would vary as γ_d/Ω_c^2. Since $|3> - |1>$ is an allowed decay channel (in contrast to $|2> - |1>$) it follows that $\gamma_b \gg \gamma_a$ and so the absorption is much less as a consequence of EIT. $\mathrm{Re}[\chi^{(1)}]$ in eqn [15] and Figure 3 is also modified significantly. The resonant value of refractive index is equal to the vacuum value where the absorption is a minimum, the dispersion is normal in this region with a gradient determined by the strength of the coupling laser, a point we will return to shortly. For an unmodified system the refractive index is also unity at resonance but in that case there is high absorption and steep anomalous absorption. Reduced group velocities result from the steep normal dispersion that accompanies EIT. Inspection of the expression [16] and Figure 3 shows that $\chi^{(3)}$ is also modified by the coupling field. The nonlinear susceptibility depends upon $1/\Omega_c^2$ as is expected for a laser dressed system, however in this case there is not destructive but rather constructive interference, between the field-split components. This result is of great importance: it ensures that the absorption can be minimized at frequencies where the nonlinear absorption remains large.

As a consequence of constructive interference the nonlinear susceptibility remains resonantly enhanced whilst the linear susceptibility vanishes or becomes very small at resonance due to destructive interference. Large nonlinearity accompanying vanishing absorption (transparency) of course match conditions for efficient frequency mixing as a large atomic density can then be used. Moreover the dispersion (controlling the refractive index) also vanishes at resonance; this leads to perfect phase matching (i.e., zero wavevector mismatch between the fields) in the limit of a simple three-level system. As a result of these features a large enhancement of the conversion efficiency in this type of scheme can be achieved.

To compute the generated field strength Maxwell's equations must be solved using these expression for the susceptibility to describe the absorption, refraction, and nonlinear coupling in the medium. We will treat this within the slowly varying envelope approximation since the fields are cw or nanosecond pulses. To be specific we assume that the susceptibilities are time independent, i.e., that we are in the steady-state (cw) limit. We make the assumptions also that there is no pump field absorption and that we have plane waves. Under these assumptions the generated field amplitude A_d is given in terms of the other field amplitudes A_i by:

$$\frac{\partial}{\partial z}A_\mathrm{d} = \mathrm{i}\frac{\omega_\mathrm{d}}{4c}\chi^{(3)}A_\mathrm{a}^2A_\mathrm{c}\mathrm{e}^{-\mathrm{i}\Delta k_\mathrm{d}z} - \frac{\omega_\mathrm{d}}{2c}\mathrm{Im}[\chi^{(1)}]A_\mathrm{d} + \mathrm{i}\frac{\omega_\mathrm{d}}{2c}\mathrm{Re}[\chi^{(1)}]A_\mathrm{d} \qquad [16]$$

where the wavevector mismatch is given by:

$$\Delta k_\mathrm{d} = k_\mathrm{d} + k_\mathrm{c} - 2k_\mathrm{a} \qquad [17]$$

The wavevector mismatch will be zero on resonance for the three-level atom considered in this treatment. In fact the contribution to the refraction from all the other atomic levels must be taken into account whilst computing Δk_d and it is implicit that these make a finite contribution to the wavevector mismatch.

We can solve this first-order differential equation with the boundary condition $A_\mathrm{d}(z=0)=0$ to find the generated intensity $I(\omega_\mathrm{d})$ after a length z:

$$I(\omega_\mathrm{d}) = \frac{3n\omega_\mathrm{d}^2}{8Z_0c^2}|\chi^{(3)}|^2|A_\mathrm{a}|^4|A_\mathrm{c}|^2 \times \frac{\left\{1+\mathrm{e}^{-\frac{\omega_\mathrm{d}}{c}\mathrm{Im}[\chi^{(1)}]z} - 2\mathrm{e}^{-\frac{\omega_\mathrm{d}}{c}\mathrm{Im}[\chi^{(1)}]z}\cos\left(\Delta k + \frac{\omega_\mathrm{d}}{2c}\mathrm{Re}[\chi^{(1)}]\right)z\right\}}{\frac{\omega_\mathrm{d}^2}{4c^2}\mathrm{Im}[\chi^{(1)}]^2 + \left\{\Delta k + \frac{\omega_\mathrm{d}}{2c}\mathrm{Re}[\chi^{(1)}]\right\}^2}$$

where Z_0 is the impedance of free space. This expression is quantitatively correct for the case of the assumptions made. More generally the qualitative predictions and general scaling remain valid in the limit where the pulse duration is significantly longer than the time required to traverse the medium. Note that both real and imaginary parts of $\chi^{(1)}$ and $\chi^{(3)}$ play an important role, as we would expect for resonant frequency mixing. The influence of that part of the medium refraction which is due to other levels is contained in the terms with Δk. In the case of a completely transparent medium this becomes a major limit to the conversion efficiency.

Propagation and Wave-Mixing in a Doppler Broadened Medium

Doppler shifts arising from the Maxwellian velocity distribution of the atoms in the medium lead to a corresponding distribution in the detunings for

the various members of the atomic ensemble. The response of the medium, as characterized by the susceptibilities, must therefore include the Doppler effect by performing a weighted sum over possible detunings. The weighting is determined by the Gaussian form of the Maxwellian velocity distribution. From this operation the effective values of the susceptibilities at a given frequency are obtained, and these quantities can be used to calculate the generated field. This step is of considerable practical importance as in most up-conversion schemes it is not possible to achieve Doppler-free geometries and the use of laser cooled atoms, although in principle possible, limits the atomic density that can be employed. The interference effects persist in the dressed profiles providing the coupling laser Rabi frequency is comparable to or larger than the inhomogeneous width. This is because the Doppler profile follows a Gaussian distribution which falls off much faster in the wings of the profile than the Lorentzian profile due to the natural broadening.

In the case considered with weak probe field, excited state populations and coherences remain small. The two-photon transition need not be strongly driven (i.e., a small two-photon Rabi frequency can be used) but a strong coupling laser is required. The coupling laser must be intense enough that its Rabi frequency is comparable to or exceeds the inhomogenous widths in the system (i.e., Doppler width), and a laser intensity of above 1 MW cm^{-2} is required for a typical transition. This is trivially achieved even for unfocused pulsed lasers, but does present a serious limit to cw lasers unless a specific Doppler-free configuration is employed. The latter is not normally suitable for a frequency up-conversion scheme if a significant up-conversion factor is required, e.g., to the vacuum ultraviolet (VUV); however recent experiments report significant progress in cw frequency up-conversion using EIT and likewise a number of other possibilities, e.g., laser-cooled atoms and standing-wave fields, have been proposed.

A transform-limited single-mode laser pulse is essential for the coupling laser field since a multimode field will cause an additional dephasing effect on the coherence, resulting in a deterioration of the quality of the interference. In contrast, whilst it is advantageous for the field driving the two-photon transition to be single mode (in order to achieve optimal temporal and spectral overlap with the EIT hole induced by the dressing laser), this is not essential since this field does not need to drive the coherence responsible for interference.

When a pulsed laser field is used additional issues must be considered. The group velocity is modified for pulses propagating in the EIT large reductions, e.g., by factors down to $<c/100$, in the group velocity have been observed. Another consideration beyond that found in the simple steady-state case is that the medium can only become transparent if the pulse contains enough energy to dress all the atoms in the interaction volume. The minimum pulse energy to prepare a transparency is:

$$E_{\text{preparation}} = \frac{f_{13}}{f_{23}} NL\hbar\omega \qquad [18]$$

where f_{ij} are the oscillator strengths of the transitions and NL the product of the density and the length. Essentially the number of photons in the pulse must exceed the number of atoms in the interaction volume to ensure all atoms are in the appropriate dressed state. This puts additional constraints on the laser pulse parameters.

Up-conversion to the UV and vacuum UV has been enhanced by EIT in a number of experiments. Only pulsed fields have so far been up-converted to the VUV with EIT enhancement. The requirements on a minimum value of $\Omega_c > \Delta_{\text{Doppler}}$ constrains the conversion efficiency that can be achieved because the $1/\Omega_c^2$ factor in eqn [17] ultimately leads to diminished values of $\chi^{(3)}$. The use of gases of higher atomic weight at low temperatures is therefore highly desirable in any experiment utilizing EIT for enhancement of four-wave mixing to the VUV. Conversion efficiencies, defined in terms of the pulse energies by E_d/E_a or E_d/E_c of a few percent have been achieved using the EIT enhancement technique. It is typically most beneficial to maximize the conversion efficiency defined by the first ratio since ω_a is normally in the UV and is the lower energy of the two applied pulses.

Nonlinear Optics with a Pair of Strong Coupling Fields in Raman Resonance

An important extension of the EIT concept occurs when two strong fields are applied in Raman resonance between a pair of states in a three-level system. Considering the system illustrated in Figure 1 we can imagine that both applied fields are now strong. Under appropriate adiabatic conditions the system evolves to produce the maximum possible value for the coherence $\varrho_{12} = 0.5$. Adiabatic evolution into the maximally coherent state is achieved by adjusting either the Raman detuning or the pulse sequence (counter to-intuitive order). The pair of fields may also be in single-photon resonance with a

third level, in which case the EIT-like elimination of absorption will be important. This situation is equivalent to the formation of a darkstate, since neither of the two strong fields is absorbed by the medium. For sufficiently strong fields the single-photon condition need not be satisfied and a maximum coherence will still be achieved.

An additional field applied to the medium can participate in sum- or difference-frequency mixing with the two Raman resonant fields. The importance of the large value of coherence is that it is the source polarization that drives the new fields generated in the frequency mixing process. Complete conversion can occur over a short distance that greatly alleviates the constraints usually set by phase-matching in nonlinear optics. Recently near unity conversion efficiencies to the far-UV were reported in an atomic lead system where maximum coherence had been created. In a molecular medium large coherence between vibrational or rotational levels has also been achieved using adiabatic pulse pairs. Efficient multi-order Raman sideband generation has been observed to occur. This latter observation may lead the way to synthesizing very short duration light pulses since the broadband Raman sideband spectrum has been proved to be phase-locked.

Pulse Propagation and Nonlinear Optics for Weak CW Fields

In a Doppler-free medium a new regime can be accessed. This is shown in Figure 4 where the possibility now arises of extremely narrow transparency dips since very small values of Ω_c are now sufficient to induce EIT. The widths of these features are typically subnatural and are therefore accompanied by very steep normal dispersion, which corresponds to a much reduced group velocity. The ultraslow propagation of pulses is one of the most dramatic manifestations of EIT in this regime. Nonlinear susceptibilities are now very large as there is constructive interference controlling the value and the splitting of the two states is negligible compared to their natural width. Nonlinear optics at very low light levels, i.e., at the few-photon limit, is possible in this regime.

Propagation of pulses is significantly modified in the presence of EIT. Figure 4 shows the changes to $\mathrm{Re}[\chi^{(1)}]$ that arise. Within the transparency dip there exists a region of steep normal dispersion. In the vicinity of resonance this is almost linear and it becomes reasonable to consider the leading term only that describes the group velocity. An analysis of the

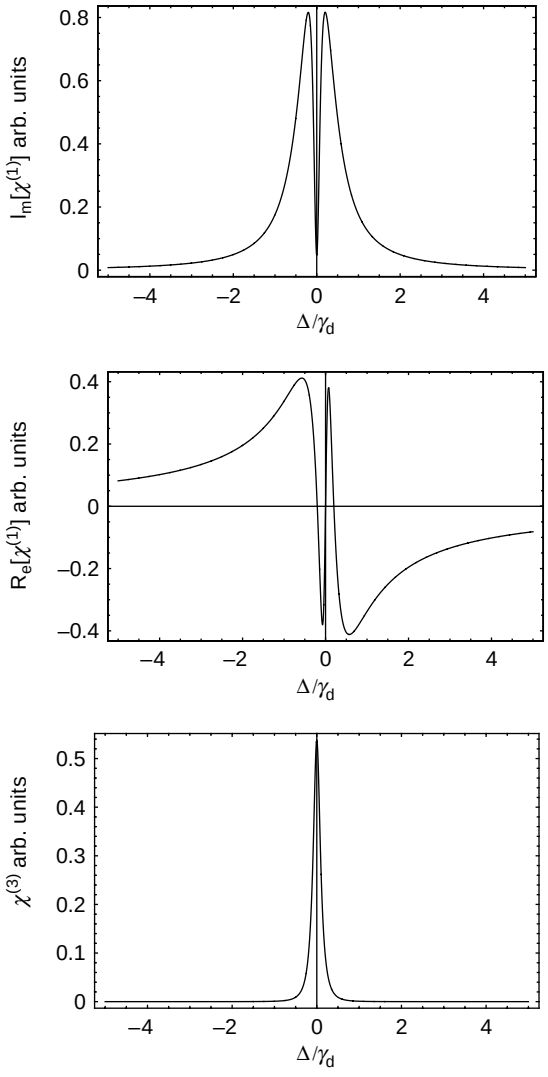

Figure 4 Electromagnetically induced transparency is shown in the case where there is no significant Doppler broadening. The values of the imaginary $\mathrm{Im}[\chi^{(1)}]$ and real $\mathrm{Re}[\chi^{(1)}]$ parts of the linear susceptibility and the nonlinear susceptibility $\chi^{(3)}$ are plotted in the three frames. We take $\Omega_c = \gamma_d/5$ and $\gamma_d = 50\gamma_a$, $\gamma_c = 0$.

refractive changes has been provided by Harris who expanded the susceptibilities (both real and imaginary parts) of the dressed atom around the resonance frequency to determine various terms in $\mathrm{Re}[\chi^{(1)}]$. The first term of the series (zero order) $\mathrm{Re}[\chi^{(1)}](\omega_{13}) = 0$ corresponds to the vanishing dispersion at resonance. The next term $\partial[\mathrm{Re}\chi^{(1)}](\omega)/\partial\omega$ gives the slope of the dispersion curve; at ω_{13} this takes the value:

$$\frac{\partial \mathrm{Re}\chi^{(1)}(\omega_{13})}{\partial\omega} = \frac{|\mu_{13}|^2 N 4(\Omega_c^2 - \gamma_a^2)}{2\pi\varepsilon_0(\Omega_c^2 + \gamma_a\gamma_d)} \qquad [19]$$

The slope of the dispersion profile leads to a reduced group velocity v_g:

$$\frac{1}{v_g} = \frac{1}{c} + \frac{\pi}{\lambda}\frac{\partial \chi^{(1)}}{\partial \omega} \qquad [20]$$

From the expression for $\partial\chi/\partial\omega$ we see that this slope is steepest (and so v_g mimimum) in the case where $\Omega_c \gg \Gamma_2$ and $\Omega_c^2 \gg \Gamma_2\,\Gamma_3$ but is still small compared to Γ_3 (i.e., $\Omega_C < \Gamma_3$) and hence $\partial\chi/\partial\omega \propto 1/\Omega_c^2$. In the limit of small Ω_c the following expression for v_g therefore holds:

$$v_g = \frac{\hbar c \varepsilon_0 [\Omega_c]^2}{2\omega_d |\mu_{13}|^2 N} \qquad [21]$$

Extremely low group velocities, down to a few meters per second, are achieved in this limit using excitation of the hyperfine split ground states in either laser cooled atomic samples or Doppler-free configurations in finite temperature samples. Recently similar light slowing has been observed in solids. Storage of the optical pulse within the medium has also been achieved by adiabatically switching off the coupling field and thus trapping the optical excitation as an excitation within the hyperfine ground states for which the storage time can be very long (>1 ms) due to very low dephasing rates. Since the storage scenario should be valid even for single photons this process has attracted considerable attention recently as a means to enable quantum information storage.

Extremely low values of Ω_c are sufficient to induce complete transparency (albeit in a very narrow dip) and at this location the nonlinear response is resonantly enhanced. Very high efficiency nonlinear frequency mixing and phase conjugation at low light levels have been reported under these conditions. It is expected that high-efficiency nonlinear optical processes will persist to ultralow intensities (the few photon level) in an EIT medium of this type.

One example of highly enhanced nonlinear interactions is the predicted large values of the Kerr type nonlinearity (nonlinear refractive index). The origin of this can be seen by considering the steep dispersion profile in the region of the transparency dip in Figure 4. Imagine that we apply an additional field ω_f, perhaps a very weak one, at a frequency close to resonance between state |2> and a fourth level |4>. The ac Stark shift caused by this new field to the other three level, although small, will have a dramatic effect upon the value of the refractive index because of the extreme steepness of the dispersion profile. Essentially even a very small shift of the resonant wavelength causes a large change in the refractive index for a field applied close to this frequency. It is predicted that strong cross-phase modulations will be created in this process between the fields ω_f and ω_d, even in the quantum limit for these fields. This is predicted to lead to improved schemes for quantum nondemolition measurements of photons through the measurement of the phase-shifts they induce (through cross-phase modulation) on another quantum field. This type of measurement has direct application in quantum information processing.

Introduction

Lidars developed for the measurement of atmospheric winds make use of the Doppler effect, in which radiation scattered or emitted from a moving object is shifted in frequency as a result of the movement of the particles. Atmospheric Doppler lidars irradiate a volume of atmosphere with a pulse of very narrowband, laser-produced radiation, then detect the change in frequency of the radiation backscattered from atmospheric aerosol particles or molecules present in the volume. Although Doppler lidars are conceptually similar to Doppler weather radars, lidar wavelengths are 3–4 orders of magnitude shorter than radar wavelengths, producing some important differences in propagation and scattering characteristics. Radiation at wavelengths in the optical region of the spectrum is efficiently scattered by aerosols and molecules, therefore Doppler lidars, unlike commonly used Doppler weather radars, do not require the presence of hydrometeors or insects to obtain useful results. Also, optical radiation can be tightly collimated, virtually eliminating effects of ground clutter and enabling lidar probing of small volumes to within a few meters of terrain or structures.

The primary disadvantage of lidar techniques is the severe attenuation of the optical radiation by cloud water droplets and fog. Doppler lidars do not typically probe beyond the edge of most atmospheric clouds – the one exception being tenuous ice clouds such as cirrus, which often are characterized by low optical extinction and high backscatter, making them excellent lidar targets. Doppler lidars also do not have the extended range, which can exceed 100 km, available from contemporary meteorological radars when scatterers are present.

In clear air, however, the characteristics and capabilities of Doppler lidar are well suited for obtaining detailed wind and turbulence observations for a wide variety of applications. Lidar beams can be easily scanned to characterize motions within very confined three-dimensional spaces such as shallow atmospheric boundary layers, narrow canyons, and turbulent structures. The relative compactness of Doppler lidars makes deployment on aircraft or other moving platforms extremely viable, and a Doppler lidar deployed on a satellite has been proposed as a way to obtain global measurements of atmospheric wind fields. By scanning a lidar beam from an orbiting satellite and analyzing the returns backscattered from clouds, aerosols, and molecules, a satellite-based instrument could provide important wind information for numerical forecast models.

Doppler Lidar Fundamentals

Backscattered Light

As laser light propagates through the atmosphere, some of the incident energy is scattered by the atmospheric molecules and constituents through which the light passes. In lidar applications, the light backscattered (scattered directly back toward the source) is collected and analyzed. The backscattering properties of an atmospheric particle depend on its refractive index, shape, and size. In the special case when the particle is much smaller than the wavelength of the incident radiation, as is the case for laser radiation scattered by atmospheric molecules, the scattering process is characterized as Rayleigh scattering. Because, in the Rayleigh scattering regime the energy backscattered by a particle increases proportionally as the inverse of the fourth power of the wavelength, Doppler lidar systems designed for molecular scatter operate at short wavelengths. Molecular Doppler lidar systems typically operate in the visible or ultraviolet spectral regions.

Aerosol particles, the other component of the atmosphere that scatters laser light, produce Mie scattering, which applies when the diameter of the scatterers is not orders of magnitude smaller than the incident wavelength. Aerosol particles present in the atmosphere include dust, soot, smoke, and pollen, as well as liquid water and ice. Although for Mie scattering the relationship between the power backscattered by an ensemble of aerosol particles and the incident wavelength is not simply characterized, most studies have shown that the energy backscattered increases roughly proportional to the first or second power of the inverse of the incident wavelength, depending on the characteristics of the scattering aerosol particles. In a polluted environment, such as in the vicinity of urban areas, an abundance of large particles often results in a roughly linear relationship between the inverse of the incident wavelength and the backscattered energy, while in more pristine environments, such as the free troposphere, the inverse wavelength/backscatter relationship can approach or exceed a square-law relationship.

The primary objective in Doppler lidar is to measure the Doppler frequency shift of the scattered radiation introduced by the movements of the scattering particles. Figure 1 shows a typical spectrum of the radiation collected at the lidar receiver for a volume of atmosphere irradiated by a monochromatic laser pulse. Molecular scattering produces the broadband distribution in Figure 1, where the broadening results from the Doppler shifts of the radiation backscattered from molecules moving at their thermal velocities. The width of the molecular velocity distribution in the atmosphere ranges from ~ 320 to 350 m s^{-1}, scaling as the square root of the temperature. In the center of the spectrum is a much narrower peak resulting from scattering of the light by aerosol particles. Because the thermal velocity of the much larger aerosol particles is very low, the width of the distribution of the aerosol return is determined by the range of velocities of particles moved about by small-scale turbulence within the scattering volume. This is typically on the order of a few m s^{-1}. Also shown in Figure 1 is an additional broadband distribution, due to scattered solar radiation collected at the receiver. If the laser source is not monochromatic, the backscattered signal spectrum is additionally broadened, with the resulting spectrum being the convolution of the spectrum shown in Figure 1 with the spectrum of the laser pulse. As seen in the figure, the entire spectrum is Doppler-shifted in frequency, relative to the frequency of the laser pulse. The object for a Doppler lidar system is to measure this shift, given by $\delta f = 2v_{\text{rad}}/\lambda$, where v_{rad} is the component of the mean velocity of the particles in the direction of propagation of the lidar pulse and λ is the laser wavelength.

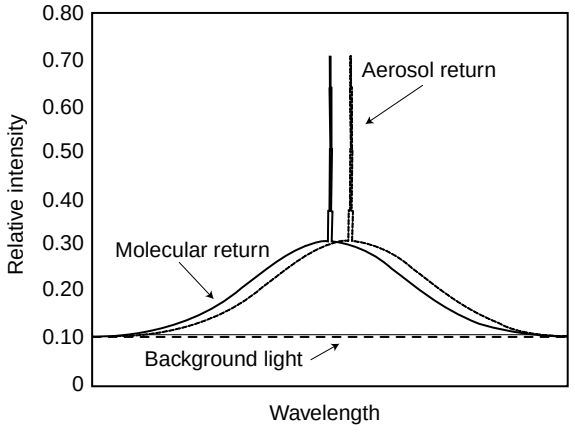

Figure 1 Distribution of wind velocities in a lidar return, showing Doppler shift resulting from wind-induced translation of the scatterers. The ratio of aerosol to molecular signals increases with increasing wavelength.

Elements of a Doppler Lidar

Doppler lidar systems can be designed primarily to measure winds from aerosol-scattered radiation, molecule-scattered radiation, or both. The type of system places specific requirements on the primary components that comprise a Doppler lidar system. A Doppler lidar consists of a laser transmitter to produce pulses of energy that irradiate the atmospheric volume of interest, a receiver which collects the backscattered photons and estimates the energy and Doppler shift of the return, and a beam pointing mechanism for directing the laser beam and receiver field of view together in various directions to probe different atmospheric volumes. Independent of whether the primary scatterers are molecules or aerosol particles, the system design criteria for a Doppler system are driven by a fundamental relationship between the error in the estimate of mean frequency shift δf_1, the bandwidth of the return f_2 (proportional to the distribution of velocities), and the number of incident backscattered photons detected N as

$$\delta f_1 \propto f_2/N^{1/2} \qquad [1]$$

Thus, the precision of the velocity estimate is improved by increasing the number of detected signal photons and/or decreasing the bandwidth of the backscattered signal. It is obvious from the equation that a significantly greater number of photons are required to achieve the same precision in a Doppler measurement from a molecular backscattered signal,

characterized by higher bandwidth f_2, compared to the number required to compute velocities from aerosol returns. The improved measurement precision gained from a narrow bandwidth return also indicates that the laser transmitter in a Doppler lidar system should be characterized by narrow spectral width (considerably narrower than the spectral broadening caused by the distribution of velocities), and to increase the number of photons detected, maximum transmit energy.

Narrowband, single-frequency pulses are obtained by employing a low-power, precisely frequency-stabilized master oscillator laser, whose radiation is either used to seed a stabilized, higher-energy laser cavity (injection seeding) or amplified in one or more optical amplifiers (master-oscillator, power amplifier, (MOPA)) to produce frequency-stabilized pulses.

The lidar receiver gathers the backscattered photons and extracts the wind velocity as a function of the range to the scattering volume. This requires a telescope, to gather and focus the scattered radiation, and a receiver to detect the scattered radiation and determine the Doppler shift. Frequency analysis in a Doppler lidar receiver is carried out using one of two techniques: coherent detection (also known as heterodyne detection) or direct detection (alternately labeled incoherent detection). The techniques differ fundamentally. In a heterodyne receiver, frequency analysis is carried out on a digitized time series created by mixing laser radiation with the backscattered radiation, while in direct detection lidar an interferometer optically analyzes the backscattered radiation to produce a light pattern which contains the information on the frequency content.

Coherent (Heterodyne) Doppler Lidar

Description

Coherent or heterodyne lidar is implemented by optically mixing the backscattered laser light with radiation from a stable, continuous-wave, local oscillator (LO) laser whose frequency is precisely controlled to be a known frequency offset, typically on the order of tens of MHz, from that of the laser transmitter (Figure 2). The mixing process at the face of an optical detector generates, after high pass filtering, an electrical signal with amplitude proportional to amplitude of the backscattered electromagnetic field and frequency equal to the difference between the backscattered field frequency and the LO laser field frequency. This signal is sampled, and then digitally processed to estimate the range-dependent mean frequency shift of the backscattered signal, from which the radial wind component can be

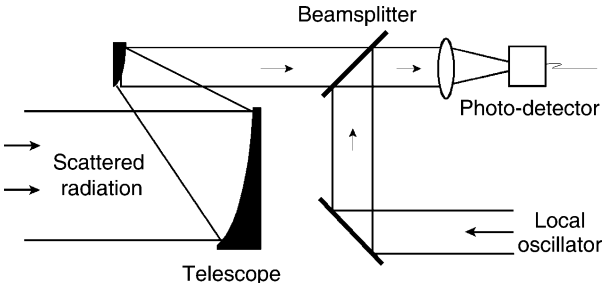

Figure 2 Schematic of coherent detection of backscattered radiation.

derived. A property of coherent lidar is that, because of constructive and destructive interference of the returns from individual scatterers, single pulse returns are characterized by random fluctuations in the amplitude and phase of the detected time series and Fourier spectrum. Consequently, averaging (sometimes referred to as accumulation) over multiple pulses usually is necessary to produce a sufficiently precise estimate of the signal mean frequency estimate. Because the phase of the detected time series is random within each pulse, averaging must be carried out in the power spectrum or autocorrelation function domain, rather than on the detected time series.

The optical mixing process in coherent Doppler lidar provides both benefits and design challenges. Because receiver efficiencies (equivalent fraction of incident photons entering the receiver that are converted to electrons) are quite high, wind velocities can be estimated from very weak backscattered signals. Also, signal processing is performed on a time series derived from the mixed signal, enabling the use of electrical filters to produce a narrow receiver bandwidth and effectively eliminating broadband solar background light as a major source of noise. As a result, unlike many lidars coherent Doppler lidar performance is not degraded under daylight conditions.

The primary limitation of coherent detection results from the added photon noise from the local oscillator radiation (which is usually much stronger than the backscattered radiation). The effect of local oscillator photon noise is to define a system noise level below which very weak signals cannot be practically extracted, even with substantial multiple-pulse averaging. In addition, because efficient mixing requires phase coherence of the backscattered signal field across the detector, coherent lidar performance at longer ranges is degraded by strong optical turbulence along the path of the laser pulse. These adverse effects of turbulence increase for shorter wavelength systems.

Although measurements at wavelengths near 1.06 μm have been demonstrated, coherent Doppler lidar systems used for regular atmospheric probing operate in the eye-safe, infrared portion of the spectrum at wavelengths longer than 1.5 μm. Currently, the two most common system wavelengths for coherent lidar wind systems are in atmospheric window spectral regions around 2 and 10.6 μm. Early coherent Doppler lidar measurements, beginning in the 1970s, employed CO_2 laser transmitters and local oscillators operating at wavelengths near 10.6 μm. Pulsed CO_2 laser transmitters with as much as 10 J of energy have since been demonstrated, and systems with 1 J lasers have probed the atmosphere to ranges of 30 km or more. In the late 1980s, solid state laser transmitters operating near 2 μm wavelengths were introduced into coherent lidar wind-measuring systems. The compact size and potential reliability advantages of solid-state transmitters, in which the transmitter laser is optically pumped by an array of laser diodes, provide advantages over larger CO_2 laser technology. Also, because for a given measurement accuracy the range-resolution obtainable is proportional to wavelength, 2 μm instruments have an enhanced capability to probe small-scale features. However, although development of higher energy, single-frequency coherent lidar sources operating at 2 μm region, as well as at 1.5 μm, is currently an active research area, solid state lasers with pulse energies greater than several tens of mJ have yet to be incorporated into lidar systems for atmospheric probing.

Applications of Coherent Doppler Lidar

Coherent lidars have been used to measure winds for a variety of applications, and from an assortment of platforms, such as ships and aircraft. Since these lidars operate in the infrared where aerosol scattering dominates molecular scattering, they require aerosol particles to be present at some level to obtain usable returns. Although clouds also provide excellent lidar targets, most of the more useful applications of coherent lidars involve probing the atmospheric boundary layer or lower troposphere where aerosol content is highest. Because of the capability to scan the narrow lidar beam directly adjacent to terrain, a unique application of lidar probing is the measurement of wind structure and evolution in complex terrain such as mountains and valleys. Over the past two decades, Doppler lidar studies have been used, for example, to study structure of damaging windstorms on the downwind side of mountain ranges, advection of pollution by drainage flows from valleys, and formation of mountain leeside turbulence as a potential hazard to landing aircraft. The interactions of wind flows with complex terrain can produce dangerous conditions for transportation, especially aircraft operations. Figure 3 shows a strong mountain wave measured by a Doppler lidar near Colorado Springs, during an investigation of the effects of downslope winds and turbulence on aircraft operations at the Colorado Springs airport. The mountains are on the right of the figure, where the strong wave with wavelength of about 6 km can be seen. Note the reversal in winds near the location where the wave descends to the surface. The Colorado Springs study was prompted by the crash of a passenger jet while landing at the airport during a period when the winds were down the slope of the Rocky Mountains just to the west of the airport.

A Doppler lidar was recently deployed in an operational mode for wind shear detection at the new Hong Kong International Airport. Because winds flowing over mountainous terrain just south of the

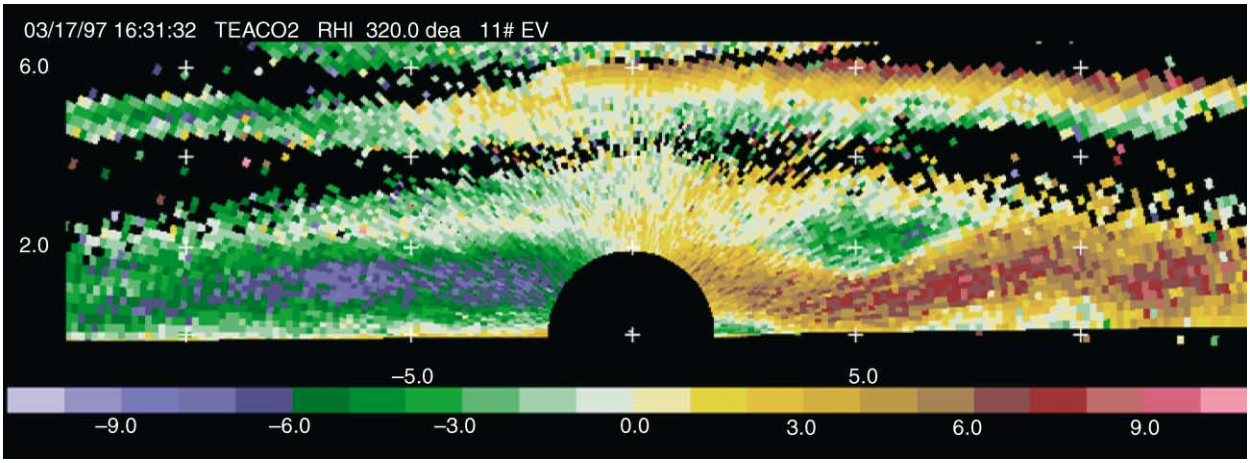

Figure 3 Vertical scan of the winds in a mountain wave measured by a 10.6 μm coherent Doppler lidar near Colorado Springs, Colorado. Courtesy L. Darby, NOAA.

airport can produce mountain waves and channeled flows, wind shear is frequently encountered during landing and takeoff operations. Figure 4 shows a gust front situated just to the west of the airport, characterized by a sharp wind change (which would produce a corresponding change in airspeed) approaching 13 m s^{-1} over a distance of less than one kilometer. Providing a capability to detect such events near the airport and warn pilots during approach or preparation for takeoff was the primary reason for deployment of the lidar. Within the first year of operation the Hong Kong lidar was credited with improving wind shear detection rates and providing more timely warnings for pilots of the potentially hazardous conditions. As of August 2003 this lidar had logged more than 10 000 hours of operation.

Because coherent Doppler lidars are well matched to applications associated with probing small-scale, turbulent phenomena, they have also been deployed at airports to detect and track wing tip vortices generated by arriving or departing aircraft on nearby parallel runways. In the future, a network of ground-based lidars could provide information on vortex location and advection speed as well as wind shear, leading to a potential decrease in congestion at major airports. Also, compact lidar systems looking directly ahead of research aircraft have shown the capability to detect wind changes associated with potentially hazardous clear-air turbulence. In the future, a Doppler lidar installed on the commercial aircraft fleet could potentially look ahead and provide a warning to passengers to fasten seat belts before severe turbulence is encountered.

The high resolution obtainable in a scanning lidar enables visualization of finely structured wind and turbulence layers. Figure 5 shows an image of turbulence associated with a nocturnal low-level jet just 50 m above the surface obtained at night over flat

terrain in Kansas. Although a low-level jet was present on just about every evening during the experiment, similar images obtained at different times by the Doppler lidar illustrated markedly different characteristics, such as a wide variation in the observed mechanical turbulence along the interface. Such observations enable researchers to improve parameterizations of turbulence in models and better understand the conditions associated with vertical turbulent transport and mixing of atmospheric constituents such as pollutants.

By deploying Doppler lidars on moving platforms such as ships and aircraft, the spatial coverage of the measurements can be greatly increased. Although removal of platform motion and changes in orientation are not trivial, aircraft-mounted lidar can map out such features as the low-level jet and the structure of boundary layer convective plumes. Figure 6 shows horizontal and vertical motions associated with convective plumes measured along an approximately 60 km path over the southern Great Plains of the United States. From such measurements estimates of turbulence intensity, integral scale, and other boundary layer characteristics can be computed.

Direct Detection Doppler Lidar

Description

Direct detection or incoherent Doppler lidar has received significant attention in recent years as an alternative to coherent lidar for atmospheric wind measurements. In contrast to coherent lidar, in which an electrical signal is processed to estimate Doppler shift, an optical interferometer, usually a Fabry–Perot etalon, serves as the principal element in a direct detection lidar receiver for determining the frequency shift of the backscattered radiation.

One implementation of a direct-detection Doppler lidar receiver is the 'fringe imaging' technique. In this design, the interferometer acts as a spectrum analyzer. The backscatter radiation is directed through a

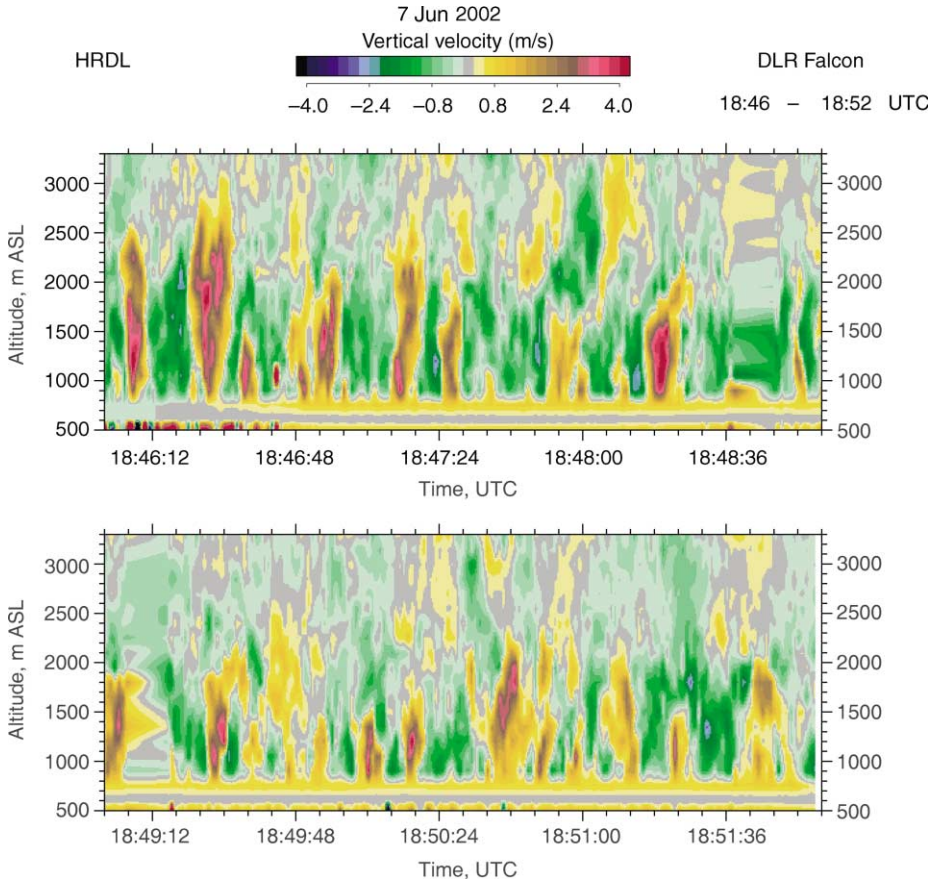

Figure 6 Vertical motion in convective plumes measured by a vertically pointing airborne coherent Doppler lidar. Total horizontal extent of the measurements is approximately 60 km, reddish colors correspond to upward motions.

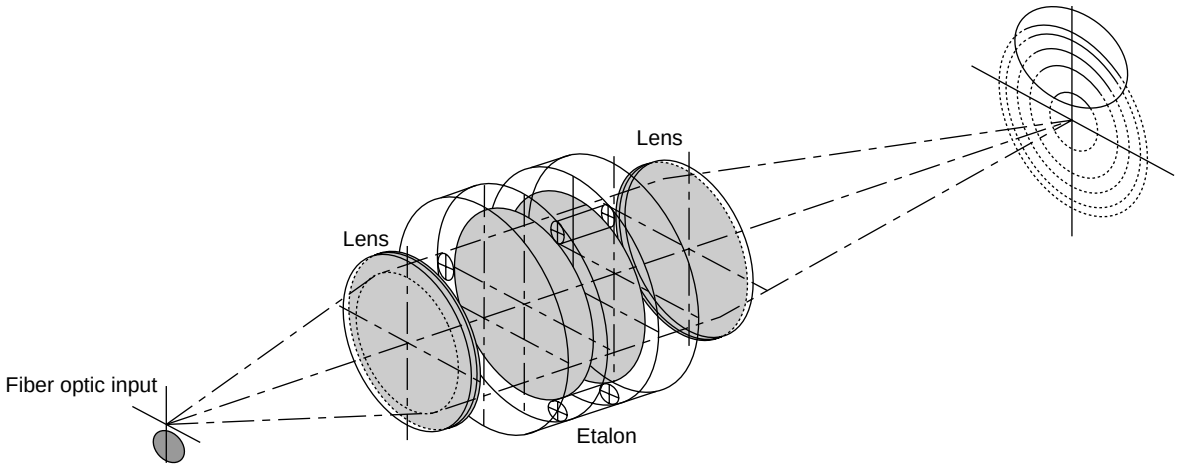

Figure 7 Schematic of Fabry–Perot etalon in a direct detection, fringe-imaging lidar receiver. Courtesy P. Hays, Michigan Aerospace Corporation.

Fabry–Perot interferometer, which produces a ring pattern in the focal plane (Figure 7). The spectral content information of the incident radiation is contained in the radial distribution of the light. Each ring corresponds to an order of the interferometer and is equivalent to a representation of the backscattered signal frequency spectrum. As the mean frequency of the backscattered radiation changes, the rings move inward or outward from the center. To extract a spectrum of the backscattered light, one or

more of the rings are imaged onto a two-dimensional detector, and the resulting pattern analyzed. The rings can either be detected using a multi-element ring detector, or can be converted to a linear pattern with a circle-to-line converter optic and then imaged on to a charge-coupled device array device.

An alternate direct detection receiver configuration, generally called the double edge technique, is to employ two interferometers as bandpass filters, with the center wavelength of each filter set above and below the laser transmitter wavelength, as shown in Figure 8. The incoming radiation is split between the two interferometers, and the wavelength shift is computed by examining the ratio of the radiation transmitted by each interferometer. Both the double edge and fringe-imaging techniques have demonstrated wind measurements to heights well into the stratosphere. The major challenge associated with the double edge receiver is optimizing the instrument when both aerosol and molecular scattered radiation are present, since in general the change in transmission as a function of velocity is different for the aerosol and molecular signals. Double edge receivers optimized for both aerosol and molecular returns place the bandpass of the etalon filters at the precise wavelength where the change in transmission with change in Doppler shift is the same for both aerosol and molecular returns.

For both types of direct detection receivers described above, much of the radiation incident on the interferometer is reflected out of the system, reducing the overall efficiency of the receiver. Recently, designs that incorporate fiber optics to collect a portion of the reflected radiation and 'recycle' it back into the etalon have been demonstrated as a method to improve the transmission efficiency of the etalon in a fringe imaging receiver.

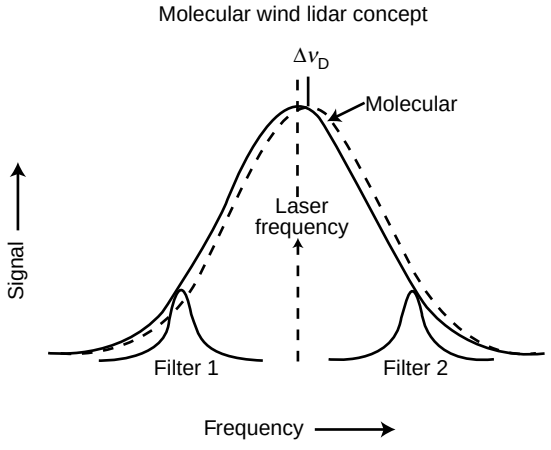

Figure 8 Spectrum of molecular lidar return showing placement of bandpass filters for a dual channel (double edge) direct detection receiver. Courtesy B. Gentry, NASA.

Doppler Wind Measurements Based on Molecular Scatter

One of the primary advantages of direct detection Doppler lidar is its capability for measurements based on scatter from atmospheric molecules. Measurement of Doppler shifts from molecular scattered radiation is challenging because of the large Doppler-broadened bandwidth of the return. Because one wants to measure a mean wind velocity with a precision of a few m s^{-1} or better, in the order of 10^5 photons are required. Some combination of multiple pulse averaging, powerful lasers, and large receiver optics is required to obtain these high photon counts from backscattered returns.

Molecular-scatter wind measurements have been demonstrated in the visible spectral region at 532 nm wavelength as well as at 355 nm in the near ultraviolet. The ultraviolet region has the dual advantages of enhanced molecular scatter and less restrictive laser eye-safety restrictions. Figure 9 shows the time series of a wind profile measured in the troposphere from both aerosols and clouds using a molecular-scatter, ground-based 355-nm wavelength Doppler fringe-imaging lidar. The figure shows measurements from receiver channels optimized for the wideband molecular signal and the narrowband aerosol return. For this measurement, backscattered photons were collected by a 0.5 m receiver aperture, averaged for 1 minute, and processed. In the absence of clouds, direct detection Doppler lidars have measured wind profiles continuously from the surface to beyond 15 km height. Figure 10 shows that the estimated wind error for the same 355 nm lidar is less than 1 m s^{-1} to about 10 km, and less than 4 m s^{-1} at 15 km height.

Heterodyne and Direct-Detection Doppler Trade-Offs

Lively debates within the lidar community have occurred over the past decade regarding the relative merits of heterodyne versus direct detection Doppler lidars. To a large extent, the instruments are complementary. Generally, heterodyne instruments are much more sensitive when significant aerosols are present. Coherent lidar processing techniques have been developed that can produce accurate wind measurement rates using only a few lidar pulses with as few as 100 detected photons, such that several wind observations per second can be obtained for nominal pulse rates. This inherent sensitivity has led to numerous applications in which a lidar beam has been scanned rapidly over a large volume to obtain time-varying, three-dimensional wind measurements.

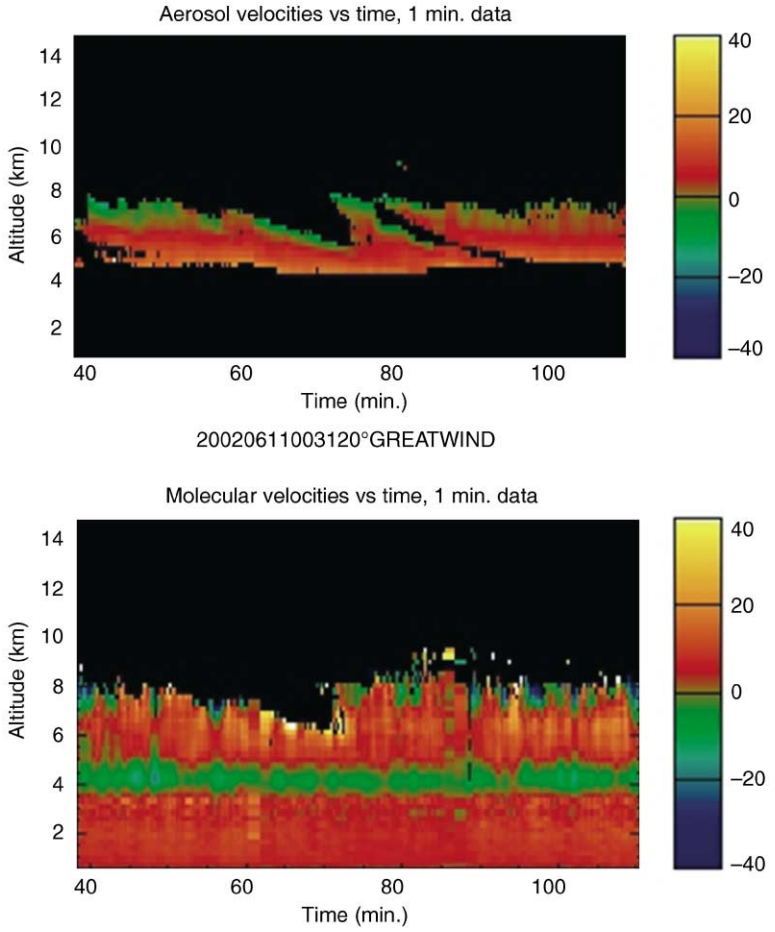

Figure 9 Time series of radial wind speed profiles measured by a 355 nm fringe-imaging direct detection lidar aerosol channel (top) and molecular channel (bottom) at Maura Loa Observatory, HI. Change in wind speed and blocking of the return by clouds is clearly seen. Courtesy C. Nardell, Michigan Aerospace Corp.

The primary advantage of direct detection instruments is their demonstrated capability to measure winds from molecular-backscattered returns in the middle and upper troposphere. In very pristine air, direct detection offers the only method for long-range wind measurements, even though significant averaging may be required. Direct-detection lidars have the additional advantage of being unaffected by atmospheric refractive turbulence. Unlike heterodyne lidars, which require a very pure laser pulse and a diffraction-limited receiver field of view matched to and precisely aligned with the transmitted beam, direct detection systems can have a wider bandwidth transmitter and a receiver field of view several times diffraction-limited. In direct detection lidar design, the field of view is usually constrained by the need to limit background light during daytime operation. A major design challenge for direct detection instruments is holding the Fabry–Perot etalon plate spacing stable over a range of temperatures and in high vibration environments.

Global Wind Measurements

A satellite-based Doppler lidar has frequently been proposed as a way to measure wind fields over most of the Earth. At present, winds are the one major meteorological variable not well-measured from orbiting platforms. Measurement of winds is especially important over regions of the Earth that are not currently well sampled, such as over Northern Hemisphere oceans, as well as over most of the tropics and Southern Hemisphere. Wind profile information is currently obtained from radiosondes and by tracking cloud and water vapor inhomogeneities using satellite imagers. Doppler lidar wind measurements would greatly augment the current data set by providing wind estimates throughout the troposphere under clear conditions, and highly height-resolved observations down to cloud tops when cloud decks are present. Observing system simulation experiments conducted in recent years indicate that satellite-based lidar global wind

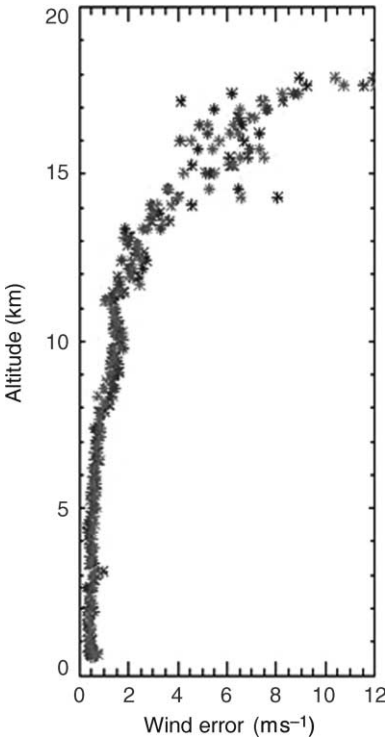

Figure 10 Estimated error in the radial velocity estimate versus altitude for a 355 nm direct detection, fringe imaging Doppler lidar system at Mauna Loa observatory on Hawaii. The lidar provides data for assimilation into local mesoscale forecast models. Courtesy C. Nardell, Michigan Aerospace Corp.

measurements could lead to a significant improvement in long-term forecast skill, provided the wind fields can be observed with sufficient accuracy and spatial resolution.

In a Doppler lidar wind mission, a satellite carrying a lidar system would orbit the Earth in a nearly polar orbit. The pulsed laser beam would be scanned conically about the nadir to obtain different components of the wind velocity. The scanning could be either continuous or 'stop and stare'. After sufficient returns are averaged at a given pointing angle to produce an acceptable estimate, the radial component of the velocity would be computed and assimilated directly into numerical analysis and forecast models.

Doppler lidar measurement of winds from space is theoretically feasible but technologically difficult. Depending on the orbital height, the scattering volume is anywhere from 450 to ~850 km from the satellite, which challenges the sensitivity of current system types. Because weight and power consumption are critical parameters for space systems, telescope diameter and laser power cannot be easily increased to obtain the necessary sensitivity. Similarly, the ability to average returns from multiple pulses is also limited by time limitations. Because a satellite moves at about 7 km s^{-1}, in order to obtain measurements over a horizontal distance of 300 km (the resolution of the radiosonde network) only about 45 seconds are available to make enough observations from multiple look angles to obtain a useful measurement. It should also be noted that, as a result of the high orbital velocity of the satellite, precise knowledge of beam pointing is extremely critical for measurements from satellites. For a lidar operating at a nadir angle of 45 degrees, an error in the knowledge of pointing angle of just 1 mrad results in an error of about 5 ms^{-1} in the measured radial component of the wind.

Despite the challenge of employing a satellite-based Doppler lidar, efforts are continuing to develop the appropriate technology and to assess the impact of the observations. The European Space Agency is planning a Doppler wind lidar demonstration mission for the late 2000s that would incorporate a nonscanning, direct-detection instrument with both aerosol and molecular channels. Doppler lidar technology research and numerical simulations aimed at satellite-based wind sensing is ongoing at several research centers within the United States, Europe, and Japan. One option currently being studied is a 'hybrid' lidar system that would combine a direct detection lidar for measurement of winds in the clear free troposphere with a low-energy coherent system that would obtain its observations from clouds and the aerosol-rich boundary. Although a hybrid instrument reduces some requirements on system power and aperture size, combining the two techniques on a single platform will likely require innovative engineering and new approaches to beam combining and scanning.

Hyperspectral Remote Sensing of Land and the Atmosphere

Introduction

Hyperspectral remote sensing is a true marriage of imaging technology with spectroscopy. Hyperspectral remote sensing systems (also known as imaging spectrometer systems) fully sample the optical wavelength range of interest, whether it be the reflected solar range (0.35 to 2.5 μm) or the range of thermal emission from the Earth's surface (3.0 to 14 μm). A hyperspectral sensor views the Earth's surface in a series of contiguous and spectrally narrow image bands. Figure 1 presents the concept of hyperspectral remote sensing, wherein each spatial element of an image has an associated full resolution spectrum. The calibrated reflectance or emittance spectra collected by a hyperspectral system are meant to be directly comparable with that of materials measured in the laboratory. With such high spectral resolution, it thus becomes possible to do reflectance or emittance spectroscopy of the Earth's surface from an overhead perspective.

Underlying Principles

Optical remote sensing is done over wavelength intervals, or windows, in which the atmosphere is largely transparent. For the reflective solar portion of the spectrum, the atmosphere is mostly transparent from approximately 0.35 to 2.5 μm. Water, CO_2, and other gases have absorptions of varying strength in this range. This window is subdivided into the range of human vision (the visible) and the region of slightly longer wavelengths known as the near infrared; together they are the visible/near infrared or VNIR and extend from approximately 0.35 to 1.0 μm. The region from approximately 1.0 to 2.5 μm is known as the short wavelength infrared or SWIR. In the range of emitted terrestrial radiation there are two window regions. The first extends from approximately 3 to 5 μm and is known as the medium wavelength infrared or MWIR, and the second, the long wavelength infrared or LWIR, extends from approximately 8 to 14 μm.

The light that is intercepted by the entrance aperture of a sensor is known by the quantity of radiance which is measured in units of microwatts per square centimeter per nanometer per unit of solid angle. Physical quantities related to the material properties of Earth surface materials are reflectance and emittance. Both properties are the result of ratios and so are unitless. One definition of reflectance is that it is the ratio of radiance reflected from a material, divided by the radiance reflected from an identically illuminated perfectly diffuse reflector. Likewise, a definition for emittance is the ratio of radiance emitted from a material, divided by the ratio

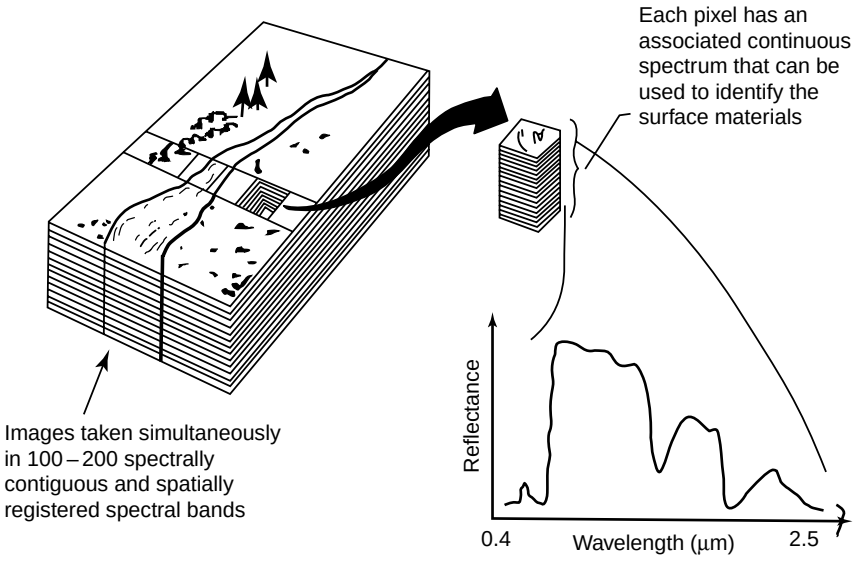

Figure 1 Hyperspectral remote sensing concept.

of radiance emitted from a perfectly emitting material of the same temperature.

Materials covering the Earth's surface, or gases in the atmosphere, can be identified in hyperspectral data on the basis of absorption features, or bands, in the spectra recorded by the sensor. Absorption bands result from the preferential absorption of energy in some wavelength interval. The principal types of processes by which light can be absorbed include, in order of decreasing energy of the process, electronic charge transfers, electronic crystal field effects, and molecular vibrations. The former two processes are observed in minerals and manmade materials that contain transition group metal cations, most usually, iron. Charge transfer absorptions are the result of cation-to-anion or cation-to-cation electron transfers. Crystal field absorptions are explainable by the quantum mechanical theory of atomic structure, wherein an atom's electrons are contained in orbital shells. The transition group metals have incompletely filled *d* orbital shells. When a transition metal cation, such as iron, is surrounded by anions, and potentially selects other cations, an electric field, known as the crystal field, exists. Crystal field absorptions occur when radiant energy causes that cation's orbital shell energy levels to be split by interaction with the crystal field. The reflectance spectra of different iron-bearing minerals are unique, because the iron cation has a unique positioning with respect to the anions and other cations that compose the mineral.

A material's component molecules have bonds to other molecules and as a result of interaction with radiant energy, these bonds can stretch or bend. These molecular vibrations, and overtones of those vibrations, are less energetic processes than the electronic absorption processes described above and so the resulting absorption features occur at longer wavelengths. Fundamental vibrational features occur in the MWIR and LWIR. Overtones and combination overtones of these vibrations are manifested as weaker absorption features in the SWIR. These overtone features in the SWIR include absorptions diagnostic of carbonate and certain clay minerals. Absorption features caused by vibrational overtones of C–H, O–H, and N–H stretches are also manifested in the SWIR and these absorption features are characteristic of important vegetative biochemical components such as cellulose, lignin, starch, and glucose. An example of the effect of the changes in reflected energy recorded at a sensor, due to the absorption of incident energy by green vegetation and other surface materials, is provided in **Figure 2**.

Laboratory spectrometers have been used for many years to analyze the diagnostic absorptions of materials caused by the above effects. More recently, spectrometers were mounted on telescopes to determine the composition of the Moon and the other solid bodies in our solar system. Technology progressed to where profiling spectrometers (instruments that measure a successive line of points on the surface) could be mounted on aircraft. The next logical step was the construction of imaging spectrometers (hyperspectral sensors) that measured spectra in two spatial dimensions. In fact, the data produced by a hyperspectral sensor are often thought of as an image cube (**Figure 3**) because they consist of three dimensions: two spatial and one spectral.

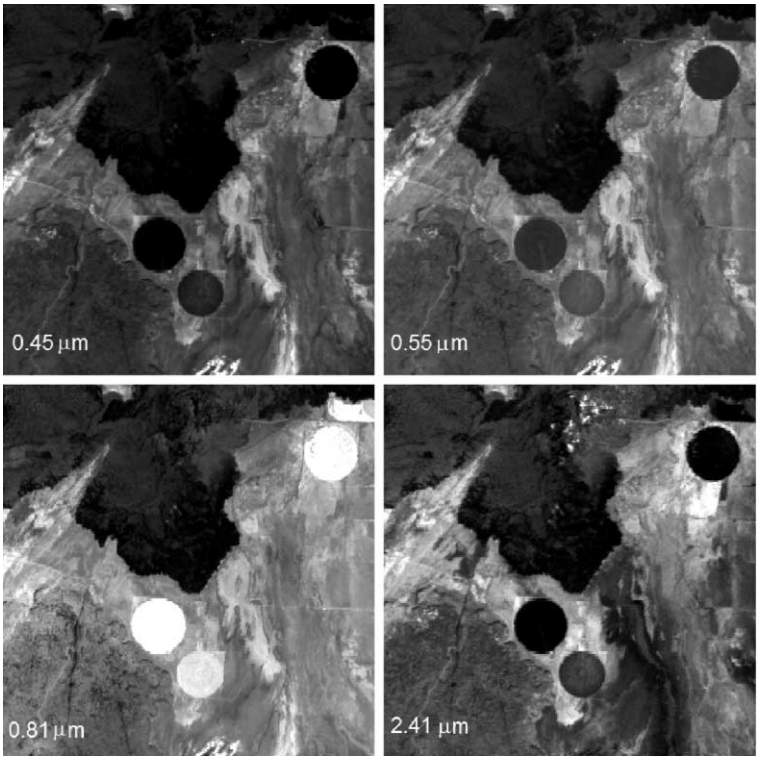

Figure 2 Portion of a scene from the Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) from Utah that includes a basalt flow, circularly irrigated grasses sparsely vegetated plains, and damp alluvial sediments. AVIRIS channels centered at 0.45, 0.55, 0.81, and 2.41 μm are shown. Green vegetation is brightest in the 0.81 μm band which samples the peak of the near infrared plateau (see **Figure 7**) just beyond the 'red edge'. The green vegetation and damp sediments are darkest in the 2.41 μm band where water has a very low reflectance (note also **Figure 8**). The bright patches in the basalt flow in the 2.41 μm image are occurrences of oxidized red cinders which have a high reflectance in the SWIR.

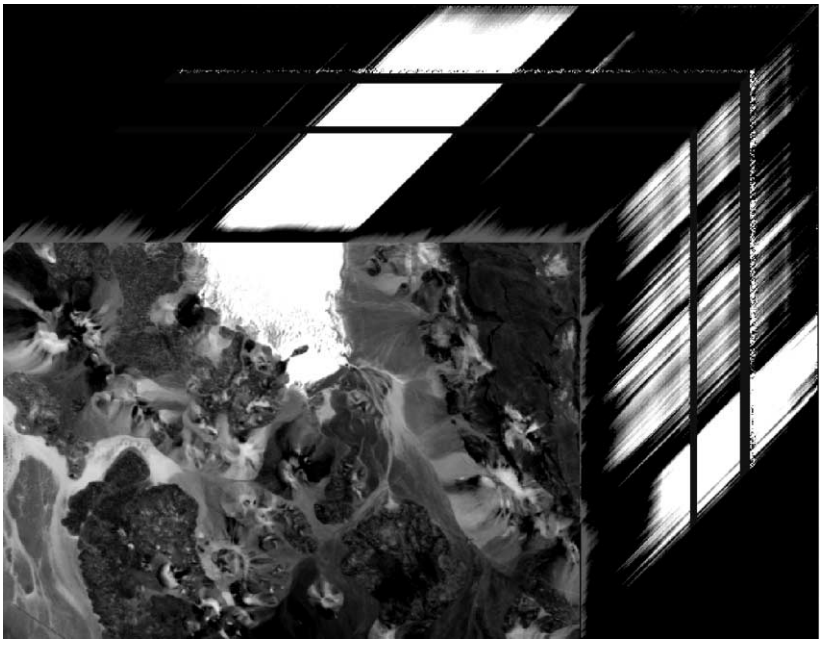

Figure 3 Visualization of a hyperspectral image cube. A 1.7 μm image band from the Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) over the Lunar Crater Volcanic Field, Nevada is shown with each of the 224 rightmost columns and 224 topmost lines arrayed behind it. In the lower right-hand corner, the low reflectance of ferric oxide-rich cinders in the blue and green show up as dark in the stacking of columns with the high reflectance in the infrared showing up as bright.

Advances in hyperspectral sensor technology have been accompanied by advances in associated technologies, such as computing power and the evolution of data processing algorithms.

Data Processing Approaches

An early impediment to the widespread use of hyperspectral data was the sheer volume of the data sets. For instance, a single scene from NASA's Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) is 614 samples by 512 lines by 224 bands. With its short integer storage format, such a scene takes up 140.8 Mbytes. However, since the dawn of the hyperspectral era, in the 1980s, computing power has expanded immensely and computing tasks, which once seemed prohibitive, are now relatively effortless. Also, numerous processing algorithms have been developed which are especially well suited for use with hyperspectral data.

Spectral Matching

In one class of algorithms, the spectrum associated with each spatial sample is compared against one or a group of model spectra and some similarity metric is applied. The model spectrum can be measured by a laboratory or field portable spectrometer of pure materials or can be a single pixel spectrum, or average of pixel spectra, covering a known occurrence of the material(s) to be mapped. A widely used similarity metric is the Spectral Angle Mapper (SAM). SAM is the angle, θ, obtained from the dot product of the image pixel spectrum, t, and the library spectrum, r, as expressed by

$$\theta = \cos^{-1}\left(\frac{t * r}{\|t\| * \|r\|}\right) \qquad [1]$$

SAM is insensitive to brightness variations and determines similarity based solely on spectral shape. Lower θ values mean more similar spectra.

In a related approach, matching is done, not on the entire spectrum, but rather on characteristic absorption features of the materials of interest. In Figure 4, the geometry of an absorption band is plotted. To map a given mineral, with a specific absorption feature, a high resolution laboratory spectrum is resampled to the spectral resolution of the hyperspectral sensor. The spectrum is subsampled to match the specific absorption feature (i.e., only bands from the short wavelength shoulder of the absorption to the long wavelength shoulder are included). A straight line continuum (calculated, based on a line between the two-band shoulders) is divided out from both the laboratory and the sensor spectra. Contrast between the library and the sensor spectra is mitigated through the use of an additive constant. This constant is incorporated into a set of equations which are solved through the use of standard least squares. The result of such a band-fitting algorithm is two data numbers per spatial sample of the hyperspectral scene. First the band depth (or, alternatively, band area) of the feature is calculated, and second, a goodness-of-fit parameter is calculated. These two parameters are most often combined in a band-depth times goodness-of-fit image. More sophisticated versions of the band-mapping algorithm target multiple absorption features and are, essentially, expert systems.

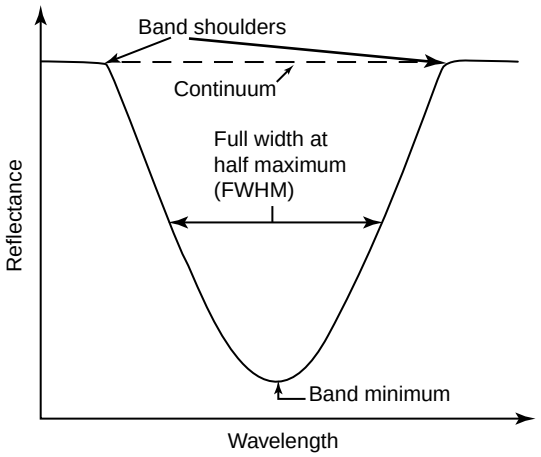

Figure 4 Parameters that describe an absorption band.

Spectral Mixture Analysis

A fundamentally different methodology for analyzing hyperspectral data sets is to model the measured spectrum of each spatial sample as a linear combination of endmember spectra. This methodology is based on the fact that the ground area corresponding to any given spatial sample likely will be covered by more than one material, with the consequence that the measured reflectance or emittance spectrum is a mixed pixel spectrum. The objective of linear SMA is to try to determine the fractional abundance of the component materials, or endmembers. The basis of linear spectral unmixing is to model the response of each spatial element as a linear combination of endmember spectra. The basis equation for linear SMA is

$$r(x, y) = \alpha\mathbf{M} + \varepsilon \qquad [2]$$

where $r(x, y)$ = the relative reflectance spectrum for the pixel at position (x, y), α = the vector of endmember abundances, $\mathbf{M}$ = the matrix of endmember spectra, and ε = the vector of residuals between the modeled and the measured reflectances. Application

of SMA results in a series of fraction images for each endmember wherein the data numbers range, ideally, between 0 and 1. Fraction image pixels with a digital number (DN) of 0 are taken to be devoid of the endmember material. Fraction image pixels with a DN of 1.0 are taken to be completely covered with the endmember material.

Techniques related to SMA have been developed which also map the abundance of a target material on a per pixel basis. These include implementations highly similar to SMA such as Orthogonal Subspace Projection (OSP) wherein, as with SMA, all endmembers must be determined a priori. Other approaches such as Constrained Energy Minimization (sometimes referred to as 'Matched Filter') do not require a priori knowledge of the endmembers. Instead, only the reflectance or emittance spectrum of the target need be known and the undesired spectral background is estimated, and ultimately compensated for, using the principal eigenvectors of the sample correlation or covariance matrix of the hyperspectral scene.

Expert Systems and Artificial Neural Networks

Another means of extracting information from hyperspectral data sets is to use computer approaches that in some way mimic the human thought process. This can take the form of an expert system which applies a set of rules or tests as each pixel spectrum is successively analyzed. For example, if a spectrum has an absorption at 2.2 μm it could tentatively be classified as being caused by a clay mineral. Additionally, if the absorption is a doublet, the specific clay mineral is likely a kaolinite. In practice, expert system codes are lengthy and complex although excellent results can be demonstrated from their use, albeit at the expense of processing time. Another approach in this vein is the use of an artificial neural network (ANN) for data processing. The use of ANNs is motivated by their power in pattern recognition. ANN architectures are well suited for a parallel processing approach and thus have the potential for rapid data processing.

Hyperspectral Remote Sensing of the Land

Geology

Early efforts with airborne hyperspectral sensors focused on geologic remote sensing. This was, at least in part, a consequence of the mineralogic diversity of the Earth's surface and the fact that many minerals have absorption features which are unique and diagnostic of the mineral's identity. The expectation, which was soon borne out by results from these early sensors, was that, given exposure of the surface, mineralogic maps as detailed as the spatial resolution of the sensor could be derived from hyperspectral data. As some of the processing techniques discussed above have become more readily available, it has become possible to produce mineralogic maps from hyperspectral data far more rapidly and cost-effectively than geologic maps produced by standard means (e.g., by walking over the ground and manually noting which lithologies are underfoot).

The propensity for transition metals, most especially iron, to absorb energy through charge transfer and crystal field effects, is noted above. Fe–O and Fe^{2+}–Fe^{3+} charge transfers cause a profound absorption in the reflectance spectrum of Fe-bearing minerals shortwards of 0.4 μm. The wing of this absorption causes the low blue and green reflectance of Fe-bearing minerals. Crystal field bands cause an absorption feature in the 0.9 to 1.0 μm region. The ability to discriminate subtle differences among Fe-bearing minerals in hyperspectral data has proven extremely valuable in applications such as mineral exploration, volcanology, and in the characterization of abandoned mine lands.

In the SWIR, absorptions caused by vibrational overtones of molecular bonds within minerals. These include absorptions in the 2.2 and 2.3 μm region which are characteristic of many Al- and Mg-bearing clay minerals. Absorptions in the SWIR are narrower in width than the Fe-generated crystal field bands discussed previously. In fact, the requirement to efficiently resolve these vibrational overtone absorption bands (which have full width at half maximum (FWHM) bandwidths of 20 to 40 nm) helped to drive the selection of the nominal 10 nm bandwidth of early and most current hyperspectral sensors. Certain clay minerals can be indicators of hydrothermal activity associated with economic mineral deposits; thus, the SWIR is an important spectral region for mineral exploration. Clay minerals, by definition, have planar molecular structures that are prone to failure if subjected to shearing stresses. The ability to uniquely identify and map these minerals, using hyperspectral data, has thus been used to good effect to identify areas on volcanoes and other hydrothermally altered terrains that could be subject to landslides.

Minerals with adsorbed or molecularly bound OH^- and/or water have vibrational overtone absorptions near 1.45 and 1.9 μm, although these features are masked in remotely sensed data by prominent atmospheric water vapor bands at 1.38 and 1.88 μm. The reflectance of water and OH-bearing minerals decrease to near zero at wavelengths longwards of

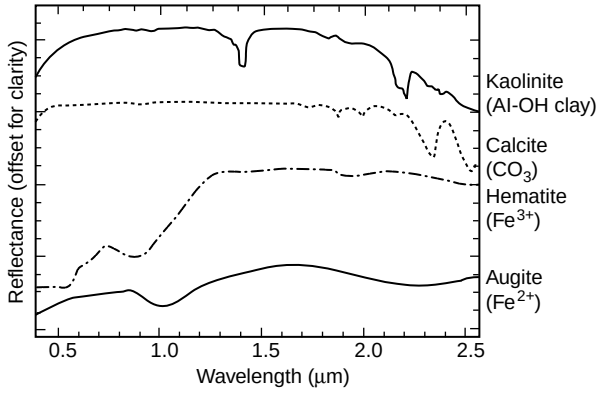

Figure 5 Reflectance spectra of representative minerals. Kaolinite represents clay minerals with its diagnostic 2.2 μm band caused by an overtone vibration of the Al–OH bond. The 2.335 μm band of calcite is caused by an overtone vibration of the carbonate molecule. The features shortwards of 1.0 μm in the hematite spectrum are caused by crystal field and charge transfer absorptions due to Fe^{3+}. The bands near 1.0 and longwards of 2.0 μm in the augite spectrum are the result of Fe^{2+} crystal field bands.

2.5 μm, due to the presence of water and OH fundamental vibrations near 3.0 μm. Minerals bearing the carbonate (CO_3^{-2}) molecule are abundant on the Earth's surface due to the ubiquitous occurrences of limestone and dolomite. Calcite and dolomite have overtone absorptions centered at 2.335 and 2.315 μm, respectively. A good test for the spectral resolution and spectral calibration of a hyperspectral sensor is its ability to successfully discriminate calcite from dolomite on the basis of the aforementioned absorption features. Figure 5 shows representative spectra of carbonate, clay, and ferric and ferrous iron-bearing minerals.

Absorptions resulting from fundamental molecular absorptions are manifested in the LWIR. These absorptions are of great geologic interest because they include absorptions resulting from vibrations of the Si–O bond and silicate minerals form the bulk of the Earth's crust. The wavelength at which the Si–O stretching feature occurs is dictated by the level of polymerization (or molecule-to-molecule bonding) of the silicate mineral. Highly polymerized framework silicate minerals, such as quartz and feldspar, have a shorter wavelength absorption than do silicate minerals, such as olivine which are composed of disconnected SiO_4 molecules. In Figure 6, laboratory emission spectra of highly and poorly polymerized silicate minerals are shown.

Vegetation and the Environment

While different minerals are, by definition, generally composed of diverse component molecules, different species of vegetation represent variations of the same general biochemical constituents (e.g., chlorophyll, proteins, lignin, cellulose, sugar, starch, etc.). In the thermal IR, vegetation has a generally flat emittance, thus it is in the reflective solar spectrum that most vegetative remote sensing is performed. The major features in the reflectance spectrum of green vegetation are shown in Figure 7. In the visible, the major absorption features are caused by the presence of chlorophyll. Chlorophyll has strong absorptions in the blue and the red, leaving a reflectance maximum (the green peak) at 0.55 μm. In the NIR, scattering in the leaf structure causes high reflectance leaving a profound absorption edge (the red edge) between

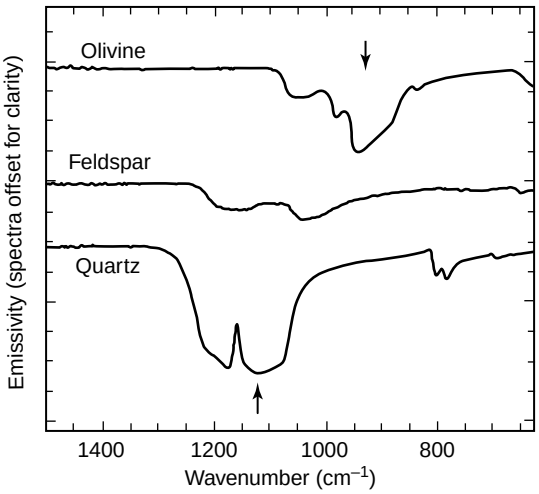

Figure 6 Emissivity spectra of SiO_4-bearing minerals showing the shift in band minimum to higher wave number with increasing polymerization.

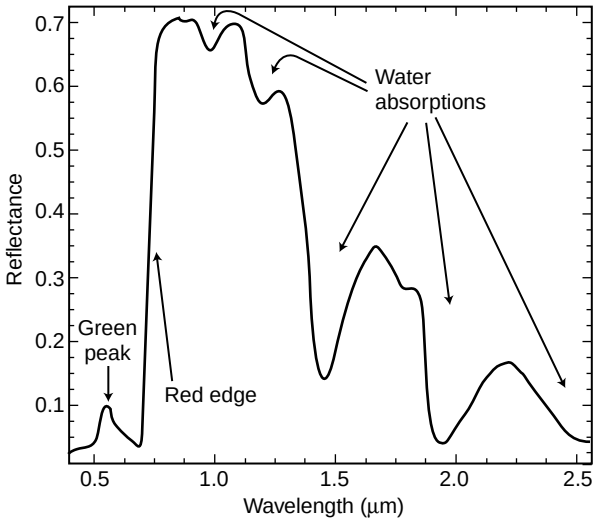

Figure 7 Major spectral features in the reflectance spectrum of green vegetation.

0.7 and 0.78 μm. Past the red edge and into the SWIR, the spectrum of green vegetation is dominated by water in the leaf, with leaf water absorptions occurring at 0.97, 1.19, 1.45, 1.93, and 2.50 μm. Studies of vegetation, using multispectral systems, have made use of a number of broadband indices. Hyperspectral systems allow for the discrimination of individual absorption features and subtle spectral shape differences in vegetation spectra which are unresolvable using broadband multispectral systems. For example, the absorptions caused by chlorophyll can be used for studies of chlorophyll content in vegetative canopies. The unique interaction of chlorophyll with leaf structures can provide a morphology to the green peak that is unique to a given species and thus is mappable using a spectral feature fitting approach.

A desired goal in the study of vegetation and ecosystem processes is to be able to monitor the chemistry of forest canopies. The foliar biochemical constituents making up forest canopies have associated absorption features in the SWIR, that result from vibrational overtones and combinations of C–O, O–H, C–H, and N–H molecular bonds. However the absorptions from these biochemical components overlap so that the chemical abundance of any one plant component cannot be directly related to any one absorption feature. An even more serious challenge is introduced by the strong influence of water in the SWIR in green vegetation spectra. Water constitutes 40 to 80% of the weight of leaves. However, the unique characteristics of high-quality hyperspectral data (e.g., excellent radiometric and spectral calibration, high signal-to-noise ratio, high spectral resolution) have been used to detect even these subtle features imprinted on the stronger water features.

The amount of water present in plant leaves is, in itself, a valuable piece of information. Hyperspectral data can be used to determine the equivalent water thickness present in vegetative canopies. Conversely, the amount of dry plant litter and/or loose wood can be estimated using spectral mixture analysis and related techniques. Taken together, all these data: vegetation species maps, determinations of leaf water content and the relative fractions of live vegetation versus litter, can be used to characterize woodlands for forest fire potential. The ability to map different species of vegetation has also proved useful in the field of agriculture, for assessing the impact of invasive weed species on farm and ranch land. Being able to assess the health of crops, in terms of leaf water content, is also important for agriculture.

Another subtle vegetative spectral feature, that provides information on plant vitality, is the aforementioned red edge. Shifts in the position of the red edge have been linked to vegetation stress. Studies have shown that vegetation stress and consequent shifts in the position of the red edge can be caused by a number of factors, including insufficient water intake or the intake of pernicious trace metals. Vegetation growing over mineral deposits can display red edge shifts and this can be used to assist in mineral exploration efforts.

Another application area, in which hyperspectral remote sensing has found great utility, is in the analysis of snow-covered areas. Over the reflective solar spectrum, the reflectance of snow varies from values near zero in the SWIR to values near one in the blue. Differences in the grain size of snow result in differences in reflectance as is illustrated in Figure 8. The spectral variability of snow makes it easily distinguishable from other Earth surface materials.

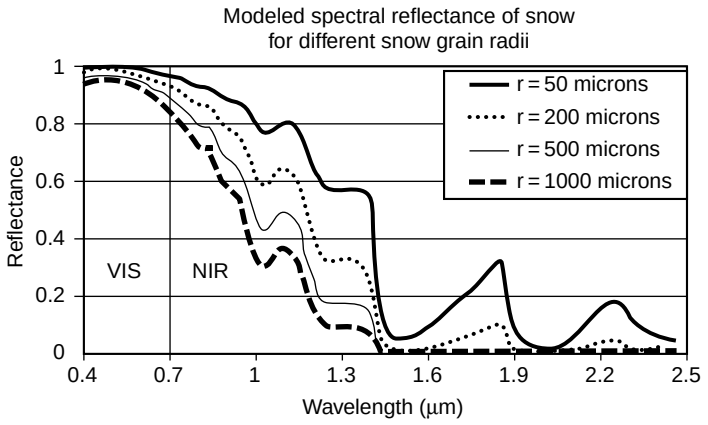

Figure 8 Differences in snow reflectance spectra resulting from differences in snow grain size. Courtesy of Dr Anne Nolin of Oregon State University.

Linear spectral unmixing, using hyperspectral data, has been shown to successfully discriminate between snow, vegetation, rock, and clouds and to accurately map snow cover fraction in mixed pixels. Accurate maps of snow cover, types of snow, and fractions of liquid water admixed with snow grains, are required for forecasting snowmelt runoff and stream discharge in watersheds dominated by snow cover.

Hyperspectral Remote Sensing of the Atmosphere

The physical quantity most often sought in land remote sensing studies is surface reflectance. However, the quantity recorded by a hyperspectral sensor is radiance at the entrance aperture of the sensor. In order to obtain reflectance, the background energy level of the Sun and/or Earth must be removed and the scattering and absorbing effects of the atmosphere must be compensated for. In the VNIR through SWIR, there are seven atmospheric constituents with significant absorption features: water vapor, carbon dioxide, ozone, nitrous oxide, carbon monoxide, methane, and oxygen. Molecular scattering (commonly called Rayleigh scattering) is strong in the blue but decreases rapidly with increasing wavelength. Above 1 μm, its effect is negligible. Scattering caused by atmospheric aerosols, or Mie scattering, also is more prominent at shorter wavelengths and decreases with increasing wavelength, but the dropoff of effects from Mie scattering is not as profound as that for Rayleigh scattering. Consequently, effects from aerosol scattering can persist into the SWIR.

There are three primary categories of methods for removing the effects of atmosphere and solar insolation from hyperspectral imagery, in order to derive surface reflectance. Methods of atmospheric corrections can be considered as being either an image-based, empirical, or model-based approach. An image-based, or 'in-scene' approach uses only data measured by the instrument. Empirical methods make use of the remotely sensed data in combination with field measurements of reflectance, to solve a simplified equation of at-sensor radiance such as eqn [3].

$$L_s = A\rho + B \qquad [3]$$

where L_s is the at-sensor radiance, ρ is the reflectance of the surface, and A and B are quantities that incorporate, respectively, all multiplicative and additive contributions to the at-sensor radiance. All the quantities expressed in eqn [3] can be considered as varying as a function of wavelength, λ. Approximations for A and B from eqn [3] constitute a set of gains and offsets derived from the empirical approach. In some empirical approaches, atmospheric path radiance is ignored and only a multiplicative correction is applied.

Model-based approaches seek to model what the at-sensor radiance should be on a pixel-by-pixel basis, including the contribution of the atmosphere. The at-sensor radiance, L_s, at any wavelength, λ, can be expressed as

$$L_s = \frac{1}{\pi}(E\rho + M_T)\tau_\theta + L_u \qquad [4]$$

where E is the irradiance at the surface of the Earth, ρ is the reflectance of the Earth's surface, M_T is the spectral radiant exitance of the surface at temperature, T, τ_θ is the transmissivity of the atmosphere at zenith angle θ, and L_u is the spectral upwelling path radiance of the atmosphere. The ability to solve eqn [4] and do atmospheric correction on a pixel-by-pixel basis is appealing, in that it negates the shortcomings of an empirical approach where a correction based on calibration targets in one part of a scene might not be appropriate for another part of the scene, due to differences in atmospheric pathlength or simple atmospheric heterogeneity. Model-based approaches are also able to take advantage of the greater spectral dimensionality of hyperspectral data sets for the derivation of atmospheric properties (e.g., the amount of column water vapor, CO_2 band depths, etc.) directly from the data.

The main atmospheric component, affecting imagery in the reflective solar portion of the spectrum, is water vapor. Model-based atmospheric correction techniques determine the column water vapor for each pixel in the scene, based on the depth of the 940 and/or 1130 nm atmospheric water bands. Thus for each pixel, an appropriate amount of water can be removed. The maps of atmospheric water vapor distribution are themselves of interest to atmospheric scientists. Absorption features caused by well-mixed gases, such as the 760 nm O_2 band, can be used by model-based programs, to produce images of approximate scene topography. More advanced model-based approaches also solve for the scattering effects of aerosols on the hyperspectral data.

As noted above, atmospheric constituents, including industrial effluents, can be detected and spatially mapped by hyperspectral sensors. The fundamental vibrational absorption of gases of interest occurs in the MWIR and the LWIR. Overtones of these gaseous molecular vibrations occur in the VNIR to SWIR, but are generally too weak to be detected. The ability to detect anthropomorphically produced gases depends on a number of factors, including the

temperature difference between the gas cloud and the background atmosphere, the concentration of gas within the cloud, and the size of the cloud (e.g., the path length of light through the cloud).

Laser Detection of Atmospheric Gases

E V Browell, W B Grant and S Ismail, NASA Langley Research Center, Hampton, VA, USA

Published by Elsevier Ltd.

Introduction

Lidar (light detection and ranging) systems are able to measure profiles of atmospheric aerosols, clouds, and gases by transmitting a pulsed laser beam into the atmosphere and collecting the backscattered radiation from aerosols and molecules in the atmosphere with a receiver located near the transmitter. The differential absorption lidar (DIAL) approach is the most widely used technique for measuring a variety of gases. In this approach, two closely spaced laser wavelengths are used: one which is absorbed by the gas of interest, and the other which is only weakly, or not at all, absorbed by the gas. A differential with respect to range and wavelength is calculated, to determine the average gas concentration along any segment of the lidar path, using the familiar Beer–Lambert law for an absorbing medium.

The DIAL equation can be expressed in its simple form as

$$N = \left(1/\left(2(R_2 - R_1)(\sigma_{on} - \sigma_{off})\right)\right) \times \ln\left(P_{off}(R_2)P_{on}(R_1)\right)/\left(P_{off}(R_1)P_{on}(R_2)\right) \quad [1]$$

where N is the average gas concentration, R is the range, σ_{on} and σ_{off} are the absorption cross sections at the on- and off-line wavelengths, and $P_{on}(R)$ and $P_{off}(R)$ are the powers received at the on- and off-line wavelengths. However, since it is performed in the atmosphere and not a laboratory, great care must be taken to ensure that the data are analyzed properly to minimize random and systematic errors. Random errors arise from noise in the backscattered signal, the solar background signal, and the inherent

detector noise, and this type of error can be reduced by signal averaging. Systematic errors arise from uncompensated instrument and atmospheric effects and must be carefully considered in system design and operation and data processing.

Another approach, the Raman lidar approach, uses inelastic scattering (scattered/emitted light has different wavelength than the illuminating light) from gases where the wavelength shift corresponds to vibrational or rotational energy levels of the molecules. Any illuminating laser wavelength can be used, but since the Raman scattering cross-section varies as λ^{-4}, where λ is the wavelength, the shorter laser wavelengths, such as in the near UV spectral region, are preferred. While even shorter wavelengths in the solar blind region below ~300 nm would permit operation in daytime, the atmospheric attenuation, due to Rayleigh scattering and UV molecular absorption, limits the measurement range. High-power lasers are used due to the low Raman scattering cross-sections. The Raman lidar measurements have to be carefully calibrated against a profile measured using another approach, such as is done for water vapor (H_2O) measurements with the launch of hygrometers on radiosondes, since the lidar system constants and atmospheric extinctions are not usually well known or modeled. In order to obtain mixing ratios of H_2O with respect to atmospheric density, the H_2O signals are ratioed to the nitrogen Raman signals. However, care must be exercised in processing these data due to the spectral dependences of atmospheric extinction.

Surface-Based Lidar Systems

Surface-based lidar systems measure the temporal evolution of atmospheric profiles of aerosols and gases. The first lidar systems used to remotely measure atmospheric gases were Raman lidar systems. The Raman lidar systems were thought to be very promising since one high-power laser could be used to measure a variety of gases. They are easier to develop and operate than DIAL systems, because the laser does not have to be tuned to a particular gas absorption feature. However, the Raman scattering cross-section is low, and the weak, inelastically scattered signal is easily contaminated by daylight background radiation, resulting in greatly reduced performance during daytime. Raman lidar systems have been developed primarily for measuring H_2O and retrieving atmospheric temperature.

Surface-based UV DIAL systems, that are part of the Network for the Detection of Stratospheric Change (NDSC) have made important contributions to the understanding of stratospheric O_3. There are DIAL systems at many locations around the Earth, with sites in Ny-Ålesund, Spitzbergen (78.9°N, 11.9°E), Observatoire Haute Provence, France (43.9°N, 5.7°E), Table Mountain, California (34.4°N, 118.2°W), Mauna Loa, Hawaii (19.5°N, 155.6°W), and Lauder, New Zealand (45.0°S, 169.7°E). First established in the 1980s, these DIAL systems are strategically located so that O_3 in different latitude bands can be monitored for signs of change. In addition, they can provide some profiles for comparison with space-based O_3 measuring instruments. The parameters of a typical ground-based UV DIAL system used in the NDSC are given in Table 1.

Airborne DIAL Systems

Airborne lidar systems expand the range of atmospheric studies beyond those possible by surface-based lidar systems, by virtue of being located in aircraft that can be flown to high altitudes and to remote locations. Thus, they permit measurements at locations inaccessible to surface-based lidar systems. In addition, they can make measurements of large atmospheric regions in times that are short compared with atmospheric motions, so that the large-scale patterns are discernible. Another advantage of airborne lidar operation is that lidar systems perform well in the nadir (down) direction since the atmospheric density and aerosol loading generally increases with decreasing altitude towards the surface, which helps to compensate for the R^{-2} decrease in the lidar

Table 1 Parameters for the Jet Propulsion Laboratory's Mauna Loa DIAL systems for stratospheric O_3 measurements

	XeCl	Nd:YAG (3rd Harmon.)
Wavelength (nm)	308 (on)	355 (off)

signal with range. For the zenith direction, the advantage is that the airborne lidar system is closer to the region being measured.

Field Measurement Programs

Global O_3 Measurements

The first airborne DIAL system, which was developed by the NASA Langley Research Center (LaRC), was flown for O_3 and aerosol investigations in conjunction with the Environmental Protection Agency's Persistent Elevated Pollution Episodes (PEPE) field experiment, conducted over the east coast of the US in the summer of 1980. This initial system has evolved into the advanced UV DIAL system that will be described in the next section. Airborne O_3 DIAL systems have also been developed and used in field measurement programs by several other groups in the United States, Germany, and France.

The parameters of the current NASA LaRC airborne UV DIAL system are given in Table 2. The on-line and off-line UV wavelengths of 288.2 and 299.6 nm are used for DIAL O_3 measurements during tropospheric missions, and 301 and 310 nm are used for stratospheric missions. This system also transmits 1,064 and 600 nm beams for aerosol and cloud measurements. The time delay between the on- and off-wavelength pulses is 400 μs, which is sufficient time for the return at the first set of wavelengths to end, but short enough that the same region of the atmosphere is sampled. This system has a demonstrated absolute accuracy for O_3 measurements of better than 10% or 2 ppbv (parts per billion by volume), whichever is larger, and a measurement precision of 5% or 1 ppbv with a vertical resolution of 300 m and an averaging time of 5 minutes (about 70 km horizontal resolution at typical DC-8 ground speeds).

The NASA LaRC airborne UV DIAL systems have made significant contributions to the understanding of both tropospheric and stratospheric O_3, aerosols, and clouds. These systems have been used in 18 international and 3 national field experiments over the past 24 years, and during these field experiments, measurements were made over, or near, all of the oceans and continents of the world. A few examples of the scientific contributions made by these airborne UV DIAL systems are given in Table 3.

The NASA LaRC airborne UV DIAL system has been used extensively in NASA's Global Tropospheric Experiment (GTE) program which was started in the early 1980s, had as its primary mission the study of tropospheric chemistry in remote regions of the Earth, in part to study and gain a better understanding of atmospheric chemistry in the unperturbed atmosphere. A related goal was to document the Earth's atmosphere in a number of places during seasons when anthropogenic influences are largely absent, then return to these areas later to document the changes. The field missions have included campaigns in Africa, Alaska, the Amazon Basin,

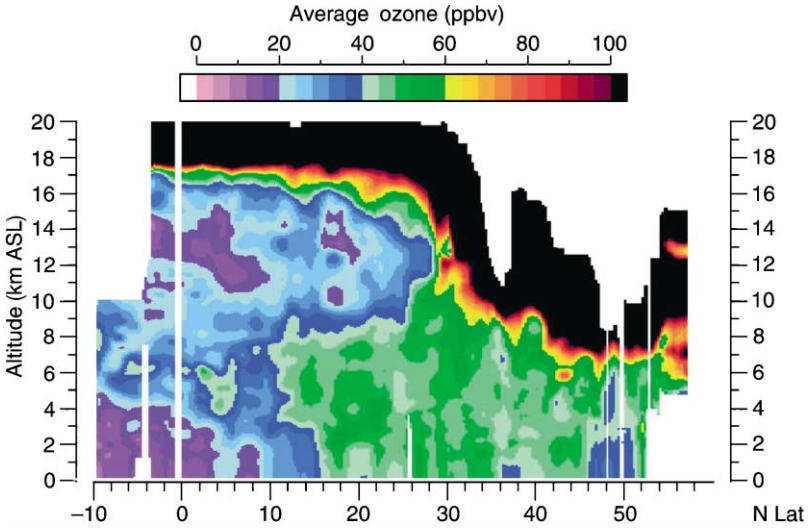

Figure 1 Latitudinal distribution of ozone over the western Pacific Ocean obtained during the second Pacific Exploratory Mission (PEM West B) in 1994.

Canada, and North America, and over the Pacific Ocean from Antarctica to Alaska, with concentrated measurements off the east coast of Asia and in the tropics. One of the bigger surprises of the two decades of field missions, was the discovery in the mid-1990s, that the tropical and South Pacific Ocean had very high tropospheric O_3 concentrations in plumes from biomass burning in Africa and South America during the austral spring. There were few indications from surface-based or space-based measurements that there were extensive biomass burn plumes in the area, primarily since the plumes were largely devoid of aerosols due to being stripped out during cloud convective lofting. Once over the ocean, horizontal transport appears to proceed relatively unimpeded unless a storm system is encountered.

The NASA LaRC airborne UV DIAL system has also been flown in all the major stratospheric O_3 campaigns starting in 1987 with the Airborne Antarctic Ozone Experiment (AAOE) to determine the cause of the Antarctic ozone hole. The UV DIAL system documented the O_3 loss across the ozone hole region. Later, when attention was turned to the Arctic and the possibility of an ozone hole there, the system was used to produce an estimate of O_3 loss during the winter season as well as to better characterize the polar stratospheric cloud (PSC) particles. The UV DIAL system was also used to study O_3 loss in the tropical stratospheric reservoir following the eruption of Mount Pinatubo in June 1991. The loss was spotted by the Microwave Limb Sounder (MLS) on the Upper Atmospheric Research Satellite (UARS), but the MLS

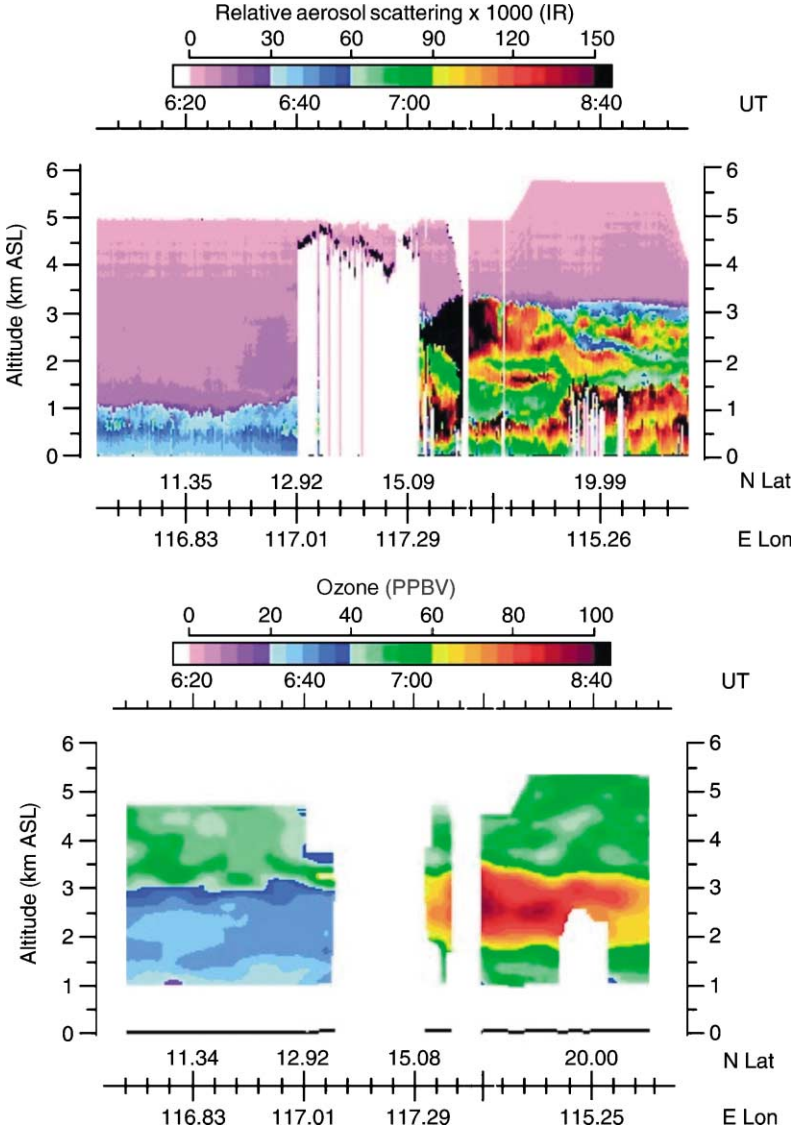

Figure 2 Pollution outflow from China over the South China Sea (right side of figure) with clean tropical air on south side of a front (left side of figure), observed during PEM West B in 1994.

was unable to study the loss in detail due to its low vertical resolution (5 km) compared to the small-scale (2–3 km) features of the O_3 loss. Other traditional space-based O_3 measuring instruments also had difficulty during this period, due to the high aerosol loading in the stratosphere following the eruption.

Space-Based O_3 DIAL System

In order to obtain nearly continuous, global distributions of O_3 in the troposphere, a space-based O_3 DIAL system is needed. A number of key issues could be addressed by a space-based O_3 DIAL system including: the global distribution of photochemical O_3 production/destruction and transport in the troposphere; location of the tropopause; and stratospheric O_3 depletion and dynamics. High-resolution airborne O_3 DIAL and other aircraft measurements show that to study tropospheric processes associated with biomass burning, transport of anthropogenic pollutants, tropospheric O_3 chemistry and dynamics, and stratosphere–troposphere exchange, a vertical profiling capability from space with a resolution of 2–3 km is needed, and this capability cannot currently be achieved using passive remote sensing satellite instruments. An example of the type of latitudinal O_3 cross-section that could be provided by a space-based O_3 DIAL system is shown in Figure 1. This figure shows many different aspects of O_3 loss and production; vertical and horizontal transport; and stratosphere–troposphere exchange that occurs from the tropics to high latitudes.

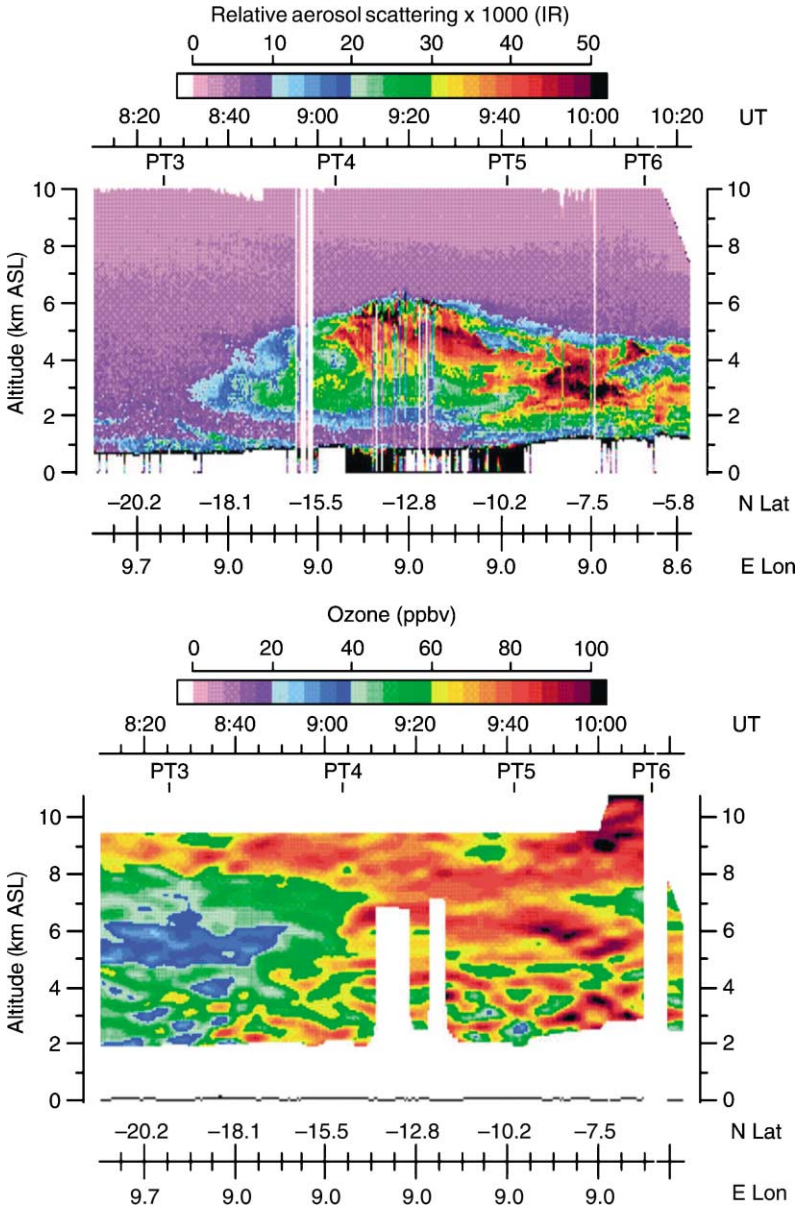

Figure 3 Biomass burning plume over the Atlantic Ocean arising from biomass burning in the central part of western Africa, observed during the TRACE-A mission in 1992.

This type of data would be available from just one pass from a space-based O_3 DIAL system. A space-based O_3 DIAL system optimized for tropospheric O_3 measurements (see system description in Table 4a,b) would also permit high-resolution O_3 measurements in the stratosphere (1 km vertical, 100 km horizontal), along with high-resolution aerosol measurements (100 m vertical, 10 km horizontal). In addition, these DIAL measurements will be useful in assisting in the interpretation of passive remote sensing measurements and in helping to improve their data processing algorithms.

Global H_2O Measurements

H_2O and O_3 are important to the formation of OH in the troposphere, and OH is at the center of most of the chemical reactions in the lower atmosphere. In addition H_2O is an excellent tracer of vertical and horizontal transport of air masses in the troposphere, and it can be used as a tracer of stratosphere–troposphere exchange. Increased aerosol sizes, due to high relative humidities, can also affect heterogeneous chemical processes and radiation budgets in the boundary layer and in cloud layers. Knowledge of H_2O is important to weather forecasting and climate

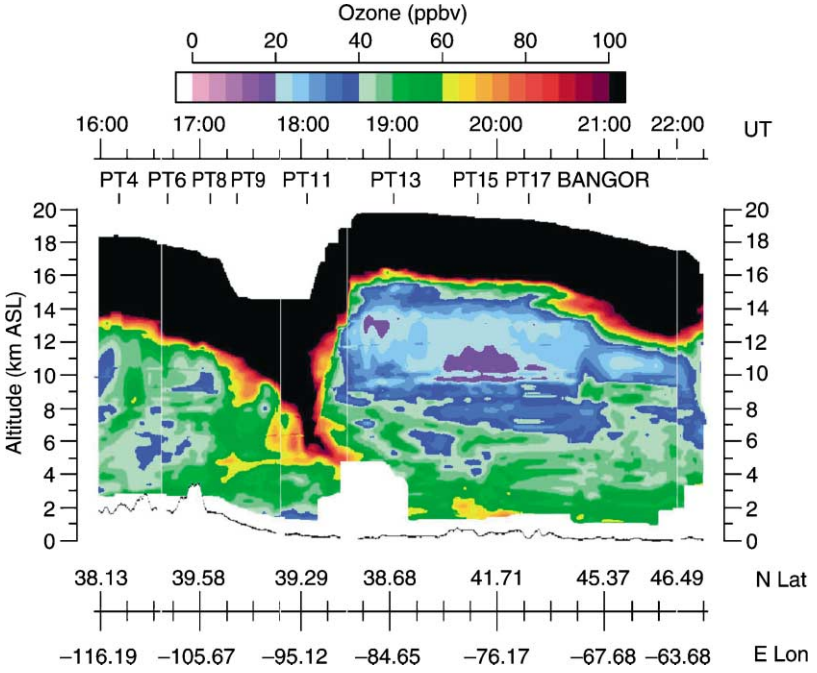

Figure 4 Ozone distribution observed on flight across US during the SASS (Subsonic Assessment) Ozone and Nitrogen Experiment (SONEX) in 1997. A stratospheric intrusion is clearly evident on left side of figure, and low ozone air from tropics transported to mid-latitudes can be seen in the upper troposphere on the right.

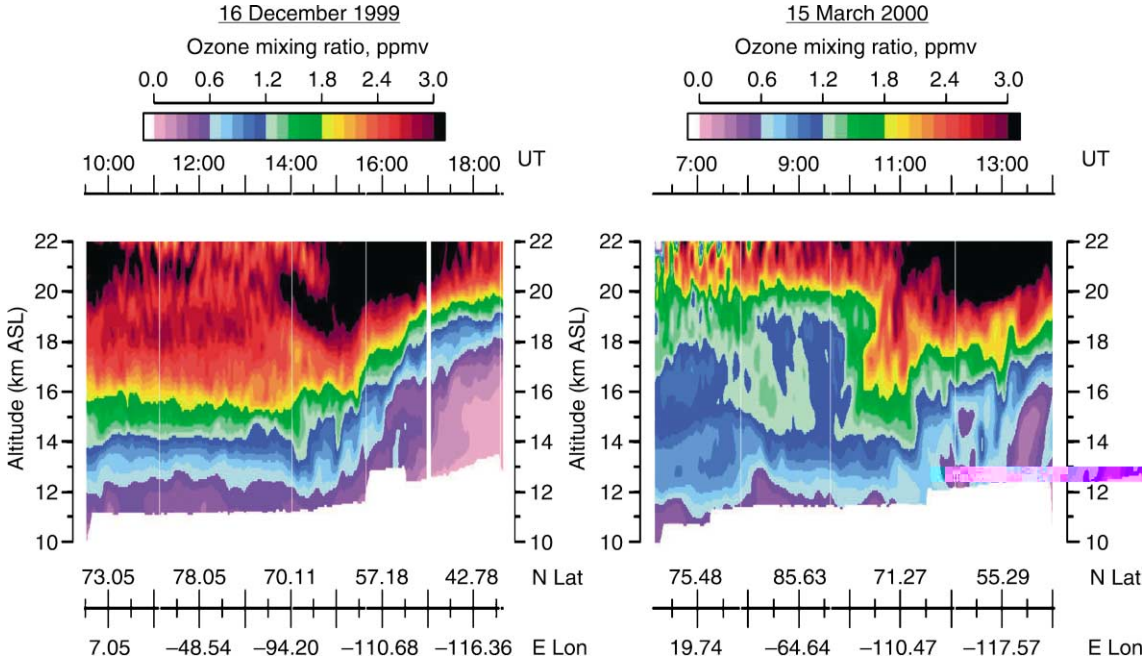

Figure 5 Ozone cross-sections in the stratosphere measured in the winter of 1999/2000 during the SOLVE mission. The change in ozone number density in the Arctic polar vortex due to chemical loss during the winter is clearly evident at latitudes north of 72°N.

predictions. Thus, H_2O distributions can be used in several different ways to better understand chemical, transport, radiation and meteorological processes in the global troposphere.

H_2O Raman Lidar Systems

The first Raman lidar measurements of H_2O were made in the late 1960s, but not much progress in using the Raman approach for H_2O was made until a

system using an abandoned searchlight mirror was employed by the NASA Goddard Space Flight Center in the mid-1980s, to show that if the signal collector (telescope) was large enough, useful Raman measurements could be made to distances of several kilometers. Until recently, Raman lidar measurements of H_2O were largely limited to night-time, due to the high sunlight background interference. Measurements are now made during daytime, using very narrow telescope fields of view and very narrowband filters in the receiver. A good example of a Raman lidar system used to measure H_2O is that at the Department of Energy's Atmospheric Radiation Measurement – Cloud and Radiation Test Bed (ARM-CART) site in Oklahoma. The site is equipped with a variety of instruments aimed at studying the radiation properties of the atmosphere. The system parameters are given in Table 4a,b.

Raman lidar systems have been used for important measurements of H_2O from a number of ground-based locations. Some of the important early work dealt with the passage of cold and warm fronts. The arrival of the wedge-shaped cold front, pushing the warm air up, was one of these studies. Raman lidar have also been located at the ARM-CART site in Kansas and Oklahoma, where they could both provide a climatology of H_2O as well as provide correlative measurements of H_2O for validation of space-based instruments.

H_2O DIAL Systems

H_2O was first measured with the DIAL approach using a temperature-tuned ruby laser lidar system in the mid-1960s. The first aircraft-based H_2O DIAL system was developed at NASA LaRC, and was flown in 1982, as an initial step towards the development of a space-based H_2O DIAL system. This system was based on Nd:YAG-pumped dye laser technology, and it was used in the first airborne H_2O DIAL atmospheric investigation, which was a study of the marine boundary layer over the Gulf Stream. This laser was later replaced with a flashlamp-pumped solid-state alexandrite laser, which had high spectral purity, i.e., little out-of-band radiation, a requirement since water vapor lines are narrow, and this system was used to make accurate H_2O profile measurements across the lower troposphere.

A third H_2O DIAL system, called LASE (Lidar Atmospheric Sensing Experiment) was developed as a prototype for a space-based H_2O DIAL system, and it was completed in 1995. This was the first fully autonomously operating DIAL system. LASE uses a Ti:sapphire laser that is pumped by a double-pulsed, frequency-doubled Nd:YAG to produce laser pulses in the 815 nm absorption band of H_2O (see Table 5). The wavelength of the Ti:sapphire laser is controlled by injection seeding with a diode laser that is frequency locked to a H_2O line using an

Table 5 Parameters of LASE H_2O DIAL system

absorption cell. Each pulse pair consists of an on-line and off-line wavelength for the H_2O DIAL measurements. To cover the large dynamic range of H_2O concentrations in the troposphere (over 3 orders of magnitude), up to three line pair combinations are needed. LASE uses a novel approach of operating from more than one position on a strongly absorbing H_2O line. In this approach, the laser is electronically tuned at the line center, side of the line, and near the wing of the line to achieve the required absorption cross-section pairs (on and off). LASE has demonstrated measurements of H_2O concentrations across the entire troposphere using this 'side-line' approach. The accuracy of LASE H_2O profile measurements was determined to be better than 6% or 0.01 g/kg, whichever is larger, over the full dynamic range of H_2O concentrations in the troposphere. LASE has participated in over eight major field experiments since 1995. See **Table 6** for a listing of topics studied using airborne H_2O DIAL systems (**Figures 6–8**).

Space-Based H_2O DIAL System

The technology for a space-based H_2O DIAL system is rapidly maturing in the areas of: high-efficiency, high-energy, high-spectral-purity, long-life lasers with tunability in the 815- and 940-nm regions; low-weight, large-area, high-throughput, high-background-rejection receivers; and high-quantum-efficiency, low-noise, photon-counting detectors. With the expected advancements in lidar technologies leading to a 1-J/pulse capability, a space-based H_2O DIAL system could be flown on a long-duration space mission this decade.

Space-based DIAL measurements can provide a global H_2O profiling capability, which when combined with passive remote sensing with limited vertical resolution, can lead to 3-dimensional measurements of global H_2O distributions. High vertical resolution H_2O (≤1 km), aerosol (≤100 m), and cloud top (≤50 m) measurements from the lidar along the satellite ground-track, can be combined with the horizontally contiguous data from nadir passive sounders to generate more complete high-resolution H_2O, aerosol, and cloud fields for use in the various studies indicated above. In addition, the combination of active and passive measurements can provide significant synergistic benefits leading to improved temperature and relative humidity measurements. There is also strong synergism with aerosol and cloud imaging instruments and with future passive instruments that are being planned or proposed for missions addressing atmospheric chemistry, radiation, hydrology, natural hazards, and meteorology.

Tunable Laser Systems for Point Monitoring

Tunable diode laser (TDL) systems are also used to measure atmospheric gases on a global scale from aircraft and balloons. TDLs are small lasers that emit extremely narrowband radiation and can be tuned in the near IR spectral region using a combination of temperature and current. TDLs can be built into very sensitive and compact systems and located on the surface or flown on aircraft or balloons and used to measure such species as CO, HCl, CH_4, and oxides of nitrogen such as N_2O and NO_2. They derive their

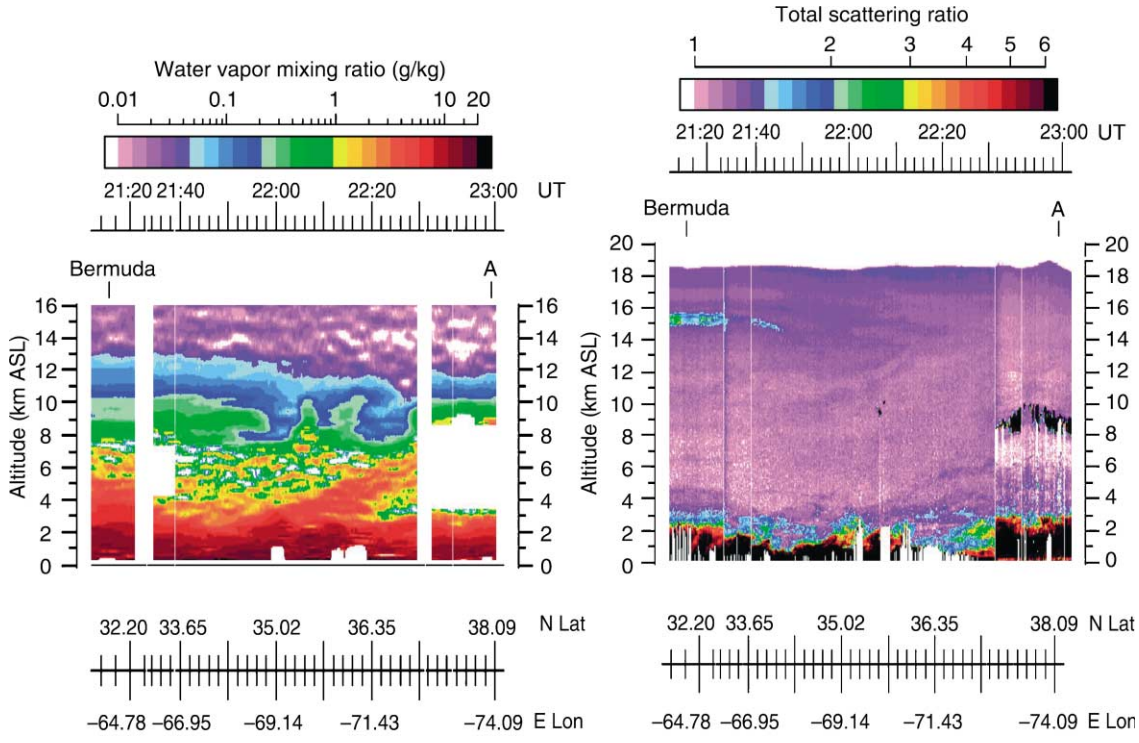

Figure 6 LASE measurements of water vapor (left) and aerosols and clouds (right) across the troposphere on an ER-2 flight from Bermuda to Wallops during the Tropospheric Aerosol Radiative Forcing Experiment (TARFOX) conducted in 1996.

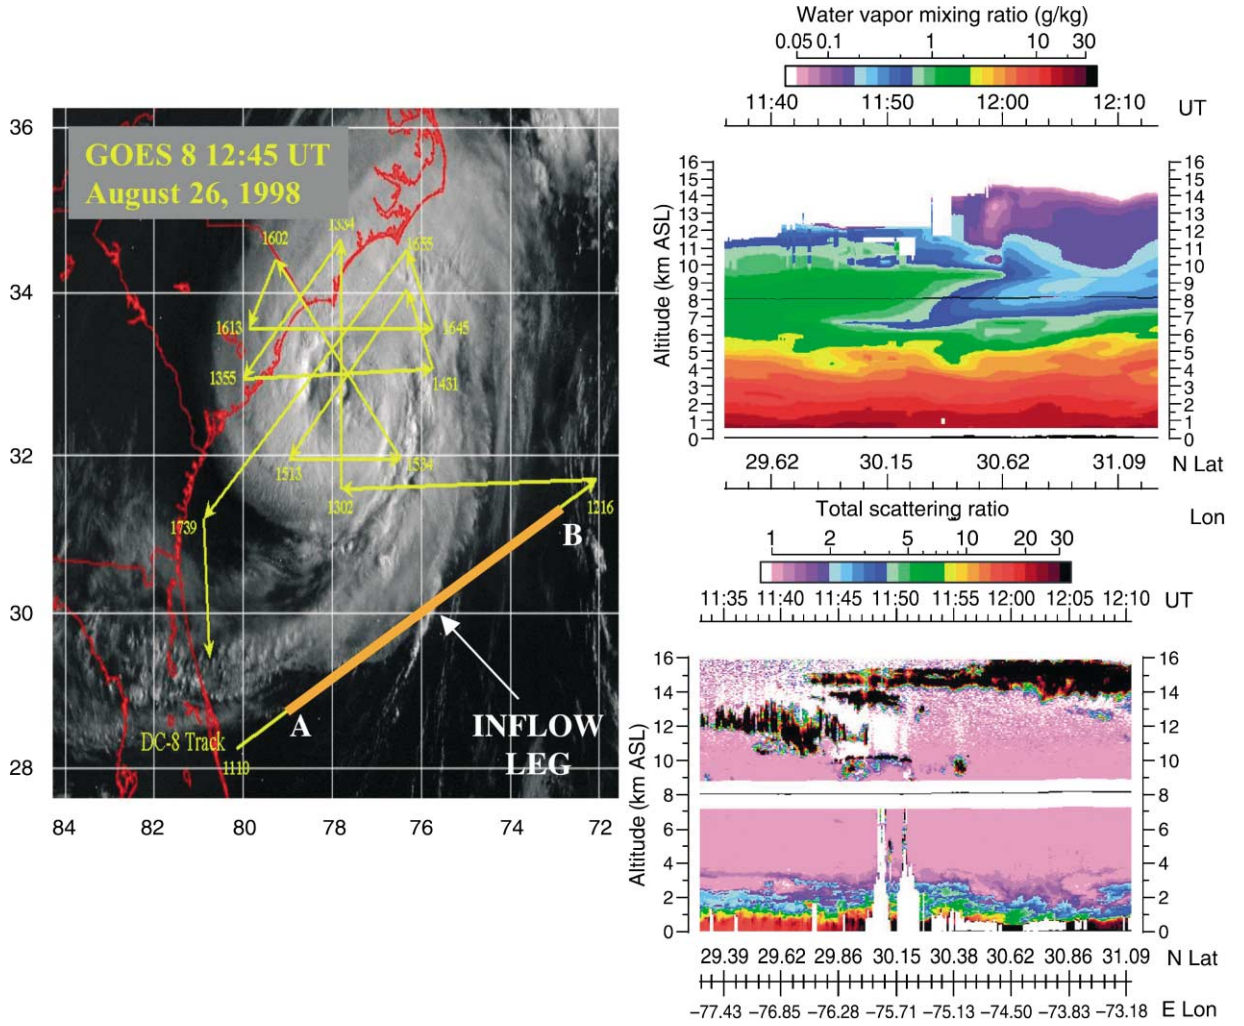

Figure 8 Measurements of water vapor, aerosols, and clouds in the inflow region of Hurricane Bonnie during 1998 Convection and Moisture Experiment (CAMEX-3). A rain band can be clearly seen at the middle of Leg-AB on the satellite and LASE cross-sections.

high sensitivity to the fact that the laser frequency is modulated at a high frequency, permitting a small spectral region to be scanned rapidly. The second- or fourth-harmonic of the scan frequency is used in the data acquisition, effectively eliminating much of the low-frequency noise due to mechanical vibrations and laser power fluctuations. In addition, multipass cells are employed, thereby generating long paths for the absorption measurements.

TDL systems have been used in a number of surface-based measurement programs. One system was mounted on a ship doing a latitudinal survey in the Atlantic Ocean and monitored NO_2, formaldehyde (HCHO), and H_2O_2. Another TDL system was located at the Mauna Loa Observatory and was used to monitor HCHO and H_2O_2 during a photochemistry experiment, finding much lower concentrations of both gases than models had predicted. The TDL system used to measure HCHO has been used in a number of additional ground-based measurement programs and has also been flown on an aircraft in a couple of tropospheric missions.

One TDL system, called DACOM (Differential Absorption CO Measurement), has been used in a large number of NASA GTE missions. It makes measurements of CO in the 4.7 μm spectral region and CH_4 in the 3.3 or 7.6 μm spectral region. This instrument is able to make measurements at a 1 Hz rate and with a precision of 0.5–2.0%, depending on the CO value, and an accuracy of ±2%. DACOM has been very useful in determining global distributions of CO due to the wide-ranging nature of the GTE missions. It has also contributed to

the characterization and understanding of CO in air masses encountered during the GTE missions (Table 7).

A pair of TDL instruments, the Airborne Tunable Laser Absorption Spectrometer (ATLAS) and the Aircraft (ER-2) Laser Infrared Absorption Spectrometer (ALIAS), have been flown on several NASA missions to explore polar O_3 chemistry and atmospheric transport. The ATLAS instrument measures N_2O, and ALIAS is a 4-channel spectrometer that measures a large variety of gases, including HCl, N_2O, CH_4, NO_2, and CO and is currently configured to measure water isotopes across the tropopause.

A new class of lasers, tunable quantum-cascade (QC) lasers, are being added to the list of those available for *in situ* gas measurement systems. Using a cryogenically cooled QC laser during a series of 20 aircraft flights beginning in September 1999 and extending through March 2000, measurements were made of CH_4 and N_2O up to ~20 km in the stratosphere over North America, Scandinavia, and Russia, on the NASA ER-2. Compared with its companion lead salt diode lasers, that were also flown on these flights, the single-mode QC laser, cooled to 82 K, produced higher output power (10 mW), narrower laser linewidth (17 MHz), increased measurement precision (a factor of 3), and better spectral stability (~0.1 cm^{-1} K). The sensitivity of the QC laser channel was estimated to correspond to a minimum-detectable mixing ratio of approximately 2 ppbv of CH_4.

Laser Long-Path Measurements

Laser systems can also be used in long-path measurements of gases. The most important of such programs entailed the measurement of hydroxyl radical (OH) in the Rocky Mountains west of

	Tropical entrainment time scales inferred from stratospheric N_2O and CH_4 observations

Boulder, Colorado. OH was measured using a XeCl excimer laser operating near 308 nm and transmitting a beam to a retroreflector 10.3 km away. The measurements were quite difficult to conduct, primarily since OH abundance is very low (10^5–10^7 cm^{-3}), yielding very low absorption ($\sim$0.02% for an abundance of 10^5 cm^{-3}) over the 20.6 km path. In addition, the excimer laser could generate OH from ambient H_2O and O_3, unless the laser energy density was kept low. To help ensure good measurements, a white light source was also employed during the measurements to monitor H_2O, O_3, and other gases. The measurements were eventually very successful and led to new values for OH abundances in the atmosphere.

Laser-Induced Fluorescence (LIF)

The laser-induced fluorescence approach has been used to measure several molecular and ionic species *in situ*. The LIF approach has been used to measure OH and HO_2 (HO_x) on the ground and on aircraft platforms. One airborne LIF system uses a diode-pumped Nd:YAG-pumped, frequency-doubled dye laser to generate the required energy near 308 nm. The laser beam is sent into a White cell where it can make 32–36 passes through the gas in the cell to increase the LIF signal strength. NO is used to convert HO_2 to OH. The detection limit in 1 minute of about 2–3 ppqv (10^{-15}) above 5 km altitude, which translates into a concentration of about 4×10^4 molec/cm^3 at 5 km and 2×10^4 molec/cm^3 at 10 km altitude. One of the interesting findings from such measurements is that HO_x concentrations are up to 5 times larger than model predictions based on NO_x concentrations, suggesting that NO_x emissions from aircraft could have a greater impact on O_3 production than originally thought.

NO is detected using the LIF technique in a two-photon approach: electrons are pumped from the ground state using 226 nm radiation and from that state to an excited state using 1.06 μm radiation. The 226 nm radiation is generated by frequency doubling a dye laser to 287 nm and then mixing that with 1.1 μm radiation derived from H_2 Raman shifting of frequency-mixed radiation from a dye laser and a Nd:YAG laser. From the excited level, 187–201 nm radiation is emitted. In order to measure NO_2, it is first converted to the photofragment NO via pumping at 353 nm from a XeF excimer laser. One of the interesting findings from airborne measurements in the South Pacific is that there appeared to be a large missing source for NO_x in the upper troposphere.

Summary

DIAL and Raman lidar systems have played important roles in studying the distribution of gases such as O_3 and H_2O on local, regional, and global scales, while TDL systems have played corresponding roles for such gases as CO, HCl, and oxides of nitrogen. It is anticipated that these approaches will continue to yield valuable information on these and other gases, as new and more capable systems are developed. Within the next decade, it is expected that a DIAL system will be placed in orbit to make truly global measurements of O_3, H_2O, and/or carbon dioxide.

Introduction

The ability to understand and model radiative transfer (RT) processes in the atmosphere is critical for remote sensing, environmental characterization, and many other areas of scientific and practical interest. At the Earth's surface, the bulk of this radiation, which originates from the sun, is found in the ultraviolet to infrared range between around 0.3 and 4 μm. This article describes the most significant RT processes for these wavelengths, which are absorption (light attenuation along the line of sight LOS) and elastic scattering (redirection of the light). Transmittance, T, is defined as one minus the fractional extinction (absorption plus scattering). At longer wavelengths (in the mid- and long-wave infrared) the major light source is thermal emission.

A few other light sources are mentioned here. The moon is the major source of visible light at night. Forest fires can be a significant source of mid-wave infrared radiation. Manmade light sources include continuum sources such as incandescent lamps and spectrally narrow sources such as fluorescent lamps and lasers. In general, spectrally narrow sources need to have a different RT treatment than continuum sources due to the abundance of narrow spectral absorption lines in the atmosphere, as is discussed below.

The challenge of atmospheric RT modeling is essentially to solve the following equation that describes monochromatic light propagation along the LOS direction:

$$\left(\frac{1}{k}\right)\frac{\mathrm{d}I}{\mathrm{d}u} = -I + J \qquad [1]$$

where I is the LOS radiance (watts per unit area per unit wavelength per steradian), k is the extinction coefficient for the absorbing and scattering species (per unit concentration per unit length), u is the material column density (in units of concentration times length), and J is the radiance source function. I is a sum of direct (i.e., from the sun) and diffusely scattered components. The source function represents the diffuse light scattered into the LOS, and is the angular integral over all directions Ω_i of the product of the incoming radiance, $I(\Omega_i)$, and the scattering phase function, $p(\Omega_o, \Omega_i)$:

$$J(\Omega_o) = \int_{\Omega_i} p(\Omega_o, \Omega_i) I(\Omega_i) \mathrm{d}\Omega_i \qquad [2]$$

The scattering phase function describes the probability density for incoming light from direction Ω_i scattering out at angle Ω_o, and is a function of the difference (scattering) angle θ.

The direct radiance component, I', is described by eqn [1] with the source function omitted. Integrating along the LOS leads to the well-known Beer's Law

equation for transmittance:

$$T = I'/I'_0 = \exp(-ku) \qquad [3]$$

where I'_0 is the direct radiance at the boundary of the LOS. The quantity $ku = \ln(1/T)$ is known as the optical depth.

Atmospheric Constituents

The atmosphere has a large number of constituents, including numerous gaseous species and suspended liquid and solid particulates. Their contributions to extinction are depicted in Figure 1. The largest category is gases, of which the most important are water vapor, carbon dioxide, and ozone. Of these, water vapor is the most variable and carbon dioxide the least, although the CO_2 concentration is gradually increasing. In atmospheric RT models, carbon dioxide is frequently taken to have a fixed and altitude-independent concentration, along with other 'uniformly mixed gases' (UMGs). The concentration profiles of the three major gas species are very different. Water vapor is located mainly in the lowest 2 km of the atmosphere. Ozone has a fairly flat profile from the ground through the stratosphere (~30 km). The UMGs decline exponentially with altitude, with a scale height of around 8 km.

Gases

Gas molecules both scatter and absorb light. Rayleigh scattering by gases scales inversely with the fourth power of the wavelength, and is responsible for the sky's blue color. For typical atmospheric conditions, the optical depth for Rayleigh extinction is approximately $0.009/\lambda^4$ per air mass (λ is in μm and air mass is defined by the vertical column from ground to space). The Rayleigh phase function has a $(1 + \cos^2\theta)$ dependence.

Absorption by gases may consist of a smooth spectral continuum (such as the ultraviolet and visible electronic transitions of ozone) or of discrete spectral lines, which are primarily rotation lines of molecular vibrational bands. In the lower atmosphere (below around 25 km altitude), the spectral shape of these lines is determined by collisional broadening and described by the normalized Lorentz line shape formula:

$$f_{\text{Lorentz}}(\nu) = \frac{\alpha_c/\pi}{\alpha_c^2 + (\nu - \nu_0)^2} \qquad [4]$$

Here ν is the wavenumber (in cm^{-1}) [$\nu = (10\,000\ \mu\text{m}/\text{cm})/\lambda$], ν_0 is the molecular line transition frequency and α_c is the collision-broadened half-width (in cm^{-1}), which is proportional to pressure. The constant of proportionality, known as the pressure-broadening parameter, has a typical value on the order of 0.06 $\text{cm}^{-1}\,\text{atm}^{-1}$ at ambient temperature. The extinction coefficient $k(\nu)$ is the product of $f_{\text{Lorentz}}(\nu)$ and the integrated line strength S, which is commonly in units of $\text{atm}^{-1}\,\text{cm}^{-2}$.

At higher altitudes in the atmosphere the pressure is reduced sufficiently that Doppler broadening

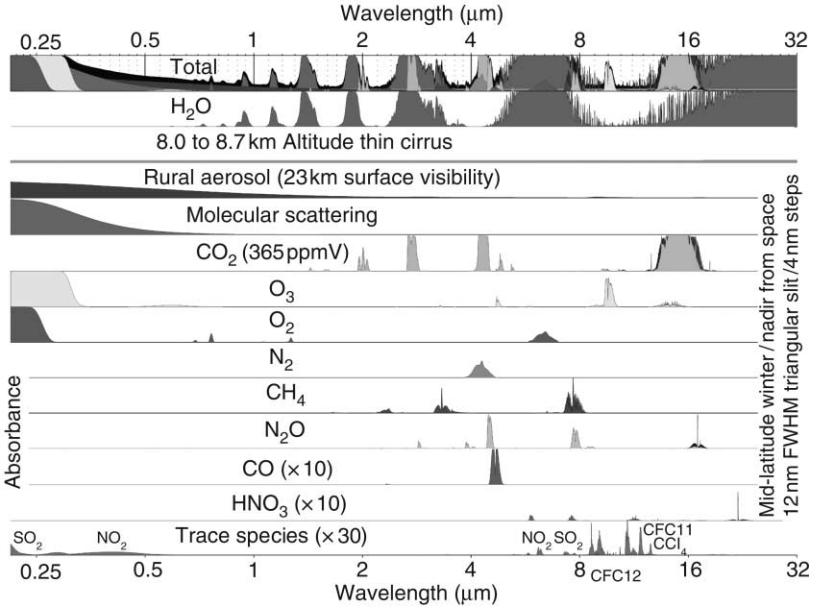

Figure 1 Spectral absorbance (1 – transmittance) for the primary sources of atmospheric extinction. The 12 nm resolution data were generated by MODTRAN for a vertical path from space with a mid-latitude winter model atmosphere.

becomes competitive with collisional broadening, and the Lorentz formula becomes inaccurate. The general lineshape for combined collisional and Doppler broadening is the Voigt lineshape, which is proportional to the real part of the complex error (probability) function, w:

$$f_{\text{Voigt}}(\nu) = \frac{1}{\alpha_{\text{d}}\sqrt{\pi}}\text{Re}\left[w\left(\frac{\nu-\nu_0}{\alpha_{\text{d}}} + \frac{\alpha_{\text{c}}}{\alpha_{\text{d}}}\text{i}\right)\right] \qquad [5]$$

Here, α_{d} is the Doppler 1/e half-width.

Comprehensive spectral databases have been compiled of the transition frequencies, strengths, and pressure-broadened half-widths for atmospherically important molecules throughout the electromagnetic spectrum. Perhaps the most notable of these databases is HITRAN, which was developed by the US Air Force Research Laboratory and is currently maintained at the Harvard-Smithsonian Center for Astrophysics in Cambridge, MA.

Liquids and Solids

The larger particulates in the atmosphere (greater than a few μm in radius) typically belong to clouds. Low-altitude clouds consist of nearly spherical water droplets, while high-altitude cirrus clouds are mainly a collection of ice crystals. Other large particulates include sand dust. Their light scattering is close to the geometric limit at visible and ultraviolet wavelengths. This means that the extinction is nearly wavelength-independent, and the scattering phase function and single-scattering albedo may be reasonably modeled with ray-tracing techniques that account for the detailed size and shape distributions of the particles. However, Mie scattering theory is typically used to calculate cloud optical properties because it is exact for spherical particles of any size.

The smaller particulates in the atmosphere belong to aerosols, which are very fine liquid particles, and dusts, which are solids such as minerals and soot. These particulates are concentrated mainly in the lower 2 km or so of the atmosphere; however, they are also present at higher altitudes in smaller concentrations. Their optical properties are typically modeled using Mie theory. The wavelength dependence of the scattering is approximately inversely proportional to a low power of the wavelength, typically between 1 and 2, as befits particulates intermediate in size between molecular and geometric-limit. The scattering phase functions have a strong forward-scattering peak; values of the asymmetry parameter g (the average value of $\cos\theta$) typically range from 0.6 to 0.8 at solar wavelengths.

Solution Methods

Geometry

Atmospheric properties are primarily a function of altitude, which determines pressure, temperature and species concentration profiles. Accordingly, most RT methods define a stratified atmosphere. The most accurate treatments of transmission and scattering account for the spherical shape of the layers and refraction; however, most RT models use a plane-parallel approximation for at least some computations, such as multiple scattering.

Spectral Resolution

Optical instruments have finite, and frequently broad, wavelength responses. Nevertheless, modeling their signals requires accounting for the variation of absorption on an extremely fine wavelength scale, smaller than the widths of the molecular lines.

'Exact' monochromatic methods

The most accurate RT solution method involves explicitly solving the RT problem for a very large number of monochromatic wavelengths. This line-by-line method is used in a number of RT models, such as FASCODE. It allows Beer's law to be applied to combine transmittances from multiple LOS segments, and provides an unambiguous definition of the optical parameters. It is suitable for use with spectrally structured light sources, such as lasers. The one major drawback of this method is that it is computationally intensive, and therefore may not be practical for problems where large wavelength ranges, multiple LOS views and multiple atmospheric conditions need to be treated.

To alleviate the computational burden of monochromatic calculations, some approximate methods have been developed that model RT in finite spectral intervals, as described below.

Statistical band models

The band model method represents spectral lines in a narrow interval, $\Delta\nu$, statistically using such parameters as the total line strength, the mean pressure-broadening parameter, and the effective number of lines in the interval. An example of a popular band model-based RT algorithm is MODTRAN, which is described below.

A key to the success of band models is the availability of approximate analytical formulas for the integrated absorption for an individual molecular transition of strength S, known as the single-line total

equivalent width, W_{sl}:

$$W_{sl} = \int_{-\infty}^{\infty} [1 - \exp(-Suf_{\nu})]\mathrm{d}\nu \qquad [6]$$

In the optically thin (small absorption) limit, W_{sl} is proportional to the molecular species column density, while in the optically thick (large absorption) limit it scales as the square root of the column density. A further assumption made by MODTRAN is that the line centers are randomly located within the interval, i.e., spectrally uncorrelated. With this assumption, the net transmittance can be expressed as the product of the transmittances for each individual line, whether the line belongs to the same molecular species or a different species.

A particular challenge in band models is treatment of the inhomogeneous path problem – that is, the variations in path properties along a LOS and their effect on the statistical line parameters, which arise primarily from differences in pressure and hence line width. The Curtis–Godson path averaging method provides a reasonable way to define 'equivalent' homogeneous path parameters for the band model. Another challenge is to define an effective extinction optical depth for each layer in order to solve the RT problem with scattering. One option in MODTRAN is to define it by computing the cumulative transmittance through successive layers in a vertical path.

Correlated-*k* model

Another well-known approximate RT algorithm for spectral intervals is the correlated-*k* method. This method starts with an 'exact' line-by-line calculation of extinction coefficients (k's) within the interval on a fine spectral grid, from which a *k*-distribution (vs. cumulative probability) is computed. A database of *k* values and probabilities summing to 1 is built from these *k*-distributions for a grid of atmospheric pressures and temperatures, and for all species contributing to the spectral interval. Inhomogeneous paths are handled by recognizing that the size order of the k's is virtually independent of pressure and typically only weakly dependent on temperature. LOS transmittances, LOS radiances, and fluxes are calculated by interpolating the database over temperature and pressure to define the k's for each LOS segment, solving the monochromatic RT equation at each fixed distribution location, and finally integrating over the distribution. The correlated-*k* method has been found to be quite accurate for atmospheric paths containing a single molecular species; however, corrections must be applied for spectral intervals containing multiple species.

Scattering Methods

When the diffuse light field is of interest, scattering methods are used to calculate the source function *J* of eqns [1] and [2].

Single scattering

If scattering is weak, the approximation may be made that the solar radiation scatters only once. Thus the integral over the scattering phase function, eqn [2], is straightforwardly calculated using the direct radiance component, which is given by eqn [3]. The neglect of multiple scattering (i.e., the diffuse contribution to the source function) means that the diffuse radiance is underestimated; however, single scattering is sufficiently accurate for some atmospheric problems in clear weather and at infrared wavelengths.

Multiple scattering

A number of different methods have been developed to solve the multiple scattering problem. Two-stream methods, which are the simplest and fastest, resolve the radiance into upward and downward directions. These methods generally produce reasonably accurate values of hemispherically averaged radiance, which are also referred to as horizontal fluxes or irradiances.

A much more accurate approach to the multiple scattering problem is the method of discrete ordinates. It involves expansion of the radiation field, the phase function and the surface reflectance as a series of spherical harmonics, leading to a system of linear integral equations. Evaluation of the integrals by Gaussian quadrature leads to a solvable system of linear differential equations. An important approximation called delta-M speeds up convergence of the discrete ordinates method, especially when scattering phase functions are strongly forward peaked, by representing the phase function as the sum of a forward direction δ-function and a remainder term. For most scattering problems, the solution is converged upon with a modest number ($\sim$8 to 16) of quadrature points (streams).

A very different type of multiple scattering technique, called the Monte Carlo method, is based on randomly sampling a large number of computer-simulated 'photons' as they travel through the atmosphere and are absorbed and scattered. The basic idea here is that sensor radiance can be expressed as a multiple path integral over the local source terms, and Monte Carlo methods solve integrals by sampling the integrand. The major advantage of this method is that it is flexible enough to allow for all of the complexity of a realistic atmosphere, often neglected by other methods. The major drawback is its

computational burden, as a large number of photons is required for reasonable convergence; the Gaussian error in the calculation declines with the square root of the number of photons. The convergence problem is moderated to a large extent by using the physics of the problem being solved to bias the selection of photon paths toward those trajectories which contribute most; mathematically, this is equivalent to requiring that the integrand be sampled most often where its contributions are most significant.

An Example Atmospheric RT Model: MODTRAN

MODTRAN, developed collaboratively by the Air Force Research Laboratory and Spectral Sciences, Inc., is the most widely used atmospheric radiation transport model. It defines the atmosphere using stratified layering and computes transmittances, radiances, and fluxes using a moderate spectral resolution band model with IR through UV coverage. The width of the standard spectral interval, or bin, in MODTRAN is 1 cm^{-1}. At this resolution, spectral correlation among extinction sources is well characterized as random. Thus, the total transmittance from absorption and scattering of atmospheric particulates and molecular gases is computed as the product of the individual components.

Rayleigh, aerosol, and cloud extinction are all spectrally slowly varying and well represented by Beer's Law absorption and scattering coefficients on a 1 cm^{-1} grid. Calculation of molecular absorption is more complex because of the inherent spectral structure and the large number of molecular transitions contributing to individual spectral bins. As illustrated in Figure 2, MODTRAN partitions the spectral bin molecular attenuation into 3 components:

- *Line center absorption* from molecular transitions centered within the spectral bin;
- *Line tail absorption* from the tails of molecular lines centered outside of the spectral bin but within 25 cm^{-1}; and
- H_2O and CO_2 *continuum absorption* from distant (>25 cm^{-1}) lines.

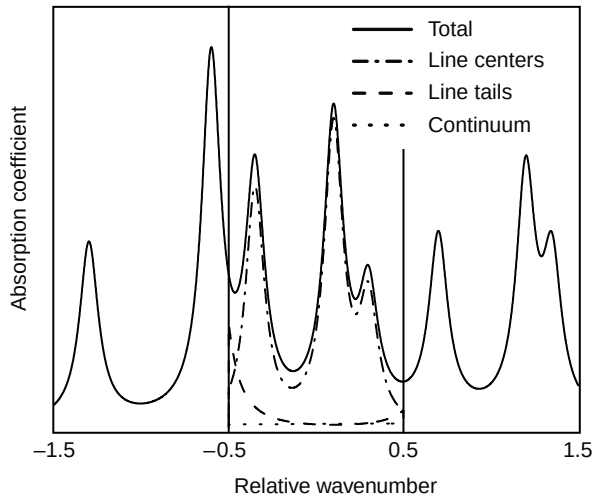

Figure 2 Components of molecular absorption. The line center, line tail and continuum contributions to the total absorption are illustrated for the central 1 cm^{-1} spectral bin.

Within the terrestrial atmosphere, only H_2O and CO_2 have sufficient concentrations and line densities to warrant inclusion of continuum contributions. These absorption features are relatively flat and accurately modeled using 5 cm^{-1} spectral resolution Beer's Law absorption coefficients.

Spectral bin contributions from neighboring line tails drop off, often rapidly, from their spectral bin edge values, but the spectral curves are typically simple, containing at most a single local minimum. For MODTRAN, these spectral contributions are pre-computed for a grid of temperature and pressure values, and fit with Padé approximants, specifically the ratio of quadratic polynomials in wavenumber. These fits are extremely accurate and enable line tail contributions to be computed on an arbitrarily fine grid. MODTRAN generally computes this absorption at a resolution equal to one-quarter the spectral bin width, i.e., 0.25 cm^{-1} for the 1.0 cm^{-1} band model.

The most basic *ansatz* of the MODTRAN band model is the stipulation that molecular line center absorption can be approximated by the absorption of n identical Voigt lines randomly distributed within the band model spectral interval, $\Delta\nu$. Early in the development of RT theory, Plass derived the expression for the transmittance from these n randomly distributed lines:

$$T = \left(1 - \frac{W'_{sl}}{\Delta\nu}\right)^n \qquad [7]$$

MODTRAN's evolution has resulted in a fine tuning of the methodology used to define both the effective line number n and the in-band single-line equivalent width W'_{sl}. The effective line number is initially estimated from a relationship developed by Goody, in which lines are weighted according the to square root of their strength, but MODTRAN combines nearly degenerate transitions into single lines because these multiplets violate the random distribution assumption. The initial effective line number values are refined to insure a match with higher resolution transmittance predictions degraded to the band model resolution. The in-band equivalent

width is computed for an off-centered Voigt line of strength S. Lorentz and Doppler half-widths are determined as strength-weighted averages. The off-center distance is fixed to insure that the weak-line Lorentz equivalent width exactly equals the random line center value.

MODTRAN scattering calculations are optimally performed using the DISORT discrete ordinates algorithm developed by Stamnes and co-workers. Methods for computing multiple scattering such as DISORT require additive optical depths, i.e., Beer's Law transmittances. Since the in-band molecular transmittances of MODTRAN do not satisfy Beer's Law, MODTRAN includes a correlated-k algorithm option. The basic band model *ansatz* is re-invoked to efficiently determine k-distributions; tables of k-data are pre-computed as a function of Lorentz and Doppler half-widths and effective line number, assuming spectral intervals contain n randomly distributed identical molecular lines. Thus, MODTRAN k-distributions are statistical, only dependent on band model parameter values, not on the exact distribution of absorption coefficients in each spectral interval.

Applications

Among the many applications of atmospheric transmission and scattering calculations, we briefly describe two complementary ones in the area of remote sensing, which illustrate many of the RT features discussed earlier as well as current optical technologies and problems of interest.

Earth Surface Viewing

The first example is Earth surface viewing from aircraft or spacecraft with spectral imaging sensors. These include hyperspectral sensors, such as AVIRIS, which have typically a hundred or more contiguous spectral channels, and multispectral sensors, such as Landsat, which typically have between three and a few tens of channels. These instruments are frequently used to characterize the surface terrain, materials and properties for such applications as mineral prospecting, environmental monitoring, precision agriculture, and military uses. In addition, they are sensitive to properties of the atmosphere such as aerosol optical depth and column water vapor. Indeed, in order to characterize the surface spectral reflectance, it is necessary to characterize and remove the extinction and scattering effects of the atmosphere.

Figure 3 also shows an example of data collected by the AVIRIS sensor at ~3 km altitude over thick vegetation. The apparent reflectance spectrum is the observed radiance divided by the Top-of-Atmosphere horizontal solar flux. Atmospheric absorption by water vapor, oxygen, and carbon dioxide is evident, as well as Rayleigh and aerosol scattering. Figure 3 shows the surface reflectance spectrum inferred by modeling and then removing these atmospheric effects (this process is known as atmospheric removal, compensation, or correction). It has the characteristic smooth shape expected of vegetation, with strong chlorophyll absorption in the visible and water bands at longer wavelengths. A detailed analysis of such a spectrum may yield information on the vegetation type and its area coverage and health.

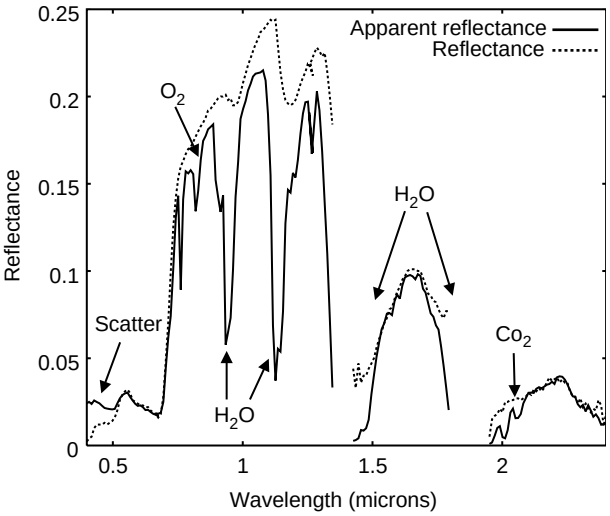

Figure 3 Vegetation spectrum viewed from 3 km altitude before (apparent reflectance) and after (reflectance) removal of atmospheric scatter and absorption.

Sun and Sky Viewing

The second remote sensing example is sun and sky viewing from the Earth's surface with a spectral radiometer, which can yield information on the aerosol content and optical properties as well as estimates of column concentrations of water vapor, ozone, and other gases. Figure 4 shows data from a Yankee Environmental Systems, Inc. multi-filter rotating shadow-band radiometer, which measures both 'direct flux' (the direct solar flux divided by the cosine of the zenith angle) and diffuse (sky) flux in narrow wavelength bands. The plot of ln(direct signal) versus the air mass ratio is called a Langley plot, and is linear for most of the bands, illustrating Beer's Law. The extinction coefficients (slopes) vary with wavelength consistent with a combination of Mie and Rayleigh scattering. The water-absorbing 940 nm band has the lowest values and a curved

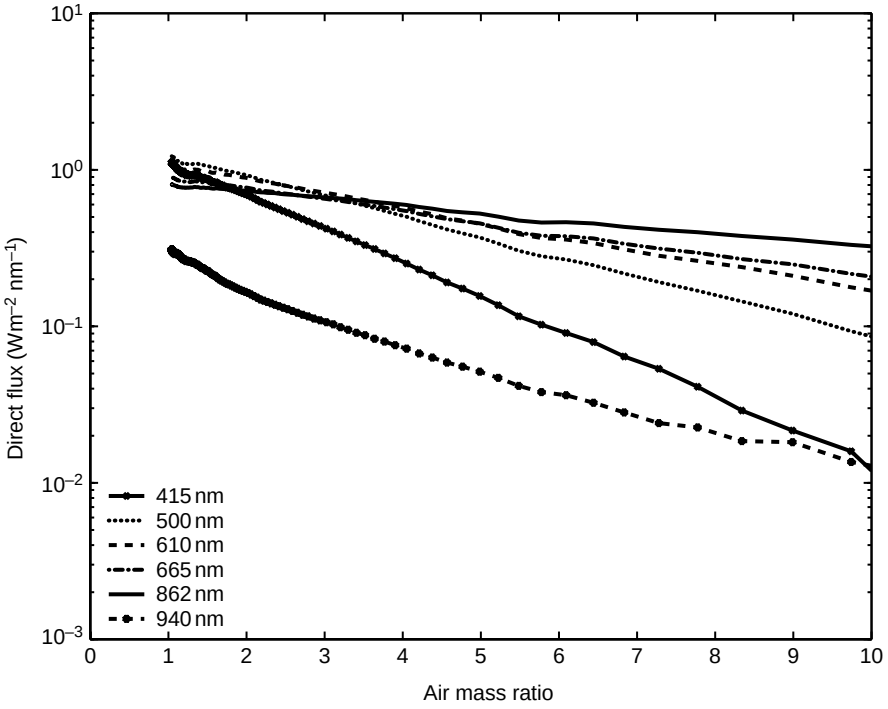

Figure 4 Direct solar flux versus air mass at the surface measured by a Yankee Environmental Systems, Inc. multi-filter rotating shadow-band radiometer at different wavelengths.

plot, in accordance with the square-root dependence of the equivalent width for optically thick lines. The diffuse fluxes, which arise from aerosol and Rayleigh scattering, have a very different dependence on air mass than the direct flux. In particular, the diffuse contributions often increase with air mass for high sun conditions.

The ratio of the diffuse and direct fluxes is related to the total single-scattering albedo, which is defined as the ratio of the total scattering coefficient to the extinction coefficient. Results from a number of measurements showing lower than expected diffuse-to-direct ratios have suggested the presence of black carbon or some other continuum absorber in the atmosphere, which would have a significant impact on radiative energy balance at the Earth's surface and in the atmospheric boundary layer.

List of Units and Nomenclature

Line shape function [cm]	f_ν
Lorentz line shape function [cm]	$f_{\text{Lorentz}}(\nu)$
Voigt line shape function [cm]	$f_{\text{Voigt}}(\nu)$
Scattering asymmetry parameter	g
Direct plus diffuse radiance (W cm^{-1} sr^{-1} or W cm^{-2} μm^{-1} sr^{-1})	I
Direct radiance (W cm^{-1} sr^{-1} or W cm^{-2} μm^{-1} sr^{-1})	I'
Direct radiance at the LOS boundary (W cm^{-1} sr^{-1} or W cm^{-2} μm^{-1} sr^{-1})	I'_0
Source function (W cm^{-1} sr^{-1} or W cm^{-2} μm^{-1} sr^{-1})	J
Extinction coefficient (cm^{-1} atm^{-1})	k
Effective number of lines in bin	n
Scattering phase function (sr^{-1})	p
Line strength (cm^{-2} atm^{-1})	S
Transmittance	T
Column density (atm cm)	u
Complex error (probability) function	w
Single-line total equivalent width (cm^{-1})	W_{sl}
Single-line in-band equivalent width (cm^{-1})	W'_{sl}
Collision-broadened half-width at half maximum (cm^{-1})	α_{c}
Doppler half-width at 1/e (cm^{-1})	α_{d}
Spectral interval (bin) width (cm^{-1})	$\Delta\nu$
Scattering angle (radian)	θ
Wavelength (μm)	λ
Wavenumber (cm^{-1})	ν
Molecular line transition frequency	ν_0
Direction of incoming light (sr)	Ω_{i}
Direction of outgoing light (sr)	Ω_{o}

Introduction

It is said that some in ancient Greece knew that light could be guided inside slabs of transparent material. From this purported little-known curiosity in the ancient world, guided wave optics has grown to be the technology of the physical level of the systems which transfer most of the information about the world; the waveguide of the worldwide telecommunications network is the optical fiber. The optical fiber itself is but a passive waveguide, and guided wave optics is the technology which includes all of the passive and active components which are necessary to prepare optical signals for transmission, regenerate optical signals during transmission, route optical signals through systems and code onto optical carriers, and decode the information from optical carriers, to more conventional forms. In this article, some introduction to this rather encompassing topic will be given.

This article will be separated into four parts. In the first section, discussion will be given to fiber optics, that is, the properties of the light guided in optical waveguides which allow the light to be guided in distinctly nonrectilinear paths over terrestrial distances. The second section will then turn to the components which can be used along with the fiber optical waveguides in order to form useful systems. These components include sources and detectors as well as optical amplifiers. In the third section, we will discuss the telecommunications network which has arisen due to the availability of fiber optics and fiber optic compatible components. The closing section will discuss integrated optics, the field of endeavor which has such great promise to form the future of optical technology.

Fiber Optics

Fiber optics is a term which generally refers to a technology in which light (actually infrared, visible, or ultraviolet radiation) is transmitted through the transparent cores of small threads of composite material. These threads, or fibers as they are called, when surrounded by a cladding material and coated with polymer for environmental protection (see Figure 1) can be coiled like conventional wire and

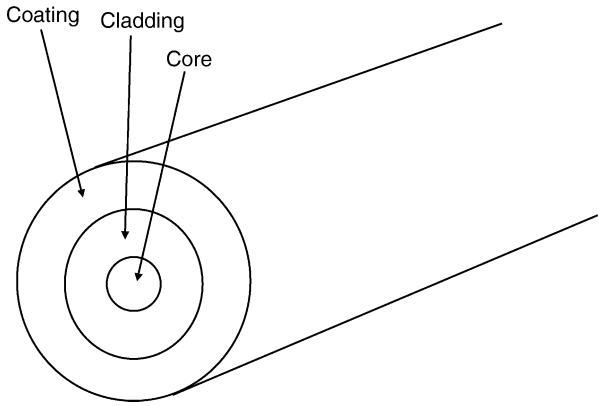

Figure 1 A depiction of the structure of an optical fiber. The innermost cylinder is the core region in which the majority of the light is confined. The next concentric region is the cladding region which is still made of a pure material but one of a lower index of refraction than the innermost core region, such that the light of the lightwave decays exponentially with extension into this region. The outermost region is a coating which protects the fused silica of the core and cladding from environmental contaminants such as water. For telecommunications fibers, the core is comprised of fused silica doped with germanium and typically has an index of refraction of 1.45, whereas the cladding differs from this index by only about 1%. The coating is often a polyimide plastic which has a higher index (perhaps 1.6) but no light guided light should see the cladding-coating interface.

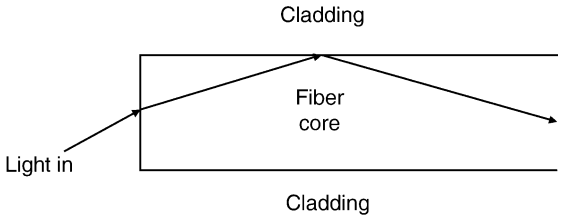

Figure 2 Schematic depiction of the geometrical optics interpretation of the coupling of light into an optical fiber. Here a ray that is incident on the center of the fiber core at an upward angle is first refracted at the fused silica–air interface into the fused silica core. The ray is then totally internally reflected at the core cladding interface such that the ray power remains in the core. The ray picture of light coupling is applicable to single rays coupling to a multimode fiber. When there are multiple rays, interference between these rays must be taken into account which is difficult to do in the ray picture. When there is only one (diffraction limited) mode in the fiber, the interference between a congruence of (spatially coherent) incident rays is necessary to describe the coupling. This description is more easily effected by a quasi-monochromatic mode picture of the propagation.

when cabled can resemble (a very lightweight flexible version of) conventional transmission wire. Although most of the optical fiber in use today is fabricated by a process of gas phase chemical deposition of fused silica doped with various other trace chemicals, fiber can be made from a number of different material systems and in a number of different configurations for use with various types of sources. In what follows in this opening section, we will limit discussion to the basic properties of the light guided by the fiber and leave more technological discussion to following sections.

There are two complementary mathematical descriptions of the propagation of light in an optical waveguide. In the ray description, light incident on a fiber endface is considered to be made up of a bundle of rays. In a uniform homogeneous medium, each ray is like an arrow that exhibits rectilinear propagation from its source to its next interface with a dissimilar material. These rays satisfy Snell's laws of reflection and refraction at interfaces between materials with dissimilar optical properties that they encounter along their propagation path. That is, at an interface, a fraction of the light is reflected backwards at an angle equal to the incident angle and a portion of the light is transmitted in a direction which is more directed toward the normal to the interface when the index increases across the boundary and is directed more away from the normal when the index decreases. At the input endface of a waveguide, a portion of the energy guided by each ray is refracted due to the change in refractive index at the guide surface and then exhibits a more interesting path within the fiber. In a step index optical fiber, where the index of refraction is uniformly higher in the fiber core than in a surrounding cladding, the rays will propagate along straight paths until encountering the core cladding interface. Guided rays (see Figure 2) are totally internally reflected back into the fiber core to again be totally internally reflected at the next core cladding interface and so on. Radiating rays (see Figure 3) will be only partially reflected at the core cladding interface and will rapidly die out in propagating down the fiber when it is taken into account that typical distances between successive encounters with the boundary may be sub-millimeter and total propagation distances may be many kilometers. In graded index fibers, the refractive index within the fiber core varies continuously from a maximum somewhere within the core to a minimum at which the core ends and attaches continuously to a cladding. The ray paths within such fibers are curved and the guided rays are characterized by the fact that once in the fiber they never encounter the cladding. Radiating rays encounter the cladding and are refracted out of the fiber. This description of fiber propagation is quite simple and pleasing but does not take into account that each ray actually is carrying a clock that remembers how long it has been following its given path. When two rays come together, they can

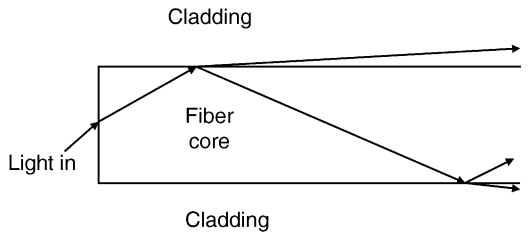

Figure 3 Schematic depiction of the existence of a cut-off angle for coupling into an optical fiber. A ray incident from air on the center of the fused silica fiber core is refracted at the air fused silica interface and then split when it comes to the core cladding interface within the fiber. Were the refracted angle of this ray zero (along the core cladding interface) we would say the ray is totally internally reflected and no power escapes. As it is, there is refracted power into the cladding and the ray will rapidly attenuate as it propagates along the fiber. Although most telecommunications fiber in this day and age is graded index (the rays will curve rather than travel along straight paths), a typical repeat period in such a fiber is a millimeter, whereas propagation distances may be 100 km. With a loss of even only 0.1% at each reflection form the cladding, the light light at cut-off will be severely attenuated in one meter, no loss, one kilometer.

either add or subtract, depending on the reading on their respective clocks. When the light is nearly monochromatic, the clocks' readings are simply a measure of the phase of the ray when it was radiated from its source and the interference between rays can be quite strong. This interference leads to conditions which only allow certain ray paths to be propagated. When the light has a randomly varying phase in both space and time (and is therefore polychromatic), the interference all but disappears. But the condition that allows coupling to a specific ray path (mode) also is obliterated by the phase randomness, and coupling to a single mode guide, for example, becomes inefficient.

When we need to preserve phase relations in order to preserve information while it propagates along a fiber path, we need to use single modes excited by nearly transform limited sources, that is sources whose time variation exhibits well-defined (nonrandom) phase variation. As a monochromatic wave carries no information, we will require a source which can be modulated. When modulation can be impressed on a carrier without loss of phase information of either information or carrier, information can be propagated at longer distances than when the frequency spectrum of the carrier is broadened by noise generated during the modulation. We refer to such a source that can be modulated without broadening as a coherent or nearly coherent source. We cannot easily adapt the ray picture to the description of propagation of such coherent radiation in an optical fiber. Instead we must resort to using the time harmonic form of Maxwell's equations, the equations which describe electromagnetic phenomena, whereas rays can be described by a simplification of the time-dependent form of these equations. In the time harmonic approach, we assume that the source is monochromatic and then solve for a set of modes of the fiber at the assumed frequency of the source. These modes have a well-defined phase progression as a function of carrier frequency and possess a given shape in the plane transverse to the direction of propagation. Information can be included in the propagation by assuming the quasi-monochromatic variation of the source, that is, one assumes that the source retains the phase relations between the various modulated frequency components even while its amplitude and phase is being varied externally. When one assumes that time harmonically (monochromatic) varying fields are propagating along the fiber axis, one obtains solutions of Maxwell's equations in the form of a summation of modes. These are guided modes, ones that propagate down the fiber axis without attenuation. There are also radiation modes that never couple into a propagating mode in the fiber. These modes are analogous to the types of rays we see in the ray description of fiber propagation. There are also another set of modes which are called evanescent modes which show up at discontinuities in the fiber or at junctions between the fiber and other components. In the modal picture of fiber propagation, each of these modes is given an independent complex coefficient (that is, a coefficient with both amplitude and phase). These coefficients are determined first by any sources in the problem and then must be recalculated at each discontinuity plane along the propagation path in the fiber. When the source(s) in the problem is not transform limited, the phases of the coefficients become smeared out and the coupling problems at discontinuities take on radically different solutions.

In some limit, these randomized solutions must appear as the ray solutions. Optical fibers are generally characterized by their numerical aperture (NA), as well as the number which characterizes its transverse dimension. The numerical aperture is essentially the sine of the maximum angle into which the guide will radiate into free space. When the guide is multimoded, then the transverse dimension is generally given as a diameter. When a guide is single-moded, the transverse dimension is generally given as a spotsize, that is, by a measure of the size of a unity magnification image of the fiber endface. Multimode guides can be excited by even poorly coherent sources so long as they radiate into the NA or capture angle at the input of the guide. Single-mode fibers require an excitation which matches the shape and size of their fundamental mode.

Active Fiber Compatible Components

Our discussion of propagation in fiber optic waveguides would be a rather sterile one if there were not a number of fiber compatible components that can generate, amplify, and detect light streams available to us in order to construct fiber optic systems. In this section, we will try to discuss some of the theory of operation of active optical components in order to help elucidate some of the general characteristics of such components and the conditions that inclusion of such components in a fiber system impose on the form that the system must take.

In a passive component such as an optical fiber, we need only consider the characteristics of the light that is guided. Operation of active components requires that the optical fields interact with a medium in such a manner that energy can be transferred from the field through an excitation of the medium to the controlling electrical stream and/or vice versa. Generally one wants the exchange to go only one way, that is from field to electrical stream or from electrical stream to field. In a detector this is not difficult to achieve, whereas in lasers and amplifiers it is quite hard to eliminate the back reaction of the field on the device. Whereas a guiding medium can be considered as a passive homogeneous continuum, the active medium has internal degrees of freedom of its own as well as a granularity associated with the distribution of the microscopic active elements. At least, we must consider the active medium as having an active index of refraction with a mind (set of differential equations anyway) of its own. If one also wants to consider noise characteristics, one needs to consider the lattice of active elements which convert the energy. The wavelength of operation of that active medium is determined by the energy spacing between the upper and lower levels of a transition which is determined by the microscopic structure of these grains, or quanta, that make up the medium. In a semiconductor, we consider these active elements to be so uniformly distributed and ideally spaced that we can consider the quanta (electron hole pairs) to be delocalized but numerous and labeled by their momentum vectors. In atomic media such as the rare earth doped optical fibers which serve as optical amplifiers, we must consider the individual atoms as the players. In the case of the semiconductor, a current, flowing in an external circuit, controls the population of the upper (electronic) and lower (hole) levels of each given momentum state within the semiconductor. When the momentum states are highly populated with electrons and holes, there is a flow of energy to the field (at the transition wavelength) and when the states are depopulated, the field will tend to be absorbed and populate the momentum states by giving up its energy to the medium. The situation is similar with the atomic medium except that the pump is generally optical (rather than electrical) and at a different wavelength than the wavelength of the field to be amplified. That is to say, one needs to use a minimum of three levels of the localized atoms in the medium in order to carry out an amplification scheme.

The composition of a semiconductor determines its bandgap, that is, the minimum energy difference between the electron and hole states of a given momentum value. A source, be it a light emitting diode (LED) or laser diode (see **Figure 4**) will emit light at a wavelength which corresponds to an energy slightly above the minimum gap energy (wavelength equals the velocity of light times Planck's constant divided by energy) whereas a detector can detect almost any energy above the bandedge. Only semiconductors with bandgaps which exhibit a minimum energy at a zero momentum transfer can be made to emit light strongly. Silicon does not exhibit a direct gap and although it can be used as a detector, it cannot be used as a source material. The silicon laser is and has been the 'Holy Grail' of electronics because of the ubiquity of silicon electronics. To even believe that a 'Holy Grail' exists requires a leap of faith. Weak luminescence has been

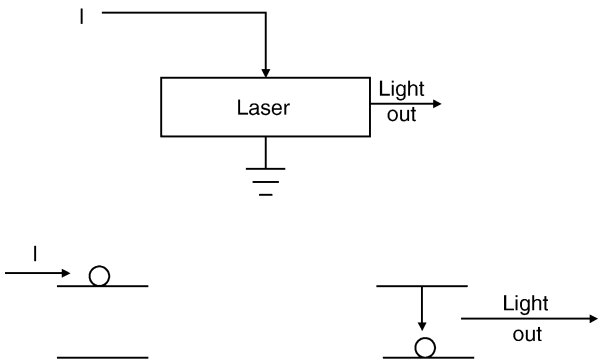

Figure 4 A schematic depiction of the workings of a semiconductor laser light source. The source is fabricated as a diode, and normal operation of this diode is in forward bias, that is, the p-side of the junction is biased positively with respect to ground which is attached to the n-side of the junction. With the p-side positively biased, current should freely flow through the junction. This is not quite true as there is a heterojunction region between the p- and n-regions in which electrons from the n-side may recombine with holes from the p-side. This recombination gives off a photon which is radiated. In light emitting diodes (LEDs), the photon simply leaves the light source as a spontaneously emitted photon. In a laser diode, the heterojunction layer serves as a waveguide and the endfaces of the laser as mirrors to provide feedback and allow laser operation in which the majority of the photons generated are generated in stimulated processes.

observed in certain silicon structures. This luminescence has been used for mid-infrared sources (where thermal effects mask strong luminescence) and in concert with rare earth dopants to make visible light emitting diodes. The silicon laser is still only a vision.

Source materials are, therefore, all made of compound semiconductors. Detectors are in essence the inverse of sources (see Figure 5) but also must detect at wavelengths above their gap energy. For primarily historical reasons, as will be further discussed below, telecommunications employs essentially three windows of wavelengths for different applications, wavelengths centered about 0.85 microns in the first window, wavelengths about 1.3 microns in the second window, and wavelengths about 1.55 microns in the third window. Materials made of layers of different compositions of AlGaAs and mounted on GaAs substrates are used in the first band, while the other bands require the increased degree of freedom allowed by the quaternary alloys of InGaAsP mounted on InP substrates. Other material mixes are possible, these above-mentioned materials are the most common. Rare earth ions exhibit many different transitions. The most useful ones have proven to be the transitions of Er in the third telecommunications window, the one that covers the spectral region to either side of 1.55 microns. Although both Nd and Pr can be made to amplify near the 1.3 micron window, amplifiers made of these materials have not proven to be especially practical.

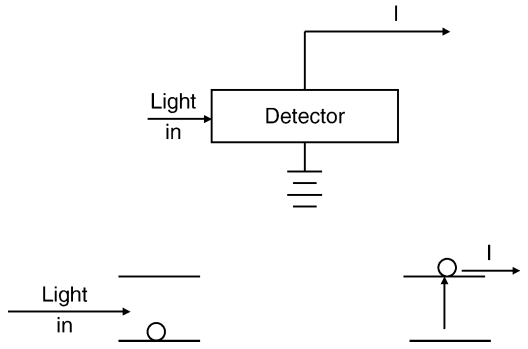

Figure 5 A schematic depiction of the workings of a semiconductor detector. As with a semiconductor source, the detector is fabricated to operate as a diode, that is a p-n junction, but in the case of the detector this diode is to be operated only in reverse bias, that is, with the n-material being biased positively with respect to the ground which is attached to the p-material's contact. In this mode of operation, no current should flow through the junction as there are no free carriers in the material, they have all been drawn out through the contacts. A photon of sufficiently high energy can change this situation by forming an electron hole pair in the material. The electron and hole are thereafter drawn to the n- and p-contacts, respectively, causing a detectable current to flow in the external circuit.

Telecommunications Technology

The physical transmission layer of the worldwide telecommunications network has come to be dominated by fiber optic technology, in particular, by wavelength division multiplexed or WDM single-mode fiber optics operating in the 1.55 micron telecommunications window. In the following, we will first discuss how this transformation to optical communications took place and then go on to discuss some of the specifics of the technology.

Already by the middle of the 1960s, it was clear that changes were going to have to take place in order that the exponential growth of the telephone system in the United States, as well as in Europe, could continue. The telephone system then, pretty much as now, consisted of a hierarchy of tree structures connected by progressively longer lines. A local office is used to connect a number of lines emanating in a tree structure to local users. The local offices are connected by trunk lines which emanate from a toll office. The lines from there on up the hierarchy are long distance ones which are termed long lines and can be regional and longer. The most pressing problem in the late 1960s was congestion in the so-called trunk lines which connect the local switching offices. The congestion was naturally most severe in urban areas. These trunk lines were generally one kilometer in length at that time. The problem was that there was no more space in the ducts that housed these lines. A solution was to use time division multiplexing or TDM to increase the traffic that could be carried by each of the lines already buried in the conduit. The problem was that the twisted pair lines employed would smear out the edges of the time varying bit streams carrying the information at the higher bitrates (aggregated rates due to the multiplexing) due to the inherent dependence of signal propagation velocity on frequency known as dispersion. After discussion and even development of a number of possible technologies, in 1975 a demonstration of a fiber optic system which employed multimode semiconductor lasers feeding multimode optical fibers all operating at 0.85 micron wavelength, proved to be the most viable model for trunk line replacement. The technology was successful and already in 1980 advances in single-mode laser and single-mode fiber technology operating at the 1.3 micron wavelength had made the inclusion of fiber into the long lines viable as well. For roughly the decade from 1985 onward, single-mode fiber systems dominated long line replacement for terrestrial as well as transoceanic links. The erbium doped fiber amplifier which operated in the 1.55 micron wavelength third telecommunication window had proven

itself to be viable for extending repeater periods by around 1990. Development of the InGaAsP quaternary semiconductor system allowed for reliable lasers to be manufactured for this window as development of strained lattice laser technology in the InGaAs system allowed for efficient pump lasers for the fiber amplifiers. As the optical amplifiers could amplify across the wavelength band that could be occupied by many aggregated channels of TDM signals, the move of the long line systems to the third telecommunications window was accompanied by the adoption of wavelength division multiplexing or WDM. That is, electronics becomes more expensive as the analog bandwidth it can handle increases. Cost-effective digital rates are now limited to a few Gb/s, and analog rates to perhaps 20 GHz. Optical center frequencies are in the order of 2×10^{14} Hz and purely optical filters can be made to cleanly separate information signals spaced as closely as 100 GHz apart on optical carriers. An optical carrier can then be made to carry hundreds of channels of 10 Gb/s separated by 100 GHz and this signal can be propagated thousands of kilometers through the terrestrial fiber optics network. Such is today's Worldwide Web.

Integrated Optics as a Future of Guided Wave Optics

As electronics has been pushed to ever greater levels of integration, its power has increased and its price has dropped. A goal implicit in much of the development of planar waveguide technology has been that optics could become an integrated technology in the same sense as electronics. This has not occurred and probably will not occur. This is not to say that integrated optical processing circuits are not being developed and that they will be not employed in the future. They most definitely will.

Integrated optics was coined as a term when it was used in 1969 to name a new program at Bell Laboratories. This program was aimed at investigation of all the technologies that were possible with which to fabricate optical integrated circuits. The original effort was in no way driven by fiber optics as the Bell System only reluctantly moved to a fiber optic network solution in 1975. The original integrated optics efforts were based on such technologies as the inorganic crystal technologies that allowed for large second-order optical nonlinearities, a necessity in order that a crystal also exhibits a large electro-optic coefficient. An electro-optic coefficient allows one to change the index of refraction of a crystal by applying a low frequency or DC electromagnetic field across the crystal.

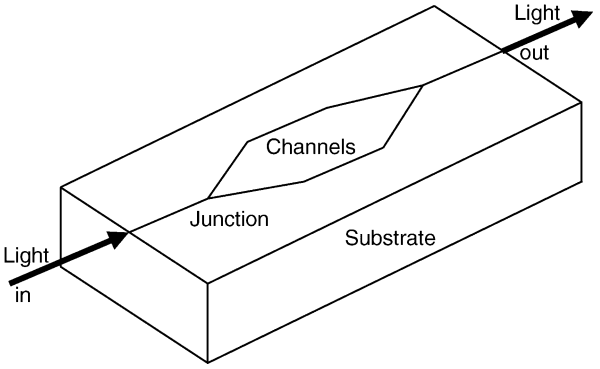

Figure 6 A schematic depiction of an integrated optical device which is often used as a high speed modulator. The device is an integrated version of a Mach–Zehnder interferometer. The basic idea behind its operation is that spatially and temporally coherent light is input into a single mode optical channel. That channel is then split into two channels by a Y-junction. Although not depicted in the figure, the two arms should not have completely equivalent propagation paths. That is to say, that if the light in one of those paths propagates a slightly longer distance (as measured in terms of phase fronts of the wave) then one cannot recombine the power from the two arms. That is, in the second Y-junction, a certain amount of the light which we are trying to combine from the two arms will be radiated out from the junction. In fact, if the light were temporally incoherent (phase fronts not well defined), exactly half of the light would be radiated form the junction. This is a statement of the brightness theorem which was thought to be a law of propagation before there were coherent sources of light. In a high speed modulator, the substrate is an electro-optic crystal and electrodes are placed over the two arms which apply the electrical signal to be impressed on the optical carrier to the channels.

Lithium niobate technology is a technology that has lasted to the present as an optical modulator technology (see **Figure 6**) and an optical switch technology (see **Figure 7**), as well as a technology for parametric wavelength conversion. Unfortunately, although low loss passive waveguide can be fabricated in lithium niobate, the crystal is not amenable to any degree of monolithic integration. Glass was also investigated as an integration technology from the early days of integrated optics, but the lack of second-order nonlinearity in glass strictly limited its applicability. Attention for a period turned to monolithic integration in the semiconductor materials which were well progressing as for use as lasers, detectors, and integrated circuits. Semiconductor crystals, however, are too pure to allow for low loss light propagation which requires the material defects to be so numerous that optical wavelengths cannot sample them. Passive waveguides in semiconductors incur huge losses that can only be mitigated by almost constant optical amplification which, unfortunately, cannot track the rapid optical field variations necessary for information transfer. Early on, attention turned to silicon

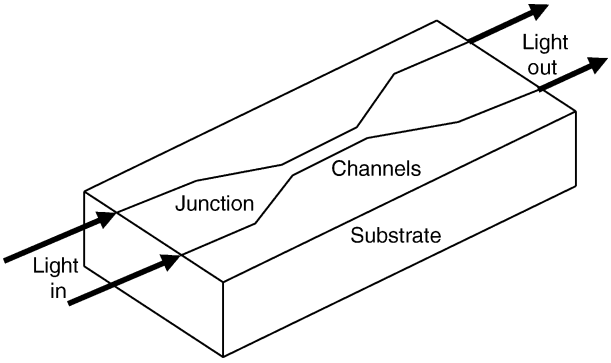

Figure 7 A schematic depiction of an integrated optical device which is often used as an optical switch. This device is interferometric but really has no free space optics counterpart as the Mach–Zhender interferometer does. In this interferometer, spatially and temporally coherent light is input into a single mode input channel. The two single optical mode input channels, which are initially so far apart from each other in terms of their mode sizes that they are effectively uncoupled, are then brought ever closer together until they are strongly coupled and their modes are no longer confined to their separate waveguides but are shared between the two channels. As the channels are symmetric, but the initial excitation, if from a single waveguide alone, is not, the pattern must evolve with propagation. Were both input channels excited, symmetry would still require a symmetry of their phases. If the phases were either equal to each other or completely out of phase, then there would be no evolution because we would have excited coupler modes. If the coupled region is the proper length, light input to one channel will emerge from the other after the channels are pulled apart. If the substrate is an electro-optic crystal and electrodes are placed over the channels, application of a voltage can affect the evolution of the interference in such a manner so as to 'decouple' the channels and switch the light back to the original channel.

optical bench technology, a technology which has presently spawned micro-electro-mechanical-system (MEMs) technology and still persists as an expensive vehicle to hybrid electro-optical integration. In silicon bench, individual components are micro-mounted with solder or silicon pop-up pieces on a silicon wafer which serves as a micro-optical bench. The technology is expensive and hybrid but pervasive in the highest end of cost classes of optical systems.

The tremendous success of the fiber optical network spawned a movement in which groups tried to achieve every possible system functionality in fibers themselves. A notable success has been the optical fiber amplifier. Significantly less successful in the fiber optic network has been the fiber Bragg grating. Attempts to carry out WDM functionalities in all fiber configuration leads to unwieldy configurations requiring large amounts of fiber and significant propagation delays, although, Bragg grating sensors have proven to be somewhat useful in sensing applications. WDM functions have been implemented in a large number of different hybrid configurations, involving various types of glasses, fused silica on silicon and simple hybrids of birefringent crystals.

The telecommunications network is not the driver that it once was. That this is so is perhaps the strongest driving force yet for integrated optics. The driver now is new applications that must be implemented in the most efficient manner. The most efficient manner is quite generally the one in which there is a maximum degree of integration. In the long run, polymer has always been the winning technology for optics of any kind, due to the flexibility of the technology and the drop in cost that accompanies mass production. Indeed, polymer integrated optics progresses. There are also a number of researchers involved in investigating strongly guiding optics, so-called photonic crystal optics. That is, in order to achieve low loss as well as low cost, the fiber and integrated optic waveguides up to the present have used small variations in optical properties of material to achieve guidance at the cost of having structures that are many wavelengths in size. In radio frequency (RF) and microwave technology, for example, guides are tiny fractions of a wavelength. This can lead to an impedance matching problem. RF and microwave impedance matching costs (versus circuit impedance matching costs) are generally quite high, precluding mass application. That radio frequency systems, such as cell phone transceivers link to the rest of the world by antenna, allows that the overall circuit dimension can be kept less than a single wavelength and impedance matching can be foregone in this so-called circuit limit. It is usually hard to keep an overall microwave system to less than a wavelength in overall extent except in the cell phone case or in a microwave oven. Optical miniaturization will require high index contrast guides, and will require optical impedance matching. There are few complete optical systems which will comprise less than an optical wavelength in overall extent. But then this so-called photonic crystal technology will likely be polymer compatible and there may be ways to find significant cost reduction. The future of integrated optics is unclear but bright.

Dispersion

L Thévenaz, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Dispersion designates the property of a medium to propagate the different spectral components of a wave with a different velocity. It may originate from the natural dependence of the refractive index of a dense material to the wavelength of light, and one of the most evident and magnificent manifestations of dispersion is the appearance of a rainbow in the sky. In this case dispersion gives rise to a different refraction angle for the different spectral components of the white light, resulting in an angular dispersion of the sunlight spectrum and explicating the etymology of the term dispersion. Despite this spectacular effect, dispersion is mostly seen as an impairment in many applications, in particular for optical signal transmission. In this case, dispersion causes a rearrangement of the signal spectral components in the time domain, resulting in temporal spreading of the information and eventually in severe distortion.

There is a trend to designate all phenomena resulting in a temporal spreading of information as a type of dispersion, namely the polarization dispersion in optical fibers that should be properly named as polarization mode delay (PMD). In this article chromatic dispersion will be solely addressed, that designates the dependence of the propagation velocity on wavelength and that corresponds to the strict etymology of the term.

Effect of Dispersion on an Optical Signal

An optical signal may always be considered as a sum of monochromatic waves through a normal Fourier expansion. Each of these Fourier components propagates with a different phase velocity if the optical medium is dispersive, since the refractive index n depends on the optical frequency ν. This phenomenon is linear and causal and gives rise to a signal distortion that may be properly described by a transfer function in the frequency domain.

Let $n(\nu)$ be the frequency-dependent refractive index of the propagation medium. When the optical wave propagates in a waveguiding structure the effective wavenumber is properly described by a propagation constant β, that reads:

$$\beta(\nu) = \frac{2\pi\nu}{c_0} n(\nu) \qquad [1]$$

where c_0 is the vacuum light velocity. The propagation constant corresponds to an eigenvalue of the wave equation in the guiding structure and normally takes a different value for each solution or propagation mode. For free-space propagation this constant is simply equal to the wavenumber of the corresponding plane wave.

The complex electrical field $E(z,t)$ of a signal propagating in the z direction may be properly described by the following expression:

$$E(z,t) = A(z,t)\, \mathrm{e}^{\mathrm{i}(2\pi\nu_0 t - \beta_0 z)}$$
$$\text{with} \quad \nu_0\text{: the central optical frequency}$$
$$\text{and} \quad \beta_0 = \beta(\nu_0) \qquad [2]$$

where $A(z,t)$ represents the complex envelope of the signal, supposed to be slowly varying compared to the carrier term oscillating with the frequency ν_0. Consequently, the signal will spread over a narrow band around the central frequency ν_0 and the propagation constant β can be conveniently approximated by a limited expansion to the second order:

$$\beta(\nu) = \beta_0 + \left.\frac{\mathrm{d}\beta}{\mathrm{d}\nu}\right|_{\nu=\nu_0} (\nu - \nu_0) + \left.\frac{\mathrm{d}^2\beta}{\mathrm{d}\nu^2}\right|_{\nu=\nu_0} (\nu - \nu_0)^2 \qquad [3]$$

For a known signal $A(0,t)$ at the input of the propagation medium, the problem consists in

determining the signal envelope $A(z,t)$ after propagation over a distance z. The linearity and the causality of the system make possible a description using a transfer function $H_z(\nu)$ such as:

$$\tilde{A}(z,\nu) = H_z(\nu)\,\tilde{A}(0,\nu) \qquad [4]$$

where $\tilde{A}(z,\nu)$ is the Fourier transform of $A(z,t)$.

To make the transfer function $H_z(\nu)$ explicit, let us assume that the signal corresponds to an arbitrary harmonic function:

$$A(0,t) = A_0\,\mathrm{e}^{\mathrm{i}2\pi ft} \qquad [5]$$

Since this function is arbitrary and the signal may always be expanded as a sum of harmonic functions through a Fourier expansion, there is no loss of generality. The envelope identified as a harmonic function actually corresponds to a monochromatic wave of optical frequency $\nu = \nu_0 + f$ as defined by eqn [2]. Such a monochromatic wave will experience the following phase shift through propagation:

$$\begin{aligned} E(z,t) &= A_0\,\mathrm{e}^{\mathrm{i}[2\pi(\nu_0+f)t-\beta(\nu_0+f)z]} \\ &= A_0\,\mathrm{e}^{\mathrm{i}2\pi ft}\mathrm{e}^{\mathrm{i}[2\pi\nu_0 t-\beta(\nu_0+f)z]} \end{aligned} \qquad [6]$$

On the other hand, an equivalent expression may be found using the linear system described by eqns [2] and [4]:

$$\begin{aligned} E(z,t) &= A(z,t)\,\mathrm{e}^{\mathrm{i}(2\pi\nu_0 t-\beta_0 z)} \\ &= A_z\,\mathrm{e}^{\mathrm{i}2\pi ft}\,\mathrm{e}^{\mathrm{i}(2\pi\nu_0 t-\beta_0 z)} \end{aligned} \qquad [7]$$

Since eqns [6] and [7] must represent the same quantities and using the definition in eqn [4], a simple comparison shows that the transfer function must take the following form:

$$H_z(\nu) = \mathrm{e}^{-\mathrm{i}[\beta(\nu)z-\beta_0 z]} \qquad [8]$$

The transfer function takes a more analytical form using the approximation in eqn [3]:

$$H_z(\nu) = \mathrm{e}^{-\mathrm{i}2\pi(\nu-\nu_0)\tau_\mathrm{D}}\,\mathrm{e}^{-\mathrm{i}\pi D_\nu(\nu-\nu_0)^2 z} \qquad [9]$$

In the transfer function interpretation the first term represents a delay term. It means that the signal is delayed after propagation by the quantity:

$$\tau_\mathrm{D} = \frac{1}{2\pi}\frac{\mathrm{d}\beta}{\mathrm{d}\nu_0}z = \frac{z}{V_\mathrm{g}} \qquad [10]$$

where V_g represents the signal group velocity. This term therefore brings no distortion for the signal and thus states that the signal is replicated at the distance z with a delay τ_D.

The second term is the distortion term which is similar in form to a diffusion process and normally results in time spreading of the signal. In the case of a light pulse it will gradually broaden while propagating along the fiber, like a hot spot on a plate gradually spreading as a result of heat diffusion. The effect of this distortion is proportional to the distance z and to the coefficient D_ν, named group velocity dispersion (GVD):

$$D_\nu = \frac{1}{2\pi}\frac{\mathrm{d}^2\beta}{\mathrm{d}\nu^2} = \frac{\mathrm{d}}{\mathrm{d}\nu}\left(\frac{1}{V_\mathrm{g}}\right) \qquad [11]$$

It is important to point out that the GVD may be either positive (normal) or negative (anomalous) and the distortion term in the transfer function in eqn [9] may be exactly cancelled by propagating in a medium with D_ν of opposite sign. It means that the distortion resulting from chromatic dispersion is reversible and this is widely used in optical links through the insertion of dispersion compensators. These are elements made of specially designed fibers or fiber Bragg gratings showing an enhanced GVD coefficient, with a sign opposite to the GVD in the fiber.

From the transfer function in eqn [9] it is possible to calculate the impulse response of the dispersive medium:

$$h_z(t) = \frac{1}{\sqrt{i|D_\nu|z}}\mathrm{e}^{\mathrm{i}\pi\frac{(t-\tau_\mathrm{D})^2}{D_\nu z}} \qquad [12]$$

so that the distortion of the signal may be calculated by a simple convolution of the impulse response with the signal envelope in the time domain.

The effect of dispersion on the signal can be more easily interpreted by evaluating the dispersive propagation of a Gaussian pulse. In this particular case the calculation of the resulting envelope can be carried out analytically. If the signal envelope takes the following Gaussian distribution at the origin:

$$A(0,t) = A_0\,\mathrm{e}^{-\frac{t^2}{\tau_0^2}} \qquad [13]$$

with τ_0 the $1/e$ half-width of the pulse, the envelope at distance z is obtained by convoluting the initial envelope with the impulse response $h_z(t)$:

$$\begin{aligned} A(z,t) &= h_z(t) \otimes A(0,t) \\ &= A_0\sqrt{\frac{\mathrm{i}z_0}{z+\mathrm{i}z_0}}\mathrm{e}^{\mathrm{i}\pi\frac{(t-\tau_\mathrm{D})^2}{D_\nu(z+\mathrm{i}z_0)}} \end{aligned} \qquad [14]$$

where

$$z_0 = -\frac{\pi\tau_0^2}{D_\nu} \qquad [15]$$

represents the typical dispersion length, that is the distance necessary to make the dispersion effect noticeable.

The actual pulse spreading resulting from dispersion can be evaluated by calculating the intensity of the envelope at distance z:

$$|A(z,t)|^2 = A_0 \frac{\tau_0}{\tau(z)} e^{-\frac{2(t-\tau_D)^2}{\tau^2(z)}} \qquad [16]$$

that is still a Gaussian distribution centered about the propagation delay time τ_D, with $1/e^2$ half-width:

$$\tau(z) = \tau_0\sqrt{1+(z/z_0)^2} \qquad [17]$$

The variation of the pulse width $\tau(z)$ is presented in Figure 1 and clearly shows that the pulse spreading starts to be nonnegligible from the distance $z = z_0$. This gives a physical interpretation for the dispersion length z_0. It must be pointed out that there is a direct formal similarity between the pulse broadening of a Gaussian pulse in a dispersive medium and the spreading of a free-space Gaussian beam as a result of diffraction. Asymptotically for distances $z \gg z_0$, the pulsewidth increases linearly:

$$\tau(z) \simeq |D_\nu| \frac{z}{\pi\tau_0} \qquad [18]$$

It must be pointed out that the width increases proportionally to the dispersion D_ν, but also inversely proportionally to the initial width τ_0. This results from the larger spectral width corresponding to a narrower pulsewidth, giving rise to a stronger dispersive effect.

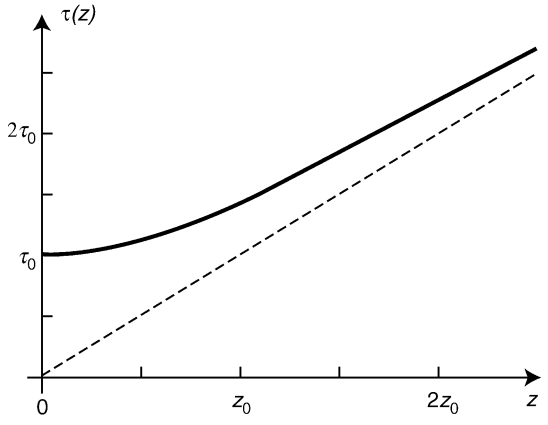

Figure 1 Variation of the $1/e^2$ half-width of a Gaussian pulse, showing the pulse spreading effect of dispersion. The dashed line shows the asymptotic linear spreading for large propagation distance.

The chromatic dispersion does not modify the spectrum of the transmitted light, as any linear effect. This can be straightforwardly demonstrated by evaluating the intensity spectrum of the signal envelope at any distance z, using the eqns [4] and [8]:

$$|\tilde{A}(z,\nu)|^2 = |H_z(\nu)\tilde{A}(0,\nu)|^2 = |e^{-i[\beta(\nu)z-\beta_0 z]}|^2|\tilde{A}(0,\nu)|^2 = |\tilde{A}(0,\nu)|^2 \qquad [19]$$

It means that the pulse characteristics in the time and frequency domains are no longer Fourier-transform limited, since after the broadening due to dispersion, the spectrum should normally spread over a narrower spectral width. This feature results from a re-arrangement of the spectral components within the pulse. This can be highlighted by evaluating the distribution of instantaneous frequency through the pulse. The instantaneous frequency ω_i is defined as the time-derivative of the wave phase factor $\phi(t)$ and is uniformly equal to the optical carrier pulsation $\omega_i = 2\pi\nu_0$ for the initial pulse, as can be deduced from the phase factor at $z = 0$ by combining eqns [2] and [13]. This constant instantaneous frequency means that all spectral components are uniformly present within the pulse at the origin.

After propagation through the dispersive medium the phase factor $\phi(t)$ can be evaluated by combining eqns [2] and [14] and evaluating the argument of the resulting expression. The instantaneous frequency ω_i is obtained after a simple time derivative of $\phi(t)$ and reads:

$$\omega_i(t) = \omega_0 + \frac{2\pi z}{D_\nu(z^2+z_0^2)}(t-\tau_D) \qquad [20]$$

For $z > 0$ the instantaneous frequency varies linearly over the pulse, giving rise to a frequency chirp. The frequency components are re-arranged in the pulse, so that the lower frequency components are in the leading edge of the pulse for a normal dispersion $D_\nu > 0$ and the higher frequencies in the trailing edge. For an anomalous dispersion $D_\nu < 0$, the arrangement is opposite, as can be seen in Figure 2. The effect of this frequency chirp can be visualized in Figure 3, showing that the effect of dispersion is equivalent to a frequency modulation over the pulse. The chirp is maximal at position z_0 and the pulsewidth takes its minimal value τ_0 when the chirp is zero. It is evident with this description that the pulse broadening may be entirely compensated through propagation in a medium of opposite

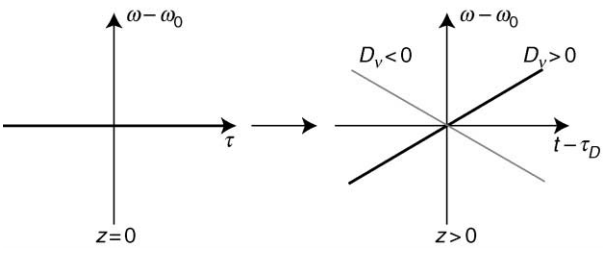

Figure 2 Distribution of the instantaneous frequency through a Gaussian pulse. At the origin the distribution is uniform (left) and the dispersion induces a frequency chirp that depends on the sign of the GVD coefficient D_ν.

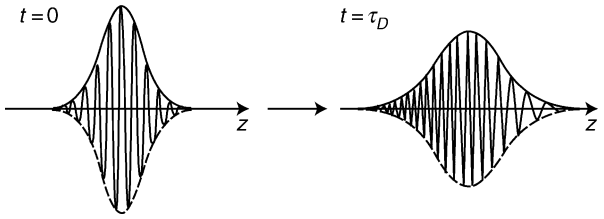

Figure 3 The dispersion results in a pulse broadening together with a frequency chirp, here for a normal GVD, that can be seen like a frequency modulation.

group velocity dispersion; this is equivalent to reversing the time direction in Figure 3. Moreover a pre-chirped pulse can be compressed to its Fourier-transform limited value after propagation in a medium with the proper dispersion sign. This feature is widely used for pulse compression after pre-chirping through propagation in a medium subject to optical Kerr effect.

The above description of the propagation of a Gaussian pulse implicitly states that the light source is perfectly coherent. In the early stages of optical communications it was not at all the case, since most sources were either light emitting diodes or multi-mode lasers. In this case the spectral extent of the signal was much larger than actually required for the strict need of modulation. Each spectral component may thus be considered as independently propagating the signal and the total optical wave can be identified to light merged from discrete sources emitting simultaneously the same signal at a different optical frequency. The group velocity dispersion will cause a delay $\delta\tau$ between different spectral components separated by a frequency interval $\delta\nu$ that can be simply evaluated by a first-order approximation:

$$\delta\tau = \frac{\mathrm{d}\tau_\mathrm{D}}{\mathrm{d}\nu}\delta\nu = \frac{\mathrm{d}}{\mathrm{d}\nu}\left(\frac{z}{V_\mathrm{g}}\right)\delta\nu = D_\nu z\delta\nu \qquad [21]$$

where eqns [10] and [11] have been used. The delay $\delta\tau$ is thus proportional to the GVD coefficient D_ν, to the propagation distance z and the frequency separation $\delta\nu$. This description can be extended to a continuous frequency distribution with a spectral width σ_ν, resulting to the following temporal broadening σ_τ:

$$\sigma_\tau = |D_\nu|\sigma_\nu z \qquad [22]$$

Traditionally the spectral characteristics of a source are given in units of wavelength and the GVD coefficient is expressed in optical fibers accordingly. Following the same description as above, the temporal broadening σ_τ, for a spectral width σ_λ in wavelength units, reads:

$$\sigma_\tau = |D_\lambda|\sigma_\lambda z \qquad [23]$$

Since equal spectral widths must give equal broadening the value of the GVD in units of wavelength can be deduced from the natural definition in frequency units:

$$D_\lambda = \frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{1}{V_\mathrm{g}}\right) = \frac{\mathrm{d}}{\mathrm{d}\nu}\left(\frac{1}{V_\mathrm{g}}\right)\frac{\mathrm{d}\nu}{\mathrm{d}\lambda} = -\frac{c_0}{\lambda^2}D_\nu \qquad [24]$$

It must be pointed out that the coefficient D_λ takes a sign opposite to D_ν; in other words, a normal dispersion corresponds to a negative GVD coefficient D_λ. It is usually expressed in units of picoseconds of temporal broadening, per nanometer of spectral width and per kilometer of propagating distance, or ps/nm km. For example, a pulse showing a spectral width of 1 nm propagating through a 100 km fiber having a dispersion D_λ of $+10$ ps/nm km, will experience, according to eqn [23], a pulse broadening σ_τ of $10 \times 1 \times 100 = 1000$ ps or 1 ns.

Material Group Velocity Dispersion

Any dense material shows a variation of its index of refraction n as a function of the optical frequency ν. This natural property is called material dispersion and is the dominant contribution in weakly guiding structures such as standard optical fibers. This natural dependence results from the noninstantaneous response of the medium to the presence of the electric field of the optical wave. In other words, the polarization field $P(t)$ corresponding to the material response will vary with some delay or inertia to the change of the incident electric field $E(t)$. This delay between cause and effect generates a memory-type response of the medium that may be described using a time-dependent medium susceptibility $\chi(t)$. The relation between medium polarization at time t and incident field results from the weighted superposition

of the effects of $E(t')$ at all previous times $t' < t$. This takes the form of the following convolution:

$$P(t) = \varepsilon_0 \int_{-\infty}^{+\infty} \chi(t - t')E(t')\mathrm{d}t' \qquad [25]$$

Through application of a simple Fourier transform this relation reads in the frequency domain as:

$$P(\nu) = \varepsilon_0 \chi(\nu)E(\nu) \qquad [26]$$

showing clearly that the noninstantaneous response of the medium results in a frequency-dependent refractive index using the standard relationship with the susceptibility χ:

$$n(\nu) = \sqrt{1 + \chi(\nu)} \quad \text{where} \quad \chi(\nu) = \mathrm{FT}\{\chi(t)\} \qquad [27]$$

This means that a beautiful natural phenomenon such as a rainbow, originates on a microscopic scale from the sluggishness of the medium molecules to react to the presence of light. For signal propagation, it results in a distortion of the signal and in most cases in a pulse spreading, but the microscopic causes are in essence identical. This noninstantaneous response is tightly related to the molecules' vibrations that also give rise to light absorption. For this reason it is convenient to express the propagation in an absorptive medium by adding an imaginary part to the susceptibility $\chi(\nu)$:

$$\chi(\nu) = \chi'(\nu) + \mathrm{i}\chi''(\nu) \qquad [28]$$

so that the refractive index $n(\nu)$ and the absorption coefficient $\alpha(\nu)$ reads in a weakly absorbing medium:

$$n(\nu) = \sqrt{1 + \chi'(\nu)}$$
$$\alpha(\nu) = -\frac{2\pi\chi''(\nu)}{\lambda n(\nu)} \qquad [29]$$

Since the response of the medium, given by the time-dependent susceptibility $\chi(t)$ in eqn [25], is real and causal, the real and imaginary part of the susceptibility in eqn [28] are not entirely independent and are related by the famous Kramers–Kronig relations:

$$\chi'(\nu) = \frac{2}{\pi}\int_0^{\infty} \frac{s\chi''(\nu)}{s^2 - \nu^2}\mathrm{d}s$$
$$\chi''(\nu) = \frac{2}{\pi}\int_0^{\infty} \frac{\nu\chi'(\nu)}{\nu^2 - s^2}\mathrm{d}s \qquad [30]$$

Absorption and dispersion act in an interdependent way on the propagating optical wave and knowing either the absorption or the dispersion spectrum is theoretically sufficient to determine the entire optical response of the medium. The interdependence between absorption and dispersion is typically illustrated in Figure 4. The natural tendency is to observe a growing refractive index for increasing frequencies in low absorption regions. In this case, the dispersion is called normal and this is the most observed situation in transparency regions of a material, which obviously offer the largest interest for optical propagation. In an absorption line the tendency is opposite, a diminishing index for increasing wavelength, and such a response is called anomalous dispersion. The dispersion considered here is the phase velocity dispersion, represented by the slope of $n(\nu)$, that must not be mistaken with the group velocity dispersion (GVD) that only matters for signal distortion. The difference between these two quantities is clarified below.

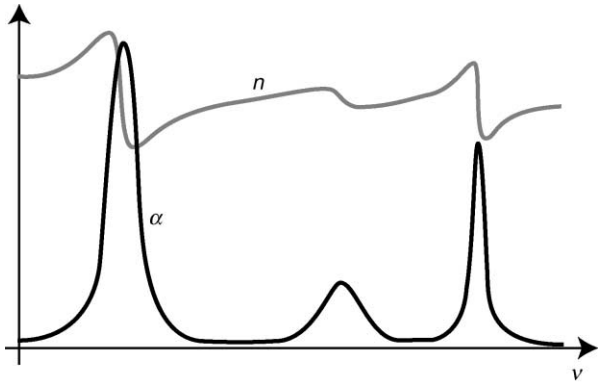

Figure 4 Typical optical response of a transparent medium, showing the spectral interdependence between the absorption coefficient α and the index of refraction n.

To demonstrate that a frequency-dependent refractive index $n(\nu)$ gives rise to a group velocity dispersion and thus a signal distortion we use eqns [1] and [10], so the group velocity V_g can be expressed:

$$V_g = \frac{c_0}{N} \quad \text{with} \quad N = n + \nu\frac{\mathrm{d}n}{\mathrm{d}\nu} = n - \lambda\frac{\mathrm{d}n}{\mathrm{d}\lambda} \qquad [31]$$

N is called group velocity index and differs from the phase refractive index n only if n shows a spectral dependence. In a region of normal dispersion ($\mathrm{d}n/\mathrm{d}\nu > 0$, the group index is larger than the phase index and this is the situation observed in the great majority of transparent materials. From eqn [31] and using eqn [24] the GVD coefficient D_λ can be expressed as a function of the refractive index $n(\lambda)$:

$$D_\lambda = \frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{1}{V_g}\right) = \frac{\mathrm{d}}{\mathrm{d}\lambda}\left(\frac{N}{c_0}\right) = -\frac{\lambda}{c_0}\frac{\mathrm{d}^2 n}{\mathrm{d}\lambda^2} \qquad [32]$$

The GVD coefficient is proportional to the second derivative of the refractive index n with respect to

wavelength and is therefore minimal close to a point of inflexion of $n(\lambda)$. As can be seen in Figure 4 such a point of inflexion is always present where absorption is minimal, at the largest spectral distance from two absorption lines. It means that the conditions of low-group velocity dispersion and high transparency are normally fulfilled in the same spectral region of an optical dielectric material. In this region the phase velocity dispersion is normal at any wavelength, but the group velocity is first normal for shorter wavelengths, then is zero at a definite wavelength corresponding to the point of inflexion of $n(\lambda)$, and finally becomes anomalous for longer wavelengths. The situation in which normal phase dispersion and anomalous group dispersion are observed simultaneously is in no way exceptional.

In pure silica the zero GVD wavelength is at 1273 nm, but is subject to be moderately shifted to larger wavelengths in optical fibers, as a result of the presence of doping species to raise the index in the fiber guiding core. This shift normally never exceeds 10 nm using standard dopings; larger shifts are observed resulting from waveguide dispersion and this aspect will be addressed in the next section. The zero GVD wavelength does not strictly correspond to the minimum attenuation in silica fibers, because the dominant source of loss is Rayleigh scattering in this spectral region and not molecular absorption. This scattering results from fluctuations of the medium density as observed in any amorphous materials such as vitreous silica and is therefore a collective effect of many molecules that does not impinge on the microscopic susceptibility $\chi(t)$. It has therefore no influence on the material dispersion characteristics and this explains the reason for the minimal attenuation wavelength at 1550 nm, mismatching and quite distant from the zero material GVD at 1273 nm.

Material GVD in amorphous SiO_2 can be accurately described using a three-term Sellmeier expansion of the refractive index:

$$n(\lambda) = \sqrt{1 + \sum_{j=1}^{3} \frac{C_j \lambda^2}{\lambda^2 - \lambda_j^2}} \qquad [33]$$

and performing twice the wavelength derivative. The coefficients C_j and λ_j are found in most reference handbooks and result in the GVD spectrum shown in Figure 5. Such a spectrum explains the absence of interest for propagation in the visible region through optical fibers, the dispersion being very important in this spectral region. It also explains the large development of optical fibers in the 1300 nm region as a consequence of the minimal material dispersion there. It must be pointed out that it is quite easy to set

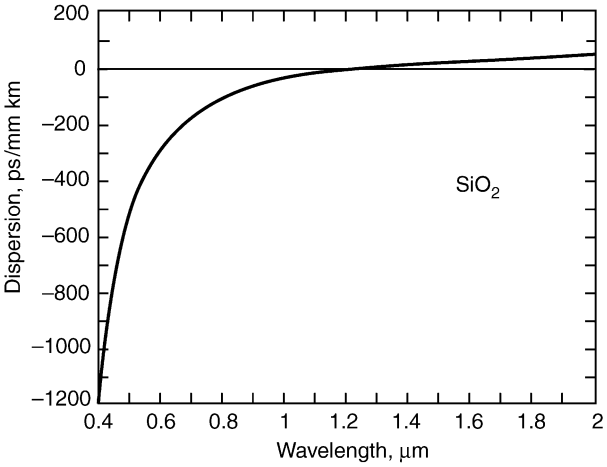

Figure 5 Material dispersion of pure silica. The visible region (0.4–0.7 μm) shows a strong normal GVD that decreases when moving into the infrared and eventually vanishes at 1273 nm. In the minimum attenuation window (1550 nm) the material GVD is anomalous.

up propagation in an anomalous GVD regime in optical fibers, since this regime is observed in the lowest attenuation spectral region. Anomalous dispersion makes possible interesting propagation features when combined with a third-order nonlinearity as the optical Kerr effect, namely soliton propagation and efficient spectral broadening through modulation instability.

Waveguide Group Velocity Dispersion

Solutions of the wave equation in an optical dielectric waveguide such as an optical fiber are discrete and limited. These solutions, called modes, are characterized by an unchanged field distribution along the waveguides and by a uniform propagation constant β over the wavefront. This last feature is particularly important if one recall that the field extends over regions presenting different refractive indices in a dielectric waveguide. For a given mode, the propagation constant β defines an effective refractive index n_{eff} for the propagation by similarity to eqn [1]:

$$\beta = \frac{2\pi\nu}{c_0} n_{\text{eff}} \qquad [34]$$

The value of this effective refractive index n_{eff} is always bound by the value of the core index n_1 and of the cladding index n_2, so that $n_2 < n_{\text{eff}} < n_1$. For a given mode, the propagation constant β, and so the effective refractive index n_{eff}, only depend on a quantity called normalized frequency V that essentially scales the light frequency to the waveguide

optical parameters:

$$V = \frac{2\pi}{\lambda} a \sqrt{n_1^2 - n_2^2} \qquad [35]$$

where a is the core radius. Figure 6 shows the dependence of the propagation constant β of the fundamental mode LP_{01} on the normalized frequency V. The variation is nonnegligible in the single-mode region and gives rise to a chromatic dispersion, since V depends on the wavelength λ, even in the fictitious case of dispersion-free refractive indices in the core and the cladding materials. This type of chromatic dispersion is called waveguide dispersion.

To find an expression for the waveguide dispersion in function of the guiding properties, let us define another normalized parameter, the normalized phase constant b, such as:

$$\beta = \frac{2\pi}{\lambda} \sqrt{n_2^2 + b(n_1^2 - n_2^2)} \qquad [36]$$

The parameter b takes values in the interval $0 < b < 1$, is equal to 0 when $n_{\text{eff}} = n_2$ at the mode cutoff, and is equal to 1 when $n_{\text{eff}} = n_1$. This latter situation is never observed and is only asymptotic for very large normalized frequencies V. Solving the wave equation provides the dispersion relation $b(V)$ and it is important to point out that this relation between normalized quantities depends only on the shape of the refractive index profile. Step-index, triangular or multiple-clad index profiles will result in different $b(V)$ relations, independently of the actual values of the refractive indices n_1 and n_2 and of the core radius a.

From the definitions in eqns [10] and [35] and in the fictitious case of an absence of material dispersion, the propagation delay per unit length reads:

$$\frac{1}{V_g} = \frac{1}{2\pi}\frac{d\beta}{d\nu} = \frac{1}{2\pi}\frac{d\beta}{dV}\frac{dV}{d\nu} = \frac{\lambda}{2\pi} V \frac{d\beta}{dV} \qquad [37]$$

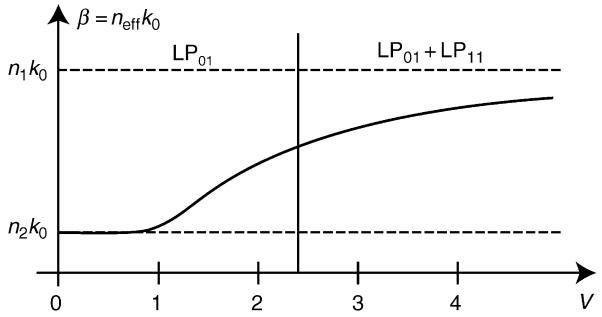

Figure 6 Propagation constant β as a function of the normalized frequency V in a step-index optical fiber. The single mode region is in the range $0 < V < 2.405$.

so that the waveguide group velocity dispersion can be expressed using the relation in eqn [24]:

$$D_\lambda^w = \frac{d}{d\lambda}\left(\frac{1}{V_g}\right) = \frac{d}{d\nu}\left(\frac{1}{V_g}\right)\frac{d\nu}{d\lambda}$$

$$= -\frac{\nu}{\lambda}\frac{d}{d\nu}\left(\frac{1}{V_g}\right) = -\frac{1}{2\pi c_0} V^2 \frac{d^2\beta}{dV^2} \qquad [38]$$

The calculation of the combined effect of material and waveguide dispersions results in very long expressions in which it is difficult to highlight the relative effect of each contribution. Nevertheless, by making the assumption of weak guidance:

$$\frac{n_1 - n_2}{n_2} \simeq \frac{N_1 - N_2}{N_2} \ll 1 \qquad [39]$$

where N_1 and N_2 are the group indices in the core and the cladding, respectively, defined in eqn [31], the complete expression can be drastically simplified to obtain for the delay per unit length:

$$\frac{1}{V_g} = \frac{1}{c_0}\left[N_2 + (N_1 - N_2)\frac{d(bV)}{dV}\right] \qquad [40]$$

and for the total dispersion:

$$D_\lambda = D_2 + (D_1 - D_2)\frac{d(bV)}{dV} - (N_1 - N_2)\frac{N_2}{n_1}\frac{1}{\lambda c_0} V \frac{d^2(bV)}{dV^2} \qquad [41]$$

where

$$D_1 = -\frac{\lambda}{c_0}\frac{d^2 n_1}{d\lambda^2} \quad \text{and} \quad D_2 = -\frac{\lambda}{c_0}\frac{d^2 n_2}{d\lambda^2} \qquad [42]$$

are the material GVD in the core and the cladding, respectively.

The first two terms in eqn [41] represent the contribution of material dispersion weighted by the relative importance of core and cladding materials for the propagating mode. In optical fibers, the difference between D_1 and D_2 is small, so that this contribution can be often well approximated by D_2, independently of any guiding effects.

The last term represents the waveguide dispersion and is scaled by 2 factors:

- *The core-cladding index difference* $n_1 - n_2 \simeq N_1 - N_2$. The waveguide dispersion will be significantly enhanced by increasing the index difference between core and cladding.
- *The shape factor* $V(d^2(bV)/dV^2)$. This factor uniquely depends on the shape of the refractive index profile and may substantially modify the

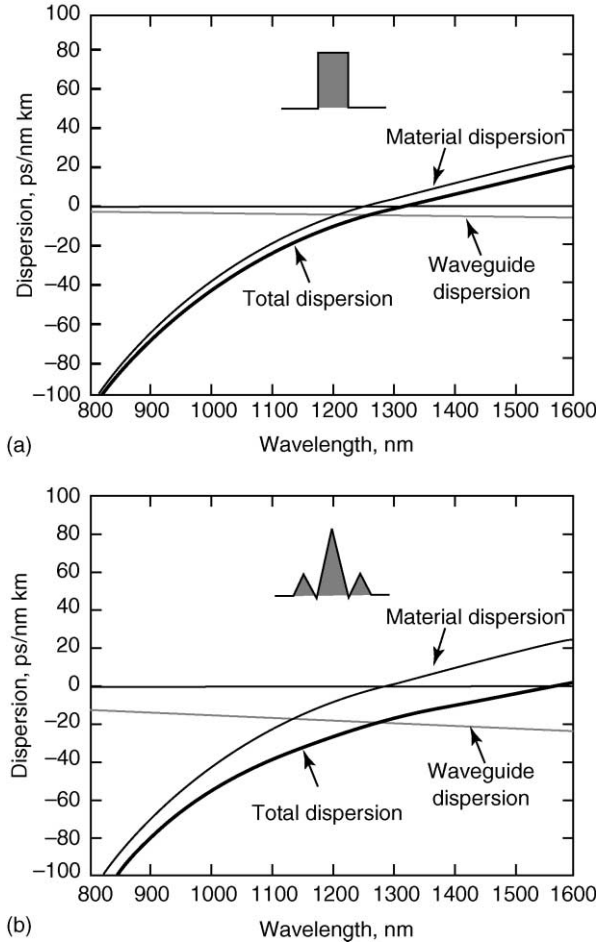

Figure 7 Material, waveguide and total group velocity dispersions for: (a) step-index fiber; (b) triangular profile fiber. The waveguide dispersion can be significantly enhanced by changing the shape of the index profile, making possible a shift of the zero GVD to the minimum attenuation window.

spectral dependence of the waveguide dispersion, making possible a great variety of dispersion characteristics.

Due to this degree of freedom brought by waveguide dispersion it is possible to shift the zero GVD wavelength to the region of minimal attenuation at 1550 nm in silica optical fibers. Figure 7a shows the total group velocity dispersion of a step-index core fiber, together with the separate contributions of material and waveguide GVD. In this case, the material GVD is clearly the dominating contribution, while the small waveguide GVD results in a shift of the zero GVD wavelength from 1273 nm to 1310 nm. A larger shift could be obtained by increasing the core-cladding index difference, but this also gives rise to an increased attenuation from the doping and no real benefit can be expected from such a modification. In Figure 7b, the core shows a triangular index profile to enhance the shape factor in eqn [41], so that the contribution of waveguide GVD is significantly increased with no impairing attenuation due to excessive doping. This makes it possible to realize the ideal situation of an optical fiber showing a zero GVD at the wavelength of minimum attenuation. These dispersion-shifted fibers (DSF) have now become successful in modern telecommunication networks.

Nevertheless, the absence of dispersion favors the efficiency of nonlinear effects and several classes of fibers are now proposed, showing a small but nonzero GVD at 1550 nm, with positive or negative sign, nonzero DSF (NZDSF). By interleaving fibers with positive and negative GVDs it is possible to propagate along the optical link in a dispersive medium and thus minimize the impact of nonlinearities, while maintaining the overall GVD of the link close to zero and canceling any pulse spreading accordingly.

List of Units and Nomenclature

Chromatic dispersion [ps nm^{-1} km^{-1}]	D_λ
Electric field [V m^{-1}]	E
Group index	N
Group velocity [m s^{-1}]	V_g
Group Velocity Dispersion GVD [s^2 m^{-1}]	D_ν
Linear attenuation coefficient [m^{-1}]	α
Medium susceptibility	χ
Normalized frequency	V
Optical frequency [s^{-1}]	ν
Propagation constant [m^{-1}]	β
Propagation delay [s]	τ_D
Polarization density field [A s m^{-2}]	P
Refractive index	n
Vacuum light velocity [m s^{-1}]	c_0

Introduction

The drawing of optical fibers from silica preforms has, over a short period of time, progressed from the laboratory to become a manufacturing process capable of producing millions of kilometers of telecommunications fiber a year. Modern optical fiber fabrication processes produce low-cost fiber of excellent quality, with transmission losses close to their intrinsic loss limit. Today, fiber with transmission losses of 0.2 dB per kilometer of fiber are routinely drawn through a two-stage process that has been refined since the 1970s.

Although fibers of glass have been fabricated and used for hundreds of years, it was not until 1966 that serious interest in the use of optical fibers for communication emerged. At this time, it was estimated that the optical transmission loss in bulk glass could be as low as 20 dB km^{-1} if impurities were sufficiently reduced, a level at which practical applications were possible. At this time, no adequate fabrication techniques were available to synthesize glass of high purity, and fiber-drawing methods were crude.

Over the next five years, efforts worldwide addressed the fabrication of low-loss fiber. In 1970, a fiber with a loss of 20 dB km^{-1} was achieved. The fiber consisted of a titania doped core and pure silica cladding. This result generated much excitement and a number of laboratories worldwide actively began researching optical fiber. New fabrication techniques were introduced, and by 1986, fiber loss had been reduced close to the theoretical limit.

All telecommunications fiber that is fabricated today is made of silica glass, the most suitable material for low-loss fibers. Early fiber research studied multicomponent glasses, which are perhaps more familiar optical materials; however, low-loss fiber, could not be realized, partly due to the lack of a suitable fabrication method. Today other glasses, in particular the fluorides and sulfides, continue to be developed for speciality fiber applications, but silica fiber dominates in most applications.

Silica is a glass of simple chemical structure containing only two elements, silicon and oxygen. It has a softening temperature of about 2,000°C at which it can be stretched, i.e. drawn into fiber. An optical fiber consists of a high purity silica glass core, doped with suitable oxide materials to raise its refractive index (Figure 1). This core, typically on the order of 2–10 microns in diameter, is surrounded by silica glass of lower refractive index. This cladding layer extends the diameter to typically 125 microns. Finally a protective coating covers the entire structure. It is the phenomenon of total internal reflection at the core cladding interface that confines light to the core and allows it to be guided. The basic requirements of an optical fiber are as follows:

1. The material used to form the core of the fiber must have a higher refractive index than the cladding material, to ensure the fiber is a guiding structure.

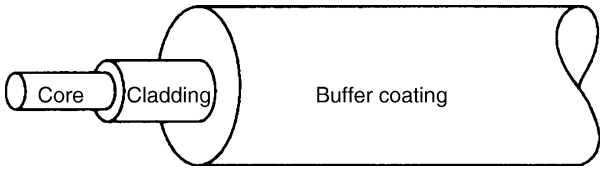

Figure 1 Structure of an optical fiber.

2. The materials used must be low loss, providing transmission with no absorption or scattering of light.
3. The materials used must have suitable thermal and mechanical properties to allow them to be drawn down in diameter into a fiber.

Silica (SiO_2) can be made into a glass relatively easily. It does not easily crystallize, which means that scattering from unwanted crystalline centers within the glass is negligible. This has been a key factor in the achievement of a low-loss fiber. Silica glass has high transparency in the visible and near-infrared wavelength regions and its refractive index can be easily modified. It is stable and inert, providing excellent chemical and mechanical durability. Moreover, the purification of the raw materials used to synthesize silica glass is quite straightforward.

In the first stage of achieving an optical fiber, silica glass is synthesized by one of three main chemical vapor processes. All use silicon tetrachloride ($SiCl_4$) as the main precursor, with various dopants to modify the properties of the glass. The precursors are reacted with oxygen to form the desired oxides. The end result is a high purity solid glass rod with the internal core and cladding structure of the desired fiber.

In the second stage, the rod, or preform as it is known, is heated to its softening temperature and stretched to diameters of the order of 125 microns. Tens to hundreds of kilometers of fiber are produced from a single preform, which is drawn continuously, with minimal diameter fluctuations. During the drawing process one or more protective coatings are applied, yielding long lengths of strong, low-loss fiber, ready for immediate application.

Preform Fabrication

The key step in preparing a low-loss optical fiber is to develop a technique for completely eliminating transition metal and OH ion contamination during the synthesis of the silica glass. The three methods most commonly used to fabricate a glass optical fiber preform are: the modified chemical vapor deposition process (MCVD); the outside vapor deposition process (OVD); and the vapor-axial deposition process (VAD).

In a typical vapor phase reaction, halide precursors undergo a high temperature oxidation or hydrolysis to form the desired oxides. The completed chemical reaction for the formation of silica glass is, for oxidation:

$$SiCl_4 + O_2 \rightarrow SiO_2 + 2Cl_2 \qquad [1]$$

For hydrolysis, which occurs when the deposition occurs in a hydrogen-containing flame, the reaction is:

$$SiCl_4 + 2H_2O \rightarrow SiO_2 + 4HCl \qquad [2]$$

These processes produce fine glass particles, spherical in shape with a size of the order of 1 nm. These glass particles, known as soot, are then deposited and subsequently sintered into a bulk transparent glass. The key to low-loss fiber is the difference in vapor pressures of the desired halides and the transition metal halides that cause significant absorption loss at the wavelengths of interest. The carrier gas picks up a pure vapor of, for example, $SiCl_4$, and any impurities are left behind.

Part of the process requires the formation of the desired core/cladding structure in the glass. In all cases, silica-based glass is produced with variations in refractive index produced by the incorporation of dopants. Typical dopants used are germania (GeO_2), titania (TiO_2), alumina (Al_2O_3), and phosphorous pentoxide (P_2O_5) for increasing the refractive index, and boron oxide (B_2O_2) and fluorine (F) for decreasing it. These dopants also allow other properties to be controlled, such as the thermal expansion of the glass and its softening temperatures. In addition, other materials, such as the rare earth elements, have also been used to fabricate active fibers that are used to produce optical fiber amplifiers and lasers.

MCVD Process

Optical fibers were first produced by the MCVD method in 1974, a breakthrough that completely solved the technical problems of low-loss fiber fabrication (Figure 2).

As shown schematically in Figure 3, the halide precursors are carried in the vapor phase by oxygen carrier gas into a pure silica substrate tube. An oxy-hydrogen burner traverses the length of the tube, which it heats externally. The tube is heated to temperatures of about 1,400°C which then oxidizes the halide vapor materials. The deposition temperature is sufficiently high to form a soot made of glassy particles which are deposited on the inside wall of the substrate tube but low enough to prevent the softened silica substrate tube from collapsing. The process usually takes place on a horizontal glass-working lathe.

During the deposition process, the repeated traversing of the burner forms multiple layers of soot. Changes to the precursors entering the tube and thus the resulting glass composition are introduced for layers which will form the cladding and then the core. The MCVD method allows germania to be doped into

Figure 2 Fabrication of an optical fiber preform by the MCVD method.

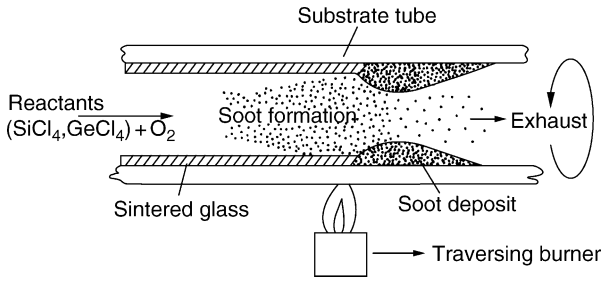

Figure 3 Schematic of preform fabrication by the MCVD method.

the silica glass and the precise control of the refractive index profile of the preform. When deposition is complete, the burner temperature is increased and the hollow, multilayered structure is collapsed to a solid rod. A characteristic of fiber formed by this process is a refractive index dip in the center of the core of the fiber. In addition, the deposition takes place in a closed system, which dramatically reduces contamination by OH^- ions and maintains low levels of other impurities. The high temperature allows high deposition rates compared to traditional chemical vapor deposition (CVD) and large performs, built up from hundreds of layers can be produced.

The MCVD method is still widely used today though it has some limitations, particularly on the preform size that can be achieved and thus the manufacturing cost. Diameter of the final preform is determined by the size of the initial silica substrate tube, which, due to the high purity required, accounts for a significant portion of the cost of the preform. A typical preform fabricated by MCVD yields about 5 km of fiber. Its success has spurred improvements to the process, in particular to address the fiber yield from a single preform.

OVD Process

The outside vapor deposition (OVD) methods, also known as outside vapor phase oxidation (OVPO), synthesize the fine glass particles within a burner flame. The precursors, oxygen, and fuel for the burner, are introduced directly into the flame. The soot is deposited onto a target rod that rotates and traverses in front of the burner. As in MCVD, the preform is built up layer by layer, though now initially by depositing the core glass and then building up the cladding layers over this. After the deposition process is complete, the preform is removed from the target rod and is collapsed and sintered into a transparent glass preform. The center hole remains, but disappears during the fiber drawing process. This technique has advantages in both size of preform which can be obtained and the fact that a high-quality silica substrate tube is no longer required. These two advantages combine to make a more economical process. From a single preform, several hundred kilometers of fiber can be produced.

VAD Process

The most recent refinement to the fabrication process was developed again to aid the mass production of high-quality fibers. In the VAD process, both core and cladding glasses are deposited simultaneously. Like OVD, the soot is synthesized and deposited by flame hydrolysis, as shown in Figure 4, the precursors are blown from a burner, oxidized, and deposited onto a silica target rod.

Burners for the VAD process consist of a series of concentrate nozzles. The first delivers an inert carrier and the main precursors $SiCl_4$, the second delivers an inert carrier glass and the dopants, the third delivers hydrogen fuel, and the fourth delivers oxygen. Gas flows are up to a liter per minute and deposition rates can be very high. With the VAD process, both core and cladding glasses can be deposited simultaneously. The main advantage is that this is a continuous process, as the soot which forms the core and cladding glasses are deposited axially onto the end of the rotating silica rod, it is slowly drawn upwards into a furnace which sinters and consolidates the soot into a transparent glass. The upward motion is such that the end at which deposition is occurring remains in a fixed position and essentially the preform is grown from this base.

The advantages of the VAD process are a preform without a central dip and, most importantly, the mass production associated with a continuous process. The glass quality produced is uniform and the resulting fibers have excellent reproducibility and low loss.

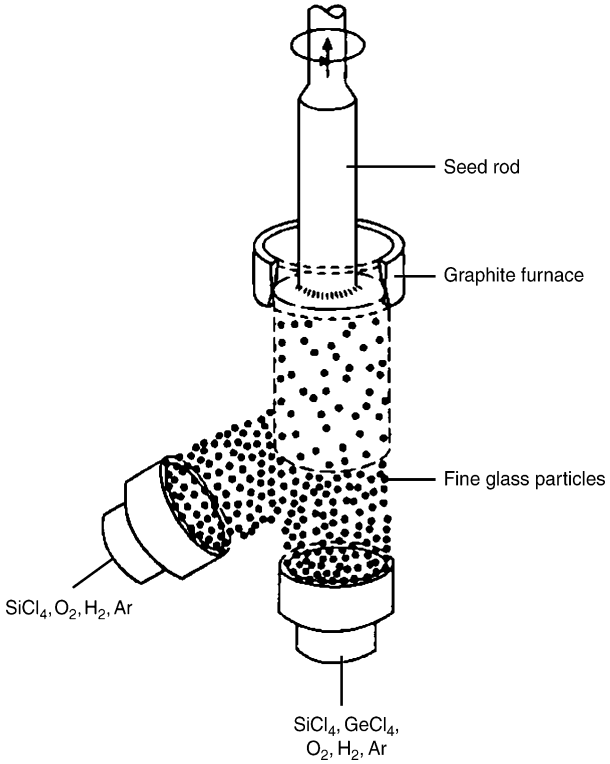

Figure 4 Schematic of preform fabrication by the VAD method.

Figure 5 A commercial scale optical fiber drawing tower.

Other Methods of Preform Fabrication

There are other methods of preform fabrication, though these are not generally used for today's silica glass based fiber. Some methods, such as fabrication of silica through sol–gel chemistry could not provide the large low-loss preforms obtained by chemical vapor deposition techniques. Other methods, such as direct casting of molten glass into rods, or formation of rods and tubes by extrusion, are better suited to and find application in other glass chemistries and speciality fibers.

Fiber Drawing

Once a preform has been made, the second step is to draw the preform down in diameter on a fiber drawing tower. The basic components and configuration of the drawing tower have remained unchanged for many years, although furnace design has become more sophisticated and processes like coating have become automated. In addition, fiber drawing towers have increased in height to allow faster pulling speeds (Figure 5).

Essentially, the fiber drawing process takes place as follows. The preform is held in a chuck which is mounted on a precision feed assembly that lowers the preform into the drawing furnace at a speed which matches the volume of preform entering the furnace to the volume of fiber leaving the bottom of the furnace. Within the furnace, the fiber is drawn from the molten zone of glass down the tower to a capstan, which controls the fiber diameter, and then onto a drum. During the drawing process, immediately below the furnace, is a noncontact device that measures the diameter of the fiber. This information is fed back to the capstan which speeds up to reduce the diameter or slows down to increase the fiber diameter. In this way, a constant diameter fiber is produced. One or more coatings are also applied in-line to maintain the pristine surface quality as the fiber leaves the furnace and thus to maximize the fiber strength.

The schematic drawing in Figure 6 shows a fiber drawing tower and its key components. Draw towers are commercially available, ranging in height from 3 m to greater than 20 m, with the tower height increasing as the draw speed increases.

Typical drawing speeds are on the order of $1\ m\ s^{-1}$. The increased height is needed to allow the fiber to cool sufficiently before entering the coating applicator, although forced air-cooling of the fiber is commonplace in a manufacturing environment.

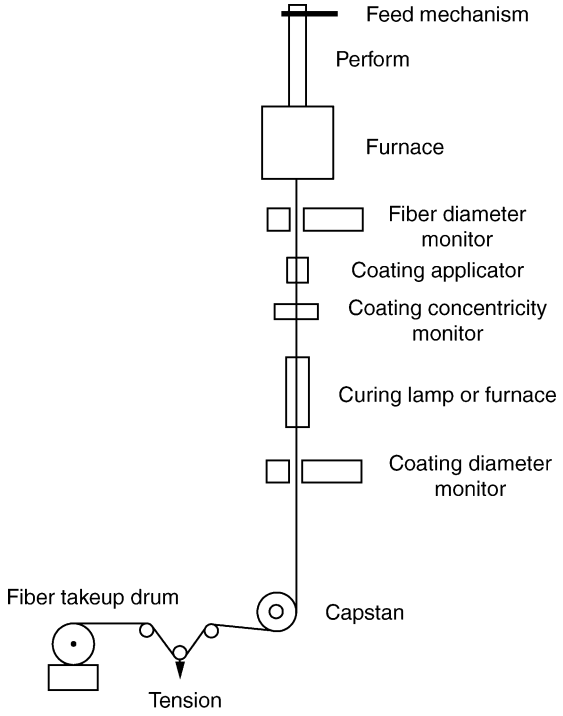

Figure 6 Schematic diagram of an optical fiber drawing tower and its components.

Furnaces

A resistance furnace is perhaps the most common and economical heating source used in a fiber drawing tower. A cylindrical furnace, with graphite or tungsten elements, provides heating to the preform by blackbody radiation. These elements must be surrounded by an inert gas, such as nitrogen or argon, to prevent oxidation. Gas flow and control is critical to prevent variations in the diameter of the fiber. In addition, the high temperature of the elements may lead to contamination of the preform surface that can then weaken the fiber.

An induction furnace provides precise clean heating through radio frequency (RF) energy that is inductively coupled to a zirconia susceptor ring. This type of furnace is cleaner than the graphite resistance type and is capable of continuous running for several months. It also has the advantage that it does not require a protective inert atmosphere and consequently the preform is drawn in a turbulence-free environment. These advantages result in high-strength fibers with good diameter control.

Diameter Measurement

A number of noncontact methods of diameter measurement can be applied to measure fiber diameter. These include laser scanning, interferometry, and light scattering techniques. To obtain precise control of the fiber diameter, the deviation between the desired diameter and the measured diameter is fed into the diameter control system. In order to cope with high drawing speeds, sampling rates as high as 1,000 times per second are used. The diameter control is strongly affected by the gas flow in the drawing furnace and is less affected by the furnace temperature variation. The furnace gas flow can be used to achieve suppression of fast diameter fluctuations. This is used in combination with drawing speed control to achieve suppression of both fast and slow diameter fluctuations. Current manufacturing processes are capable of producing several hundreds of kilometers of fiber with diameter variations of ± 1 micron.

There are two major sources of fiber diameter fluctuations: short-term fluctuations caused by temperature fluctuations in the furnace; and long-term fluctuations caused by variations in the outer diameter of the preform. Careful control of the furnace temperature, the length of the hot zone, and the flow of gas minimize the short-term fluctuations. Through optimization of these parameters, diameter errors of less than ± 0.5 microns can be realized. The long-term fluctuations in diameter are controlled by the feedback mechanism between the diameter measurement and the capstan.

Fiber Coating

A fiber coating is primarily used to preserve the strength of a newly drawn fiber and therefore must be applied immediately after the fiber leaves the furnace. The fiber coating apparatus is typically located below the diameter measurement gauge at a distance determined by the speed of fiber drawing, the tower height, and whether there is external cooling of the fiber. Coating is usually one of the limiting factors in the speed of fiber drawing. To minimize any damage or contamination of the pristine fiber leaving the furnace, this portion of the tower, from furnace to the application of the first coating, is enclosed in a clean, filtered-air chamber.

A wide variety of coating materials has been applied; however, conventional, commercial fiber generally relies on a UV curable polymer as the primary coating. Coating thickness is typically 50–100 microns. Subsequent coatings can then be applied for specific purposes. A dual coating is often used with an inner primary coating that is soft and an outer, secondary coating which is hard. This ratio of low to high elastic modulus can minimize stress on the fiber and reduce bending loss.

Alternative coatings include hermetic coatings of a low melting temperature metal, ceramics, or amorphous carbon. These can be applied in-line before the polymeric coating. Metallic coatings are applied by passing the fiber through a molten metal while ceramic or amorphous coatings utilize an in-line chemical vapor deposition reactor.

Types of Fiber

The majority of silica fiber drawn today is single mode. This structure consists of a core whose diameter is chosen such that, with a given refractive index difference between the core and cladding, only a single guide mode propagates at the wavelength of interest. With a discrete index difference between core and cladding, it is often referred to as a step index fiber. In typical telecommunications fiber, single mode operation is obtained with core diameters of 2–10 microns with a standard outer diameter of 125 microns.

Multimode fiber has core diameters considerably larger, typically 50, 62.5, 85, and 110 microns, again with a cladded diameter of 125 microns. Multimode fibers are often graded index, that is the refractive index is a maximum in the center of the fiber and smoothly decreases radially until the lower cladding index is reached. Multimode fibers find use in non-telecommunication applications, for example optical fiber sensing and medicine.

Single mode fibers, which are capable of maintaining a linear polarization input to the fiber, are known as polarization preserving fibers. The structure of these fibers provides a birefringence that removes the degeneracy of the two possible polarization modes. This birefringence is a small difference in the effective refractive index of the two polarization modes that can be guided and it is achieved in one of two ways. Common methods for the realization of this birefringence are an elliptical core in the fiber, or through stress rods, which modify the refractive index in one orientation. These fiber structures are shown in Figure 7.

While the loss minimum of silica-based fiber is near 1.55 microns, step index single-mode fiber offers zero dispersion close to 1.3 micron wavelengths and dispersion at the loss minimum is considerable. A modification of the structure of the fiber, and in particular a segmented refractive index profile in the core, can be used to shift this dispersion minimum to 1.55 microns. This fiber, illustrated in Figure 7 is known as dispersion shifted fiber. Similarly fibers, with a relatively low dispersion over a wide wavelength range, known as dispersion flattened fibers, can be obtained by the use of multiple cladding layers.

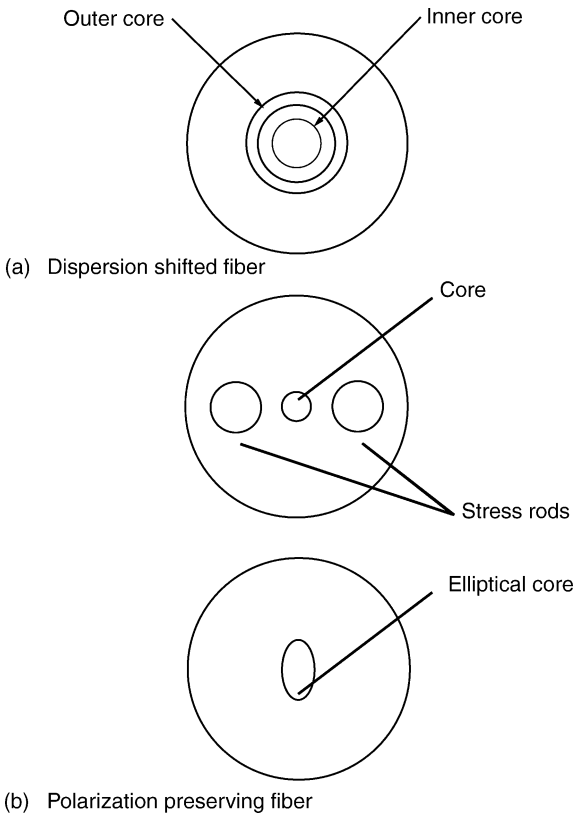

Figure 7 Structure of (a) dispersion shifted fiber and (b) two methods of achieving polarization preserving fiber.

List of Units and Nomenclature

Dopants	Elements or compounds added, usually in small amounts, to a glass composition to modify its properties.
Fiber drawing	The process of heating and thus softening an optical fiber preform and then drawing out a thin thread of glass.
Fiber loss	The transmission loss of light as it propagates through a fiber, usually measured in dB of loss per unit length of fiber. Loss can occur through the absorption of light in the core or scattering of light out of the core.
Glass	An amorphous solid formed by cooling from the liquid state to a rigid solid with no long range structure.
Modified chemical vapor deposition (MCVD)	A process for the fabrication of an optical preform where gases flow into the inside of a rotating tube, are heated and react

	to form particles of glass which are deposited onto the wall of the glass tube. After deposition, the glass particles are consolidated into a solid preform.
Outside vapor deposition (OVD)	A process for the fabrication of an optical preform where glass soot particles are formed in an oxy-hydrogen flame and deposited on a rotating rod. After deposition, the glass particles are consolidated into a solid preform.
Preform	A fiber blank, a bulk glass rod consisting of a core and cladding glass composite which is drawn into fiber.
Refractive index	A characteristic property of glass, which is defined by the speed of light in the material relative to the speed of light in a vacuum.
Silica	A transparent glass formed from silicon dioxide.
Vapor-axial deposition	A process similar to OVD, where the core and cladding layers are deposited simultaneously.

Light Propagation

F G Omenetto, Los Alamos National Laboratory, Los Alamos, NM, USA

Optical fibers have become a mainstay of our modern way of life. From phone calls to the internet, their presence is ubiquitous. The unmatched ability that optical fibers have to transmit light is an amazing asset that, besides being strongly part of our present, is poised to shape the future.

The foundation of the unique ability of optical fibers to transmit light hinges on the well-known physical concept of total internal reflection. This phenomenon is described by considering the behavior of light traveling from one material (A) to a different material (B). When light traverses the interface of the two materials with a specific angle, its direction of propagation is altered with respect to the normal to the surface, according to the well-known Snell law which relates the incident angle (onto the interface between A and B) to the refracted angle (away from the interface between A and B). This is written as $n_A \sin i = n_B \sin r$, where i is the angle of incidence, r the angle of refraction, and n_A and n_B are the refractive indices of the materials A and B. Under appropriate conditions, a critical value of the incidence angle (i_{CR}) exists for which the light does not propagate into B and is totally reflected back into A. This value is given by $i_{CR} = \arcsin(n_A/n_B)$. It follows that total internal reflection occurs when light is traveling from a medium with a higher index of

refraction into a medium with a lower index of refraction. As an approximation, this is the basic idea behind light propagation in fibers.

Optical fibers are glass strands that include a concentric core with a cladding wrapped around it. The index of refraction of the core is slightly higher than the index of refraction of the cladding, thereby creating the necessary conditions for the confinement of light within them. Such index mismatches between the core and the cladding are determined by using different materials for each, by doping the glass matrix before pulling the fiber to create an index gradient, by introducing macroscopic defects such as air-holes in the structure of the fiber cladding (such as in the recently developed photonic crystal fibers), or by using materials other than glass, such as polymers or plastic.

The real physical picture of light guiding in fibers is more complex than the conceptual description stated above. The light traveling in the fiber is, more precisely, an electromagnetic wave with frequencies that lie in the optical range, and the optical fiber itself constitutes an electromagnetic waveguide. As such, the waveguide supports guided electromagnetic modes which can take on a multitude of shapes (i.e., of energy distribution profiles), depending on the core/cladding index of refraction profiles. These profiles are often complex and determine the physical boundary conditions that influence the field distribution within the fiber. The nature of the fiber modes has been treated extensively in the literature where an in-depth description of the physical solutions can be found.

There are many distinguishing features that identify different optical fiber types. Perhaps the most important one, in relation to the electromagnetic modes that the fiber geometry supports, is the distinction that is made between single-mode fibers and multimode fibers. As the name implies, a single-mode fiber is an optical fiber whose index of refraction profile between core and cladding is designed in such a way that there is only one electromagnetic field distribution that the fiber can support and transmit. That is to say, light is propagated very uniformly across the fiber. A very common commercially used fiber of this kind is the Corning SMF-28 fiber, which is employed in a variety of telecommunication applications. Multimode fibers have larger cores and are easier to couple light into, yet the fact that many modes are supported implies that there is less control over the behavior of light during its propagation, since it is more difficult to control each individual mode.

The condition for single-mode propagation in optical fibers is determined during the design and manufacture of the fiber by its geometrical parameters and is specific to a certain operation wavelength. A quantity V is defined as $V = (2\pi/\lambda) \times a(n_{\text{core}}^2 - n_{\text{cladding}}^2)^{1/2}$, where a is the core radius and λ is the wavelength of light. For example, a step-index fiber (i.e., a fiber where the transition from the index of refraction of the core to the index of refraction in the cladding is abrupt), supports a single electromagnetic mode if $V < 2.405$.

Light propagation in optical fibers, however, is affected by numerous other factors besides the electromagnetic modes that the fiber geometry allows.

First, the ability to efficiently transmit light in optical fiber is dependent on the optical transparency of the medium that the fiber is made of. The optical transparency of the medium is a function of the wavelength (λ) of light that needs to be transmitted through the fiber. Optical attenuation is particularly high for shorter wavelengths and the transmission losses for ultraviolet wavelengths become considerably higher than in the near infrared. The latter region, due to this favorable feature, is the preferred region of operation for optical fiber based telecommunication applications. This ultimate physical limit is determined by the process of light being scattered off the atoms that constitute the glass, a process called Rayleigh scattering. The losses due to Rayleigh scattering are inversely proportional to the fourth power of the wavelength (losses $\propto \lambda^{-4}$), and therefore become quite considerable as λ is decreased.

The ability of optical fibers to transmit light over a certain set of wavelengths, is quantified by their optical attenuation. This parameter is defined as the ratio of the output power versus the input power and is usually measured in units of decibels (dB), i.e., attenuation (dB) $= 10 \log_{10}(P_{\text{out}}/P_{\text{in}})$.

The values that are found in the literature relate optical attenuation to distance and express the attenuation per unit length (such as dB/km). Single-mode fibers used in telecommunications are usually manufactured with doped silica glasses designed to work in the near infrared, in a wavelength range between 1.3 and 1.6 μm ($1\ \mu\text{m} = 10^{-6}$ m) which provides the lowest levels of Rayleigh scattering and is located before the physical infrared absorption of silica (~1.65 μm) kicks in. Such fibers, which have been developed and refined for decades, have attenuation losses of less that 0.2 dB/km at a wavelength of 1.55 μm. Many other materials have been used to meet specific optical transmission needs. While silica remains by far the most popular material used for optical fiber manufacturing, other glasses are better suited for different portions of the spectrum: quartz glass can be particularly transmissive in the ultraviolet whereas plastic is sometimes

conveniently used for short distance transmission in the visible.

The ability to collect light at the input of the fiber represents another crucial and defining parameter. Returning to total internal reflection, such an effect can only be achieved by sending light onto an interface at a specific angle. In fibers, the light needs to be coupled into a circular core and reach the core cladding interface at that specific geometrical angle. The measure of the ability to couple light in the fiber is referred to as 'coupling efficiency'. The core dimension defines the geometry of the coupling process which, in turn, determines the efficiency of the propagation of light inside the fiber. In order to be coupled efficiently and therefore guided within the fiber, the light has to be launched within a range of acceptable angles. Such a range is usually defined or derivable from the numerical aperture (NA) of the fiber which is approximately $\mathrm{NA} = (n_{\mathrm{core}}^2 - n_{\mathrm{cladding}}^2)^{1/2}$, or can be alternatively described as a function of the critical angle for total internal reflection within the fiber by $\mathrm{NA} = n_{\mathrm{core}} \sin i_{\mathrm{CR}}$. Also, light has to be focused into the core of the fiber and therefore the interplay between core size, focusability, and NA (i.e., acceptance angle) of the fiber influence the coupling efficiency into the fiber (which in turn affects transmission). Typical telecommunication fibers have a 10 μm core (a NA of ~0.2) and have very high coupling efficiencies (of the order of 70–80%). Specialized single mode fibers (such as photonic crystal fibers) can have core diameters down to a few microns, significantly lower coupling efficiencies, and high numerical apertures. Multimode fibers, in contrast, are easy to couple into given their large core size.

Other factors that contribute to losses during propagation are due to the physical path that the actual optical fiber follows. A typical optical fiber strand is rarely laid along a straight line. These types of losses are called bending losses and can be intuitively understood by thinking that when the fiber is straight, the light meets its total reflection condition at the core-cladding interface, but when the fiber bends, the interface is altered and varies the incidence conditions of light at the interface. If the bend is severe, light is no longer totally reflected and escapes from the fiber.

Another important issue that influences propagation arises when the light that travels through the fiber is sent in bursts or in pulses of light. Pulsed light is very important in fiber transmission because the light pulse is the carrier of optical information, most often representing a binary digit of data. The ability to transmit pulses reliably is at the heart of modern day telecommunication systems. The features that affect the transmission of pulses through optical fibers depend, again, largely on the structure and constituents of the fiber. One of the most important effects on pulsed light is dispersion. This phenomenon causes the broadening in time of the light pulses during their travel through the fiber. This can be easily explained by a Fourier analogy by thinking that a short pulse in time (such as the 10–20 picosecond pulse duration that is used for optical communications, $1\ \text{picosecond} = 10^{-12}$ seconds) has a large frequency content (i.e., is composed of a variety of 'colors'). Since the speed of light through bulk media, and therefore through the fiber constituent, depends on wavelength, different 'colors' will travel at different speeds, arriving at the end of the fiber slightly delayed with respect to one another. This causes a net pulse broadening and is dependent on the properties of the fiber that are depicted in the dispersion curve of the fiber. This type of dispersion is called chromatic dispersion and is dependent on the distance the pulse travels in the fiber. A measure of the pulse broadening can be calculated by multiplying the dispersion value for the fiber (measured in ps/km) at the wavelength of operation times and the distance in kilometers that the pulse travels.

There are other types of dispersion that affect pulses traveling through fibers: light with different polarization travels at a different speed, thereby causing an analogous problem to chromatic distortion. In multimode fibers, different modes travel with different properties. Dispersion issues are extremely important in the design of the next-generation telecommunication systems. As a push is made toward higher transmission capacity, pulses become shorter and these issues have to be dealt with carefully. Specifically, transmission of light in optical fibers becomes more complex because the interaction between the light and the fiber material constituents becomes nonlinear. As pulses become shorter, their energy is confined in a smaller temporal interval, making their peak power (which is equal to energy/time) increase. If the peak power becomes sufficiently high, the atoms that form the glass of which the fiber is made are excited in a nonlinear fashion adding effects that need to be addressed with caution. Energetic pulses at a certain wavelength change their shape during propagation and can become severely distorted or change wavelength (i.e., undergo a frequency conversion process), thereby destroying the information that they were meant to carry.

Several physical manifestations of optical nonlinearity affect pulsed light propagation, giving rise to new losses but also providing new avenues for efficient transmission.

Perhaps the most successful example of the positive outcome of nonlinear effects in fibers is the optical soliton. The latter is an extremely stable propagating pulse that is transmitted through the fiber undistorted, since it is a result of a peculiar balance between the linear distortion and nonlinear distortion that cancel each other by operating in a specific region of dispersion of the optical fiber (the anomalous dispersion region).

Nonlinear effects in fibers are an extremely rich area of study which, besides several drawbacks, carries immense opportunities if the nonlinearities can be controlled and exploited.

Measuring Fiber Characteristics

A Girard, EXFO, Quebec, Canada

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

The optical fiber is divided in two types: multimode and singlemode. Each type is used in different applications and wavelength ranges and is consequently characterized differently. Furthermore, the corresponding test methods also vary.

The optical fiber characteristics may be divided into four categories:

- The optical characteristics (transmission related);
- The dimensional characteristics;
- The mechanical characteristics; and
- The environmental characteristics.

These categories will be reviewed in the following sections, together with their corresponding test methods.

Fiber Optical Characteristics and Corresponding Tests Methods

The following sections will describe the following optical characteristics:

- attenuation;
- macrobending sensitivity;
- microbending sensitivity;
- cut-off wavelength;
- multimode fiber bandwidth;
- differential mode delay for multimode fibers;
- chromatic dispersion;
- polarization mode dispersion;
- polarization crosstalk; and
- nonlinear effects.

Attenuation

The spectral attenuation of an optical fiber follows exponential power decay from the power level at a cross-section 1 to the power level at cross-section 2, over a fiber length L, as follows:

$$P_2(\lambda) = P_1(\lambda) \cdot e^{-\gamma(\lambda)L} \qquad [1]$$

$P_1(\lambda)$ is the optical power transmitted through the fiber core cross-section 1, expressed in mW; $P_2(\lambda)$ is the optical power transmitted through the fiber core cross-section 2 away from cross-section 1, expressed in mW; $\gamma(\lambda)$ is the spectral attenuation coefficient in linear units, expressed in km^{-1}; and L is the fiber length expressed in km.

Attenuation may be characterized at one or more specific wavelengths or as a function of wavelength. In the later case, attenuation is referred to spectral attenuation. Figure 1 illustrates such power decay.

Equation [1] may be expressed in relative units as follows:

$$\log_{10} P_2 = (\log_{10} P_1) \cdot - \gamma L \cdot \log_{10} e \qquad [2]$$

P is expressed in dBm units using the following definition.

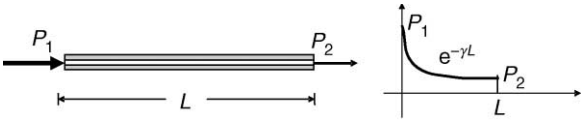

Figure 1 Power decay in an optical fiber due to attenuation.

The power in dBm is equal to 10 times the logarithm in base 10 of the power in mW; or

$$0\ \text{dBm} = 10\log_{10}(1\ \text{mW}) \quad [3]$$

Then

$$\gamma(\lambda)[\text{km}^{-1}] = [(10\log_{10} P_1) - (10\log_{10} P_2)] \div L\log_{10} e \quad [4]$$

$$\alpha(\lambda)[\text{dB/km}] = [P_1(\text{dBm}) - P_2(\text{dBm})]/L \quad [5]$$

A new relative attenuation coefficient $\alpha(\lambda)$ with units of dB/km has been introduced, which is related to the linear coefficient $\gamma(\lambda)$ with units of km^{-1} as follows:

$$\alpha(\lambda) = (\log_{10} e)\cdot\gamma(\lambda) \approx 4{,}343\,\gamma(\lambda) \quad [6]$$

$\alpha(\lambda)$ is the spectral attenuation coefficient of a fiber and is illustrated in Figure 2.

Test methods for attenuation

The attenuation may be measured by the following methods:

- cut-back method;
- backscattering method; and
- insertion loss method.

Cut-back method. The cut-back method is a direct application of the definition in which the power levels P_1 and P_2 are measured at two points of the fiber change of input conditions. P_2 is the power emerging from the far end of the fiber and P_1 is the power emerging from a point near the input after cutting the fiber.

The output power P_2 is recorded from the fiber under test (FUT) placed in the measurement setup. Keeping the launching conditions fixed, the FUT is cut to the cut-back length, for example 2 m from the launching point. The FUT attenuation, between the points where P_1 and P_2 have been measured, is calculated using P_1 and P_2, from the definition equations provided above.

Backscattering method. The attenuation coefficient of a singlemode fiber is characterized using bidirectional backscattering measurements. This method is also used for:

- attenuation uniformity;
- optical continuity;
- physical discontinuities;
- splice losses; and
- fiber length.

An optical time domain reflectometer (OTDR) is used for performing such characterization. Adjustment of laser pulsewidth and power is used to obtain a compromise between resolution (a shorter pulsewidth provides a better resolution but at lower power) and dynamic range/fiber length (higher power provides better dynamic range but with longer pulsewidth). An example of such an instrument is shown in Figure 3.

The measurement is applicable to various FUT configurations (e.g., cabled fiber in production or deployed in the field, fiber on a spool, etc.). Two unidirectional backscattering curves are obtained, one from each end of the fiber (Figure 4).

Each backscattering curve is recorded on a logarithmic scale, avoiding the parts at the two ends of the curves, due to parasitic reflections.

The FUT length is found from the time interval between the two ends of the backscattering loss

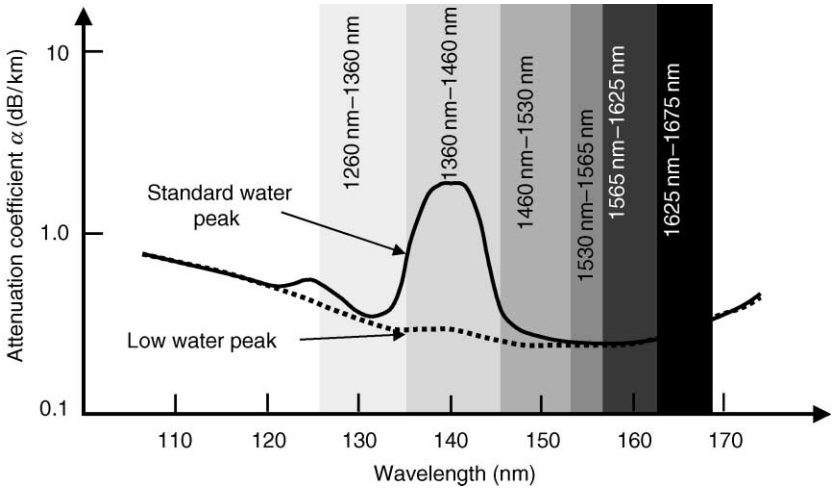

Figure 2 Typical spectral attenuation of a singlemode fiber.

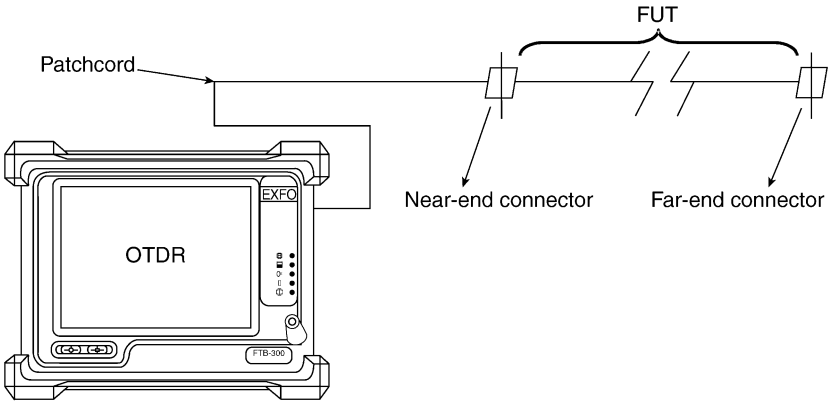

Figure 3 The backscattering method (OTDR).

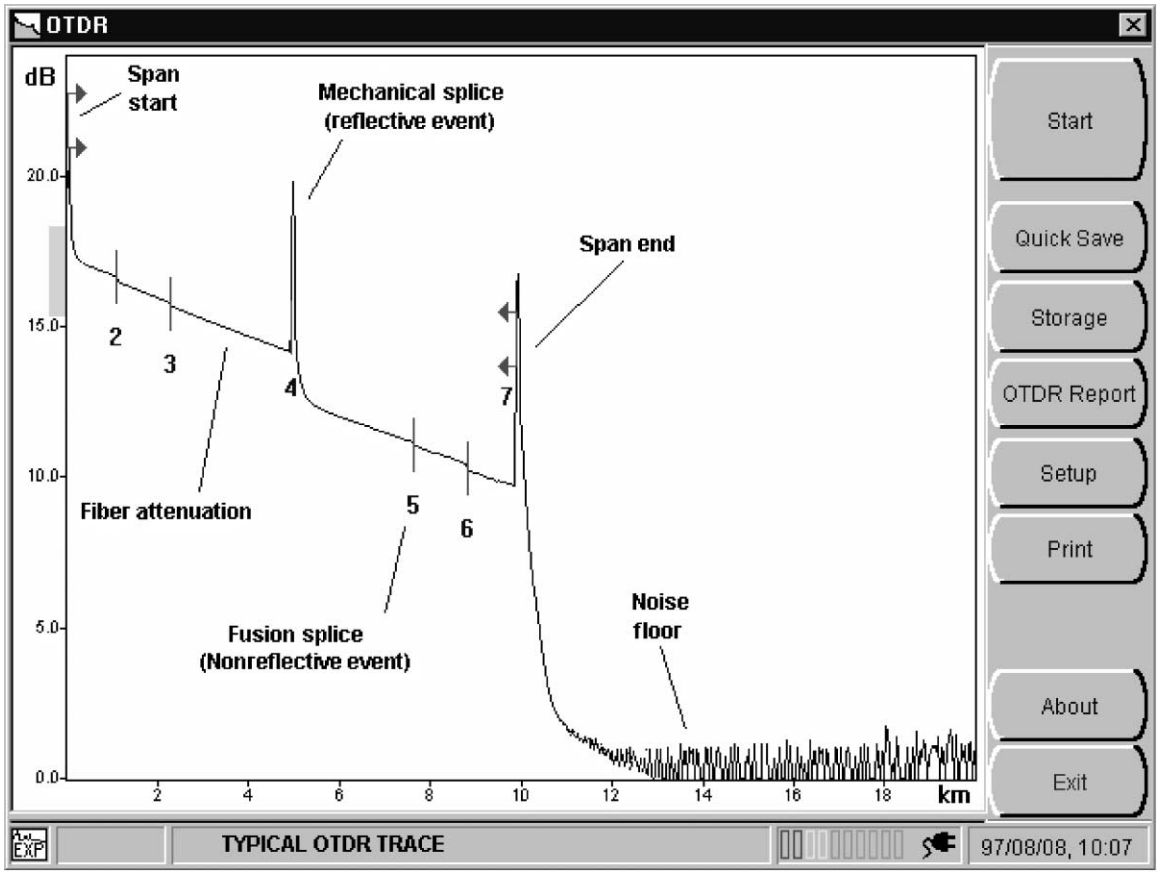

Figure 4 Unidirectional OTDR backscattering loss measurement.

curve together with the FUT group index of refraction, n_g, as:

$$L_f = c_{fs} \cdot \frac{\Delta T_f}{n_g} \quad [7]$$

c_{fs} is the velocity of light in free space.

The bidirectional backscattering curve is obtained using two unidirectional backscattering curves and calculating the average loss between them. The end-to-end FUT attenuation coefficient is obtained from the difference between two losses divided by the difference of their corresponding distances.

Insertion loss method. The insertion loss method consists of the measurement of the power loss due to

the FUT insertion between a launching and a receiving system, previously interconnected (reference condition). The powers P_1 and P_2 are evaluated in a less straightforward way than in the cut-back method. Therefore, this method is not intended for use in manufacturing.

The insertion loss technique is less accurate than the cut-back, but has the advantage of being non-destructive for the FUT. Therefore, it is particularly suitable in the field.

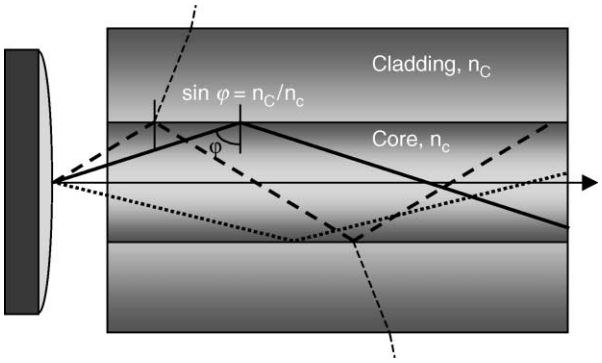

Figure 5 Total internal reflection and macrobending effect on the light rays.

Macrobending Sensitivity

Macrobending sensitivity is the property by which there is a certain amount of light leaking (loss) into the cladding when the fiber is bent and the bending angle is such that the condition of total internal reflection is no longer met at the core-cladding interface. Figure 5 illustrates such a case.

Macrobending sensitivity is a direct function of the wavelength: the longer the wavelength and/or the smaller the bending diameter, the more loss the fiber experiences. It is recognized that 1625 nm is a wavelength that is very sensitive to macrobending (see Figure 6).

The macrobending loss is measured by the power monitoring method (OTDR, especially for field assessment, see Figure 6) or the cut-back method.

Microbending Sensitivity

Microbending is a fiber property by which the core-cladding concentricity randomly changed along

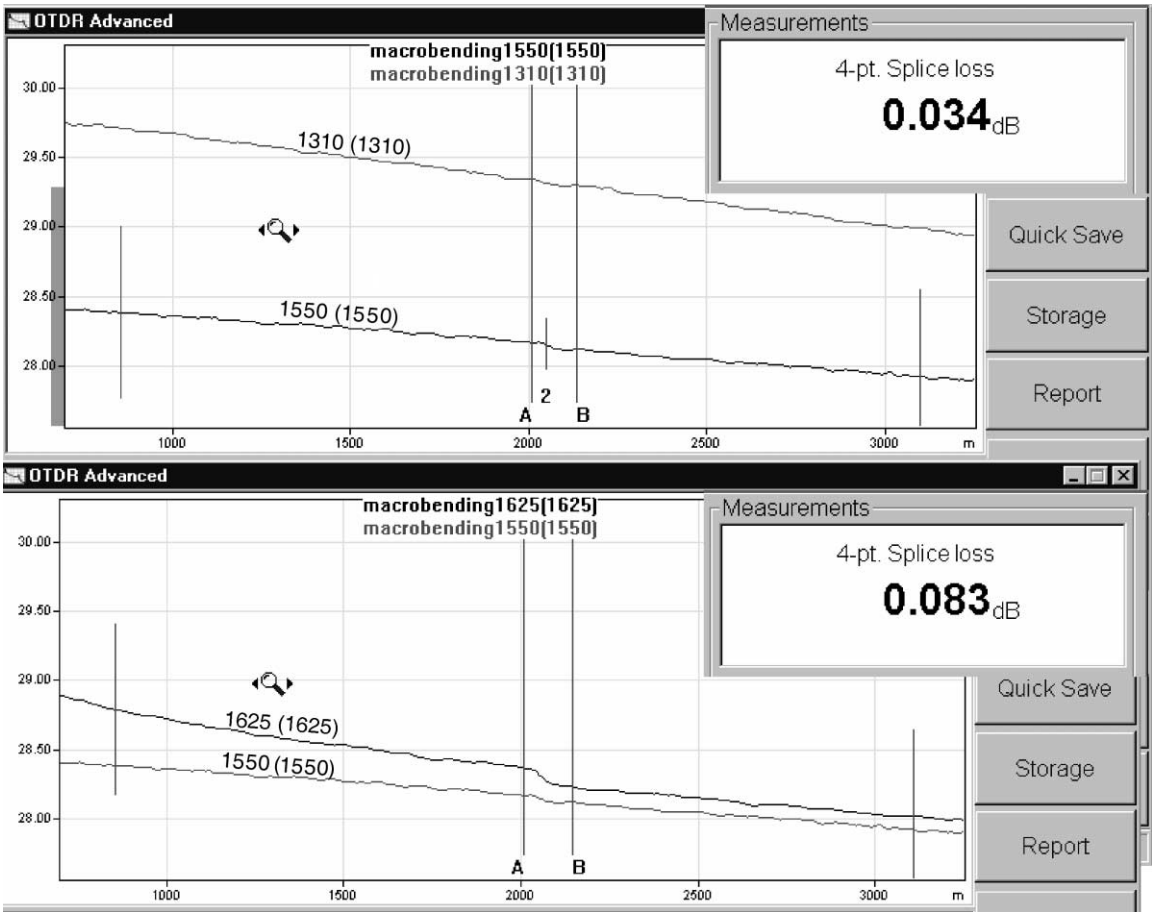

Figure 6 Macrobending sensitivity as a function of wavelength.

the fiber length. It causes the core to wobble inside the cladding and along the fiber length.

Four methods are available for characterizing microbending sensitivity in optical fibers:

- expandable drum for singlemode fibers and optical fiber ribbons over a wide range of applied linear pressure or loads;
- fixed diameter drum for step-index multimode, singlemode, and ribbon fibers for a fixed linear pressure;
- wire mesh and applied loads for step-index multimode and singlemode fibers over a wide range of applied linear pressure or loads; and
- 'basketweave' wrap on a fixed diameter drum for singlemode fibers.

The results from the four methods can only be compared qualitatively. The test is nonroutine for general evaluation of optical fiber.

Cut-off Wavelength

The cut-off wavelength is the shortest wavelength at which a single mode can propagate in a singlemode fiber. This parameter can be computed from the fiber refractive index profile (RIP). At wavelengths below the cut-off wavelength, several modes propagate and the fiber is no longer singlemode, but multimode.

In optical fibers, the change from multimode to singlemode behavior does not occur at a specific wavelength, but rather over a smooth transition as a function of wavelengths. Consequently, from a fiber-optic network standpoint, the actual threshold wavelength for singlemode performance is more critical. Thus an effective cut-off wavelength is described below.

The cut-off wavelength is defined as the wavelength greater than the ratio between the total power, in the higher-order modes and the fundamental mode, which has decreased to less than 0.1 dB. According to this definition, the second-order mode LP_{11} undergoes 19.3 dB more attenuation than the fundamental LP_{01} mode when the modes are equally excited.

Because the cut-off wavelength depends on the fiber length, bends, and strain, it is defined on the basis of the following three cases:

- fiber cut-off wavelength;
- cable cut-off wavelength; and
- jumper cable cut-off wavelength.

Fiber cut-off wavelength: Fiber cut-off wavelength λ_{fc} is defined for uncabled primary-coated fiber and is measured over 2 m with one loop of 140 mm radius loosely constrained, with the rest of the fiber kept essentially straight. The presence of a primary coating on the fiber usually will not affect λ_{fc}. However, the presence of a secondary coating may result in λ_{fc} being significantly shorter than that of the primary coated fiber.

Cable cut-off wavelength: Cable cut-off wavelength is measured prior to installation on a substantially straight 22 m cable length prepared by exposing 1 m of primary-coated fiber at both ends, the exposed ends each incorporating a 40 mm radius loop. Alternatively, this parameter may be measured on 22 m primary-coated uncabled fiber in the same configuration as for the λ_{fc} measurement.

Jumper cable cut-off wavelength: Jumper cable cut-off wavelength is measured over 2 m with one loop of 76 mm radius, or equivalent (e.g., split mandrel), with the rest of the jumper cable kept essentially straight.

Multimode Fiber Bandwidth for Multimode Fibers

The −3 dB bandwidth of a multimode optical fiber (or modal bandwidth) is defined as the lowest frequency where the magnitude of the baseband frequency response in optical power has decreased by 3 dB relative to the power at zero frequency. Modal bandwidth is also called intermodal dispersion as it takes into account the dispersion between the modes of propagation of the transmitted signal into the multimode fiber.

Various methods of reporting the results are available, but the results are typically expressed in terms of the −3 dB (optical power) frequency. Figure 7 illustrates modal bandwidth.

The bandwidth or pulse broadening may be normalized to a unit length, such as GHz · km, or ns/km.

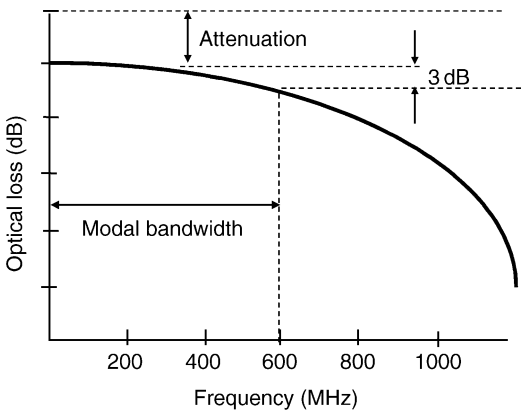

Figure 7 Determination of modal bandwidth.

Two methods are available for determining transmission capacity of multimode fibers:

- the frequency domain measurement method in which the baseband frequency response is directly measured in the frequency domain by determining the fiber response to a sinusoidally modulated light source; or
- the optical time domain measurement method (pulse distortion) in which the baseband response is measured by observing the broadening of a narrow pulse of light.

Differential Mode Delay for Multimode Fibers

Differential mode delay (DMD) characterizes the modal structure of a graded-index glass-core multimode fiber. DMD is useful for assessing the bandwidth performance of a fiber when used with short-pulse, narrow spectral-width laser sources.

The output from a singlemode probe fiber excites the multimode FUT at the test wavelength. The probe spot is scanned across the FUT endface, and the optical pulse delay is determined at specified radial offset positions between an inner and an outer limit. DMD is the difference in optical pulse delay time between the FUT fastest and slowest modes excited for all radial offset positions between and including the inner and the outer limits.

The related critical issues influencing DMD are the temporal width of the optical pulse, jitter in the timing, the finite bandwidth of the optical detector, and the mode broadening due to the source spectral width and the FUT chromatic dispersion.

The test method is commonly used in production and research facilities, but is not easily accomplished in the field. DMD may be a good predictor of the source launching conditions. DMD may be normalized to a unit length, such as ps/m.

Chromatic Dispersion

Chromatic dispersion in a singlemode fiber is a combination of material dispersion and waveguide dispersion (see Figure 8), and it contributes to pulse broadening and distortion in a digital signal.

Material dispersion is produced by the dopants used in glass and is important in all fiber types. Waveguide dispersion is produced by the wavelength dependence of the index of refraction and is critical in singlemode fibers only.

From the point of view of the transmitter, this is due to two causes:

- The presence of wavelengths in the source optical spectrum. Each wavelength has a different phase delay and group delay (different group velocities) along the fiber, because they travel under different index of refraction (or phase) as the index varies as a function of wavelengths, as shown in Figure 9.
- The other cause is the modulation of the source, which itself has two effects:
  - As bit-rates increase, the spectral width of the modulated signal increases and can become comparable to or exceed the spectral width of the source.
  - Chirp occurs when the source wavelength spectrum varies during the pulse. By convention, positive chirp at the transmitter occurs when the spectrum during the rise/fall of the pulse shifts towards shorter/longer wavelengths respectively. For a positive fiber dispersion coefficient, longer wavelengths are delayed relative to shorter wavelengths. Hence if the sign of the product of chirp and dispersion is positive, the two processes combine to produce pulse broadening. If the product is negative, pulse compression can occur over an initial fiber length until the pulse reaches a minimum width and then broadens again with increasing dispersion.

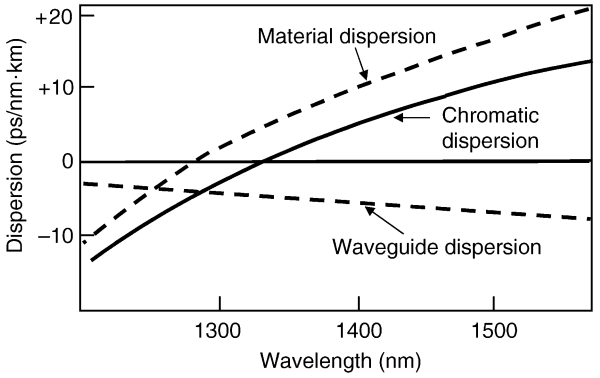

Figure 8 Contribution of the material and waveguide dispersions to the chromatic dispersion.

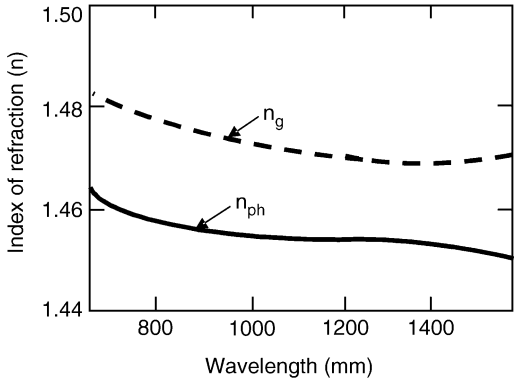

Figure 9 Difference between the phase and the group index of refraction.

The electric field propagating into the FUT may be simply described as follows:

$$E(t,z) = E_0 \sin(\omega t - \beta z) \quad [8]$$

$\omega = 2\pi c/\lambda$ [rad/s] is the angular frequency; $\beta = kn = (\omega/c)n$ is the effective index; as β has units of m^{-1} it is often referred to as wavenumber or even sometimes propagation constant; k is the propagation constant.

The group delay τ_g is then given by:

$$d\beta/d\omega = \beta_1 = \tau_g \quad [9]$$

An example of the group delay spectral distribution is shown in Figure 10. Assuming n is not complex; β_1 is the first-order derivative of β.

The group velocity v_g is given by

$$v_g = (d\beta/d\omega)^{-1} = -(\lambda^2/2\pi c)(d\beta/d\lambda)^{-1} \quad [10]$$

The FUT input–output delay is given by

$$\tau_d = L/v_g \quad [11]$$

L is the FUT length.

The group index of refraction n_g is given by

$$n_g = c/v_g = n - \lambda(dn/d\lambda) \quad [12]$$

The dispersion parameter or dispersion coefficient D (ps/nm · km) is given by

$$D = -(\omega/\lambda)(d\tau_g/d\omega) = -(2\pi c/\lambda^2)(d^2\beta/d\omega^2)$$

$$= -(\lambda/c)(d^2n/d\lambda^2) \quad [13]$$

$$d^2\beta/d\omega^2 = \beta_2 \quad [14]$$

An example of the spectral distribution of D obtained from the group delay is shown in Figure 10.

β_2 (ps^2/km) is the group velocity dispersion parameter, so D may be related to β_2, as follows:

$$D = -(\omega/\lambda)\beta_2 \quad [15]$$

When β_2 is positive then D is negative and vice-versa. The region where β_2 is positive is called normal dispersion while the negative-β_2 region is called anomalous dispersion.

At λ_0, β_1 is minimum, and $\beta_2 = 0$, then $D = 0$.

The dispersion slope S (ps/nm^2 · km), also called the differential dispersion parameter or second-order dispersion, is given by

$$S = dD/d\lambda = (\omega/\lambda)\beta_3 + (2\omega/\lambda^2)\beta_2 \quad [16]$$

$$\beta_3 = d\beta_2/d\omega = d^3\beta/d\omega^3$$

At λ_0, β_1 is minimum, $\beta_2 = 0$, then $D = 0$; but S is not zero and depends on β_3. An example of the spectral distribution of S and S_0 is illustrated in Figure 10.

Overall, the general expression of β is given by

$$\beta(\omega) = \beta_0 + (\omega - \omega_0)\beta_1 + (1/2)(\omega - \omega_0)^2\beta_2$$

$$+ (1/12)(\omega - \omega_0)^3\beta_3 + \cdots \quad [17]$$

Figure 11 illustrates the difference between dispersion unshifted fiber (ITU-T Rec. G.652), dispersion shifted fiber (ITU-T Rec. G.653) and nonzero dispersion shifted fiber (ITU-T Rec. G.655).

Test methods for the determination of chromatic dispersion

All methods measure the group delay at a specific wavelength over a range and use agreed fitting functions to evaluate λ_0 and S_0.

In the phase shift method, the group delay is measured in the frequency domain, by detecting, recording, and processing the phase shift of a sinusoidal modulating signal between a reference, a secondary fiber path, and the channel signal.

Setup variances exist and some do not require the secondary reference path. For instance, by using a reference optical filter at the FUT output it is possible to completely decouple the source from the phase-meter. With such an approach, chromatic dispersion may now be measured in the field over very long links using optical amplifiers (see Figure 12).

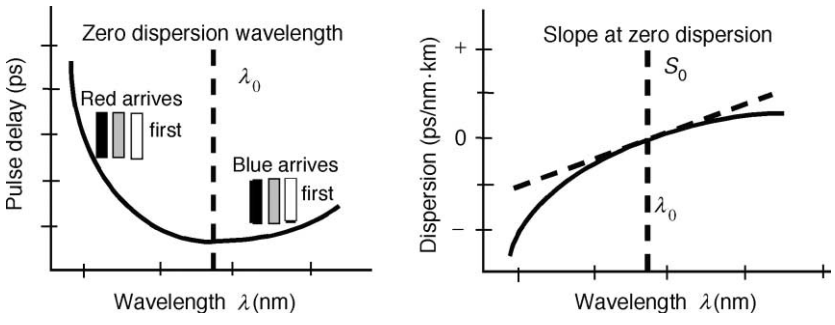

Figure 10 Relation between the pulse (group) delay and the (chromatic) dispersion.

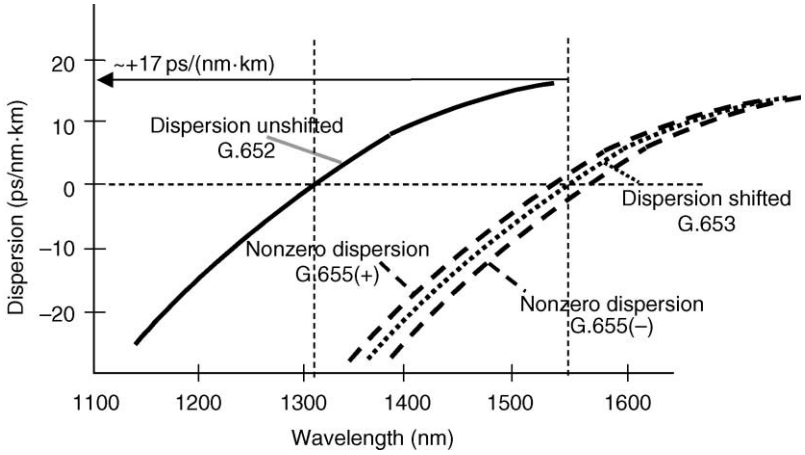

Figure 11 Chromatic dispersion for various types of fiber.

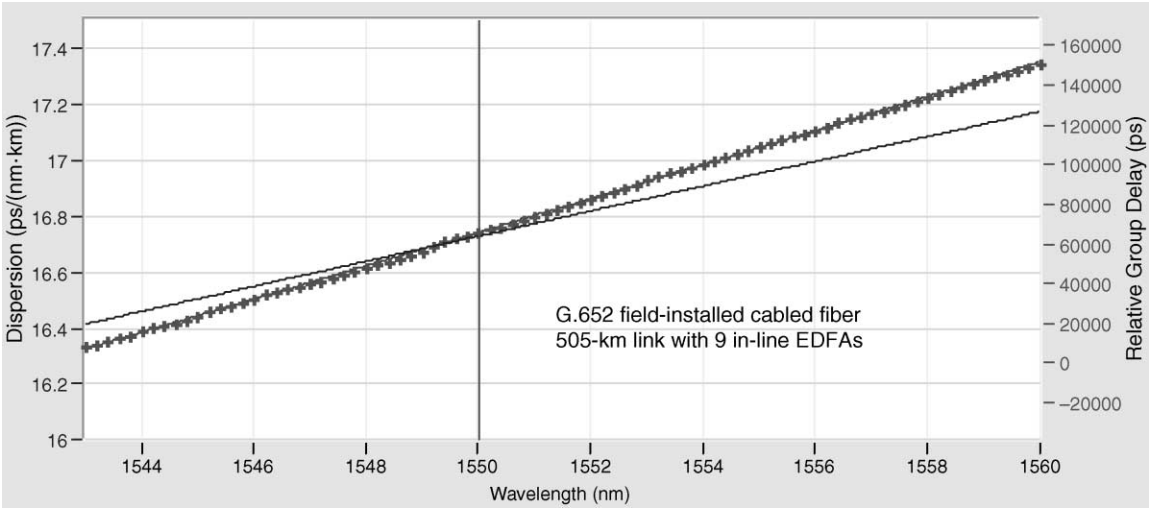

Figure 12 Test results for field-related chromatic dispersion using the phase-shift technique.

In the differential phase shift method, two detection systems are used together with two wavelength sources at the same time. In this case the chromatic dispersion may be determined directly from the two group delays. This technique usually offers faster and more reliable results but costs much more than the phase-shift technique which is usually preferred.

In the interferometric method, the group delay between the FUT and a reference path is measured by a Mach–Zehnder interferometer. The reference delay line may be an air path or a singlemode fiber standard reference material (SRM). The method can be used to determine the following characteristics:

- longitudinal chromatic dispersion homogeneity; and
- effect of overall or local influences, such as temperature changes and macrobending losses.

In the pulse delay method, the group delay is measured in the time domain, by detecting, recording, and processing the delay experienced by pulses at various wavelengths.

Polarization Mode Dispersion

Polarization mode dispersion (PMD) causes an optical pulse to spread in the time domain and may impair the performance of a telecommunications system. The effect can be related to differential phase and group velocities and corresponding arrival time of different polarization components of the pulse signal. For a sufficiently narrowband source, the effect can be related to a differential group delay (DGD), $\Delta\tau$, between a pair of orthogonally polarized principal states of polarization (PSP) at a given wavelength or optical frequency (see **Figure 13a**).

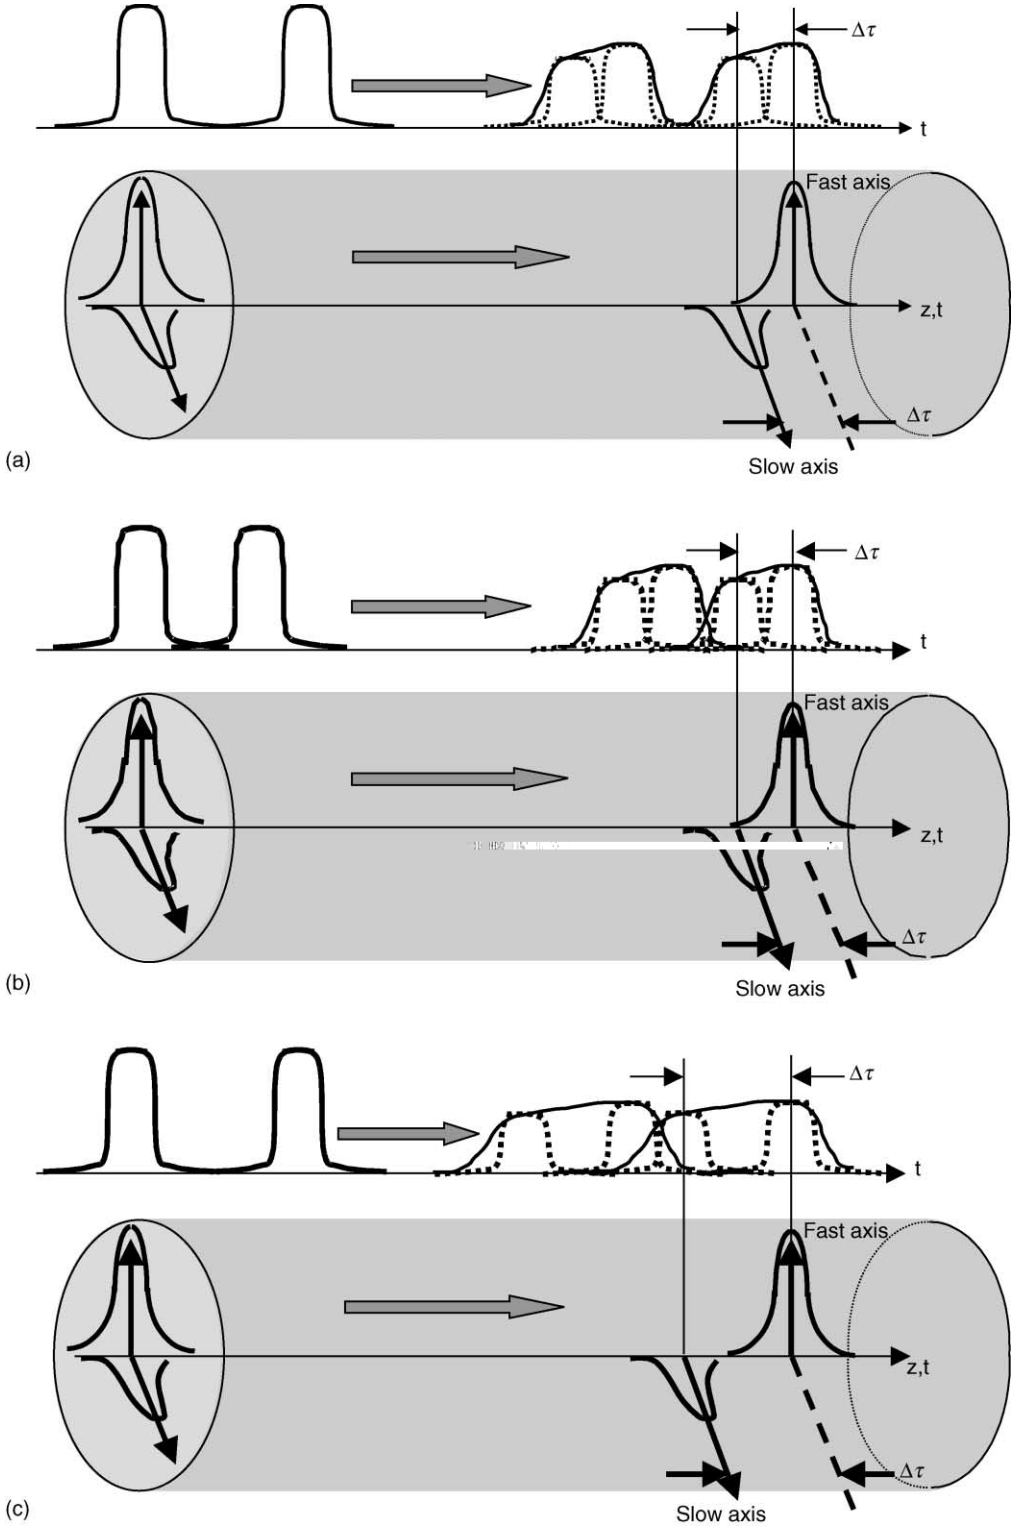

Figure 13 PMD effect on the pulse broadening and its possible pulse impairment. (a) The pulse is spread by the DGD $\Delta\tau$ but the bit rate is too low to create an impairment. (b) The pulse is spread by the DGD $\Delta\tau$ but the bit rate is high enough to create an impairment. (c) The DGD $\Delta\tau$ is large enough even at low bit rate to make the pulse spreading and creating impairment.

In an ideal circular symmetric fiber, the two PSPs propagate with the same velocity. However:

- a real fiber is not perfectly circular;
- the core is not perfectly concentric with the cladding;
- the core may be subjected to microbending;
- the core may present localized clusters of dopants; and
- the environmental conditions may stress the deployed cable and affect the fiber.

Each time the fiber undergoes local stresses and consequently birefringence. These asymmetry characteristics vary randomly along the fiber and in time, lead to a statistical behavior of PMD.

For a deployed cabled fiber at a given time and optical frequency, there always exist two PSPs such that the pulse spreading due to PMD vanishes, if only one PSP is excited. On the contrary, the maximum pulse spread due to PMD occurs when both PSPs are equally excited, and is related to the difference in their group delays, the DGD associated with the two PSPs. For broadband transmission, the DGD statistically varies as a function of wavelengths or frequencies and result in an output pulse that is spread out in the time domain (see **Figures 13a–c**). In this case, the spreading can be related to the RMS (root mean square) of DGD values $\langle \Delta\tau^2 \rangle^{1/2}$. However, if a known distribution such as the Maxwell distribution may be fit to the DGD distribution probability, then a mean (or average) value of the DGD $\langle \Delta\tau \rangle$ may be correlated to the RMS value and used as a system performance predictor in particular with a maximum value of the DGD distribution associated to a low probability of occurrence. This maximum DGD may then be used to define the quality of service that would tolerate values lower than this maximum DGD.

Test methods for polarization mode dispersion

Three methods are generically used for measuring PMD. Other methods or analyses may exist but they are generally not standardized or are limited in their applications.

- Stokes parameter evaluation (SPE)
  - Jones matrix eigenanalysis (JME)
  - Poincaré sphere analysis (PSA)
- Fixed analyzer (FA)
  - Extrema counting (EC)
  - Fourier transform (FT)
- Interferometry (INTY)
  - Traditional analysis (TINTY)
  - General analysis (GINTY).

All methods use a linearly polarized source at the FUT input and are suitable for laboratory measurements of factory lengths of fiber and cable. However, the interferometric method is the only method appropriate for measurements of cabled fiber that may be moving or vibrating such as is found in the field.

Stokes parameter evaluation. SPE determines PMD by measuring a response to a change of narrowband light (from a tuneable light source with broadband detector – JME, or a broadband source with a filtered detector such as an interferometer – PSA) across a wavelength range. The Stokes vector of the output light is measured for each wavelength. The change of these Stokes vectors with angular optical frequency (wavelength), ω and with the change in input SOP (state of polarization), yields the DGD as a function of wavelength.

For both JME and PSA analyses, three distinct and known linear SOPs (orthogonal on the Poincaré sphere) must be launched for each wavelength. **Figure 14** illustrates the test setup and examples of test results.

The JME and PSA method are mathematically equivalent.

Fixed analyzer. FA determines PMD by measuring a response to a change of narrowband light across a wavelength range. For each SOP, the change in output power that is filtered through a fixed polarization analyzer, relative to the power detected without the analyzer, is measured as a function of wavelength. **Figure 15** illustrates a test setup and examples of test results.

The resulting measured function can be analyzed in one of two ways:

- by counting the number of peaks and valleys (EC) of the curve and application of a formula. This analysis is considered as a frequency domain approach; and
- by taking the Fourier transform (FT) of the measured function. This FT is equivalent to the pulse spreading obtained by TINTY.

Interferometry. INTY uses a broadband light source and an interferometer. The fringe pattern containing the source auto-correlation, together with the PMD related cross-correlation of the emerging electromagnetic field, is determined by the interference pattern of the output light, i.e., the interferogram. The PMD determination for the wavelength range associated with the source spectrum is based on the envelope of the fringe

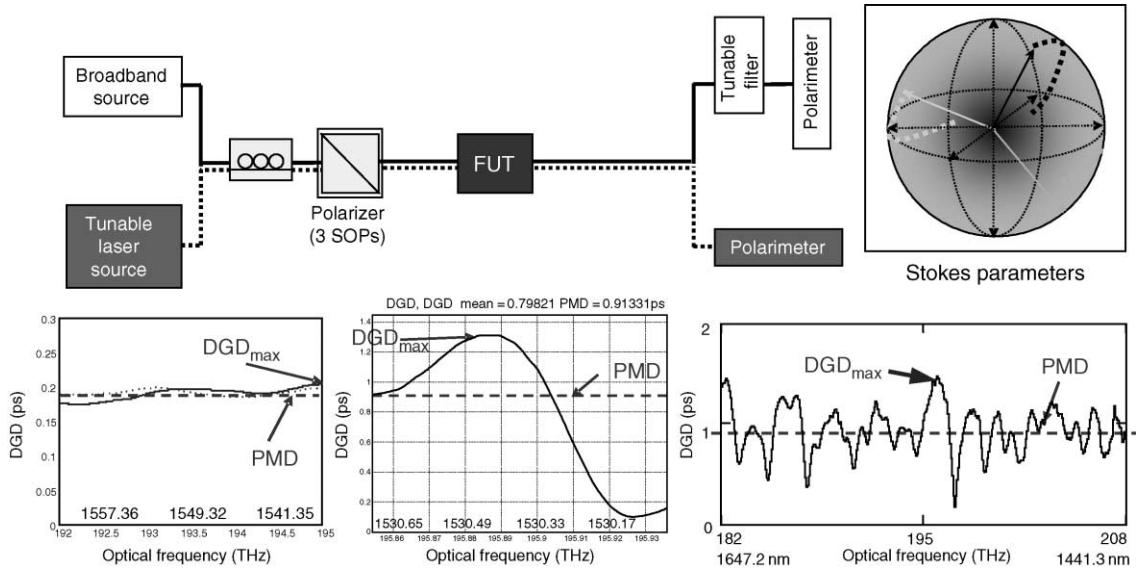

Figure 14 PMD by Stokes parameter evaluation method.

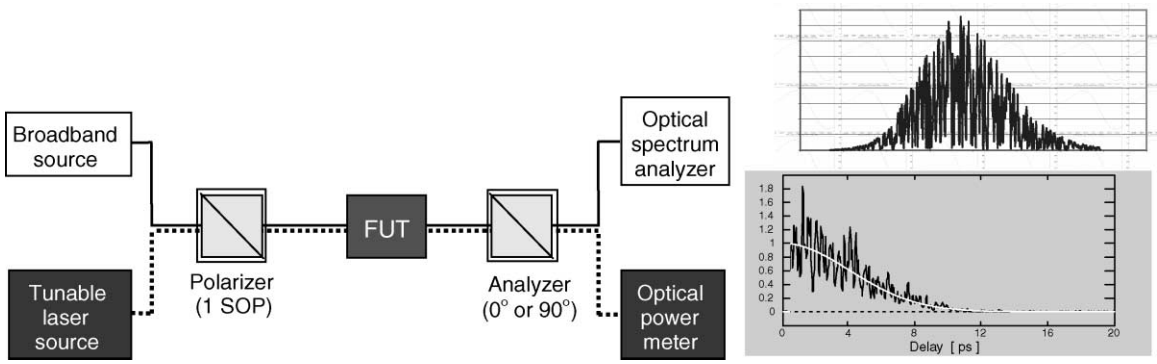

Figure 15 PMD by fixed analyzer method.

pattern interferogram. Two analyses are available to obtain the PMD:

- TINTY uses a set of specific operating conditions for its successful applications and a basic setup; and
- GINTY uses no limiting operating conditions, but in addition to the same basic setup, also using a modified setup compared to TINTY.

Figure 16 illustrates the test setup for both approaches and examples of test results.

Polarization Crosstalk

Polarization crosstalk is a characteristic of energy mixing/transfer/coupling between the two PSPs in a PMF (polarization maintaining fiber) when their isolation is imperfect. It is the measure of the strength of mode coupling or output power ratio between the PSPs within a PMF.

A PMF is an optical fiber capable of transmitting, under external perturbations, such as bending or lateral pressures, both HE_{11}^{x} and HE_{11}^{y} polarization modes whose electric field vector directions are orthogonally to each other and which have different propagation constants β_x and β_y.

Two methods are available for measuring the polarization crosstalk of PMF:

- *power ratio method*, which uses the maximum and minimum values of output power at a specified wavelength, and is applicable to fibers and connectors jointed to a PMF, and to two or more PMFs joined in series; and
- *in-line method*, which uses an analysis of the Poincaré sphere, and is applicable to single or cascaded sections of PMF, and to PMF interconnected with optical devices.

Nonlinear Effects

When the power of the transmission signal is increased to achieve longer span lengths at high bit

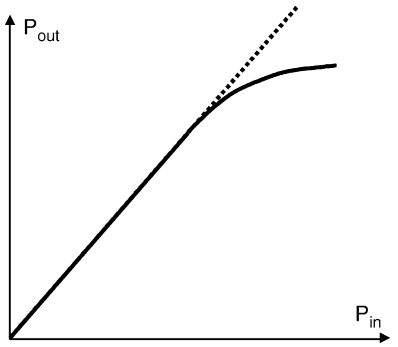

Figure 17 Power output-to-power input relationship for production of nonlinear effects.

expressed as follows:

$$n = n_0 + n_2 I \qquad [18]$$

n is the nonlinearity dependent index; n_0 is the linear part of the index; n_2 is the nonlinear index, also called the Kerr nonlinear index (2.2 to 3.4 $\times 10^{-16}$ cm^2/W); and I is the optical intensity inside the fiber.

The field propagation at a distance L into the fiber is described by the following equation:

$$E_{\text{out}}(L) = E_{\text{in}}(0)\exp[-a/2 + \mathrm{i}\beta + \gamma P(L,t)/2]L \qquad [19]$$

$a/2$ is the attenuation; $\mathrm{i}\beta$ is the phase of the wave; and $\gamma P(L,t)/2$ is the nonlinearity term;

$$\gamma = 2\pi n_2/\lambda A_{\text{eff}} \qquad [20]$$

γ is the nonlinearity coefficient and may be a complex number; A_{eff} is the fiber core effective area; $P(L,t)$ is the total power; and λ is the signal wavelength and t the time variable.

The nonlinear coefficient is defined as n_2/A_{eff}. This coefficient plays a critical role in the fiber and is closely related to system performance degradation due to nonlinearities when very high power is used.

Methods for measuring the nonlinear coefficient. Two methods are available for measuring the nonlinear coefficient:

- Continuous-wave dual-frequency (CWDF); and
- Pulsed single-frequency (PSF).

In the CWDF method, light from two wavelengths is injected into the fiber. At higher power, the light from the two wavelengths beat due to the nonlinearity and produce an output spectrum that is spread. The relationship of the power level to a particular spreading is used to calculate the nonlinear coefficient.

In the PSF method, the pulsed light from a single wavelength is injected into the fiber. Very short pulses (<1 ns) and their input peak power must be measured and related to the nonlinear spreading of the output spectrum.

Stimulated Brillouin scattering

In an intensity modulated system using a source with a narrow linewidth, significant optical power is transferred from the forward-propagating signal to a backward-propagating signal when the SBS power threshold is exceeded. At that point periodic regions of index of refraction produce a grating traveling at speed of sound away from the source. The grating reflects backward part of the incident light. The reflected sound waves (acoustic phonons) scatter light back to the source. Phase matching (or momentum conservation) dictates that the scattered light preferentially travels in the backward direction. The scattered light will be Doppler-shifted (downshifted or Brillouin-shifted) by approximately 11 GHz (at 1550 nm, for G.652 fiber). The scattered light has a very narrow spectrum (very coherent) and very close to the carrier signal and may be very detrimental.

Stimulated Raman scattering

SRS is an interaction between light and the fiber molecular vibrations as adjacent atoms vibrate in opposite directions (an 'optical phonon'). Some of the energy of the main carrier (optical pump wave) is transferred to the molecules, thereby further increasing the amplitude of their vibrations. If the vibrations become large enough, a threshold is reached at which the local index of refraction changes. These local changes then scatter light in all directions similar to Rayleigh scattering. However, unlike Rayleigh scattering, the wavelength of the Raman scattered light is shifted to longer wavelengths by an amount that corresponds to the molecular vibration frequencies and the Raman signal spreads over a large spectrum.

Self-phase modulation

SPM is the effect that a powerful pulse has on its own phase, considering that in eqn [18], $I(t)$ varies in time:

- $I(t) \rightarrow n(t) = n_0 + n_2 I(t) \rightarrow$ modulates the phase $\beta(t)$ of the pulse; and
- $\mathrm{d}I/\mathrm{d}t \rightarrow \mathrm{d}n/\mathrm{d}t \rightarrow \mathrm{d}\beta/\mathrm{d}t(\text{chirp}) \rightarrow$ broadening in the frequency domain $\rightarrow$ broadening in the time domain.

$I(t)$ peaks at the center of the pulse (peak power) and consequently increases the index of refraction. A higher index causes the wavelengths in the center of the pulse to accumulate phase more quickly than at the wings of the pulse:

- this causes wavelength stretching (shift to longer wavelengths) at pulse leading edge (risetime); and
- this causes wavelength compression (shift to shorter wavelengths) at pulse trailing edge (falltime).

The pulse will then broaden with negative (normal) dispersion and shorten with positive (anomalous) dispersion. SPM may then be used for dispersion compensation considering that self-phase modulation imposes $C > 0$ (positive chirp). It can cancel the dispersion if properly manage as a function of the sign of the dispersion. SPM is one of the most critical nonlinear effects for the propagation of soliton or very short pulses over very long distance.

Cross-phase modulation

XPM is the effect that a powerful pulse has on the phase of an adjacent pulse from another WDM system channel traveling in phase or at slightly the same group velocity. It concerns spectral interference between two WDM channels:

- the increasing $I(t)$ at the leading edge of the interfering pulse shifts the other pulse to longer wavelength; and
- decreasing $I(t)$ at the trailing edge of the interfering pulse shifts the other pulse to shorter wavelengths.

This produces spectral broadening, which dispersion converts to temporal broadening depending on the sign of the dispersion. XPM effect is similar to SPM except it depends on the channel count.

Four-wave (four-photon) mixing

FWM is the by-product production effect from two or more WDM channels. For two channels $I(t)$ modulates the phase of each signal (ω_1 and ω_2). An intensity modulation appears at the beat frequency $\omega_1 - \omega_2$.

Two sideband frequencies are created in a similar way as harmonics generation. New wavelengths are created in a number equal to $N^2(N-1)/2$, where $N =$ number of original wavelengths.

Fiber Dimension Characteristics and Corresponding Tests Methods

Table 1 provides a list of the various fiber dimensional characteristics and their corresponding test methods.

Table 1 Fiber dimensional characteristics

Fiber Geometry Characteristics

The fiber geometry is related to the core and cladding characteristics.

Core

The core center is the center of a circle which best fits the points at a constant level in the near-field intensity profile emitted from the central region of the fiber, using wavelengths above and/or below the cut-off wavelength.

The RIP can be measured by refracted near field (RNF) or transverse interferometry techniques and transmitted near field (TNF).

The core concentricity error is the distance between the core center and the cladding center. This definition applies very well for multimode fibers. The distance between the center of the near field profile and the center of the cladding is also used for singlemode fibers.

The mode field diameter (MFD) represents a measure of the transverse electromagnetic field intensity of the mode in a fiber cross-section and it is defined from the far-field intensity distribution.

The MF is the singlemode field distribution of the LP_{01} mode, giving rise to a spatial intensity distribution in the fiber.

The MF concentricity error is the distance between the MF center and the cladding center.

The core noncircularity is a measure of the core ellipticity. This parameter is one of the causes for creating birefringence in the fiber and consequently PMD.

Cladding

The cladding is the outermost region of constant refractive index in the fiber cross-section.

The cladding center is the center of a circle best fitting the outer limit (boundary) of the cladding.

The cladding diameter is the diameter of the circle defining the cladding center.

The cladding noncircularity is a measure of the difference between the diameters of the two circles defined by the cladding tolerance field divided by the nominal cladding diameter.

Coating

The primary coating is one or more layers of protective material applied to the cladding during or after the drawing process to protect the cladding surface (e.g., a 250 μm protective coating). The secondary coating is one or more layers of protective material applied over the primary coating in order to give additional protection or to provide a particular structure.

Measurement of the fiber geometrical attributes
The fiber geometry is measured by the following methods:

- TNF;
- RNF;
- Side-view technique/transverse interference;
- TNF image technique; and
- Mechanical diameter.

Test instrumentation may incorporate two or more methods such as the one shown in Figure 18.

Transmitted near-field technique. The cladding diameter, core concentricity error, and cladding noncircularity are determined from the near-field intensity distribution. Figure 19 provides a series of examples of test results from TNF measurements.

Refracted near-field technique. The RIP across the entire fiber (core and cladding) can be directly obtained from the RNF measurement, as shown in Figure 20.

The geometrical characteristics of the fiber can be obtained from the refractive index distribution using suitable algorithms:

- core/cladding diameter;
- core/cladding concentricity error;
- core/cladding noncircularity;
- maximum numerical aperture (NA); and
- index and relative index of refraction difference.

Figure 21 illustrates the core geometry.

Side-view technique/transverse interference. The side-view method is applied to singlemode fibers to determine the core concentricity error, cladding diameter and cladding noncircularity by measuring the intensity distribution of light that is refracted inside the fiber. The method is based on an interference microscope focused on the side view of an FUT illuminated perpendicular to the FUT axis. The fringe pattern is used to determine the RIP.

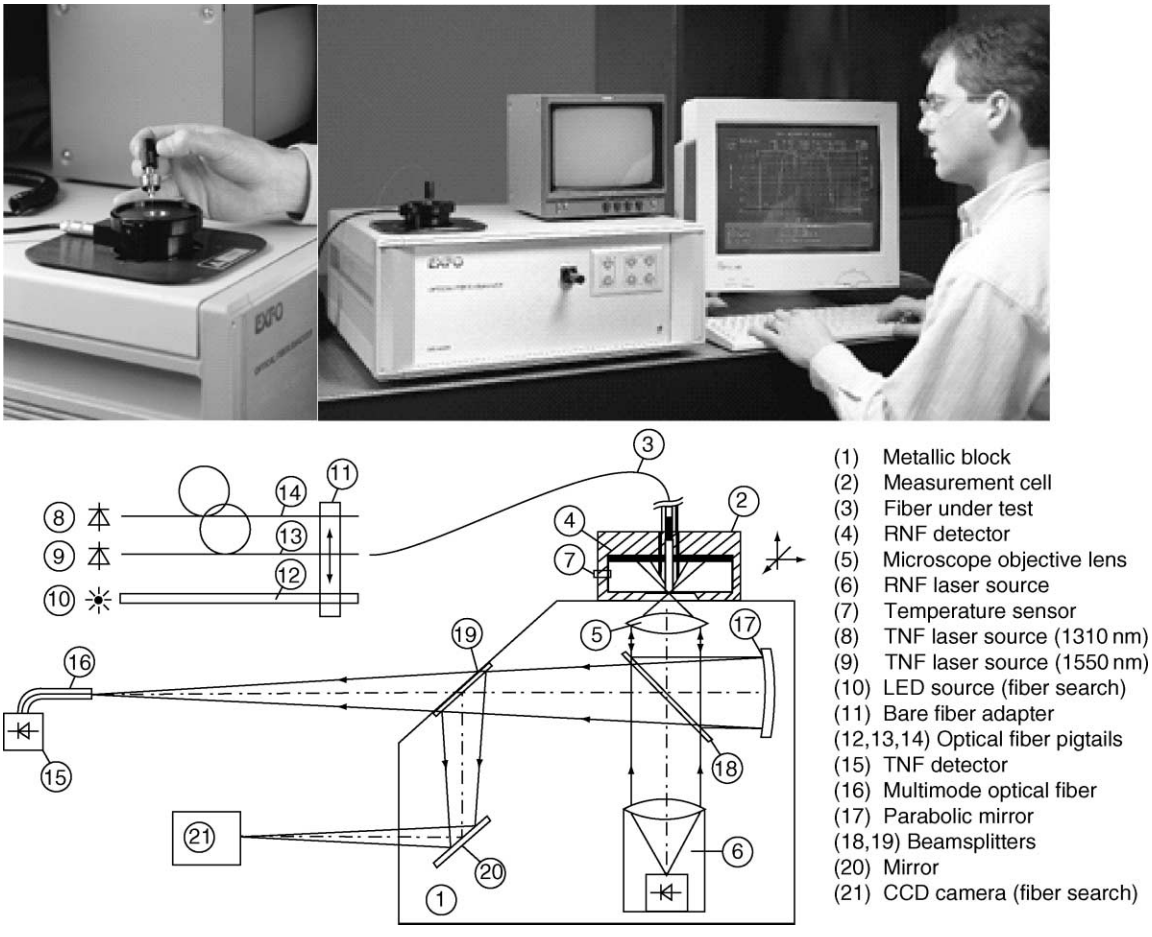

Figure 18 RNF/TNF combined instrumentation.

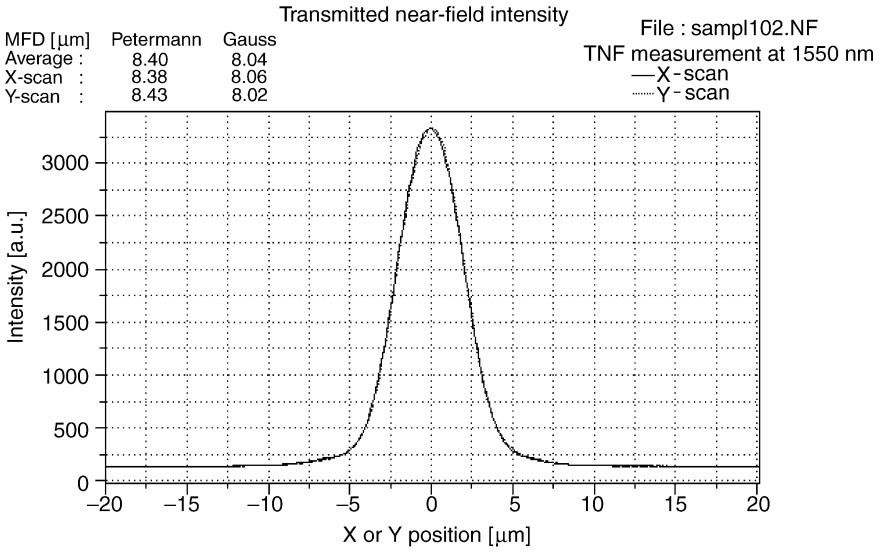

Figure 19 MFD measurement by TNF.

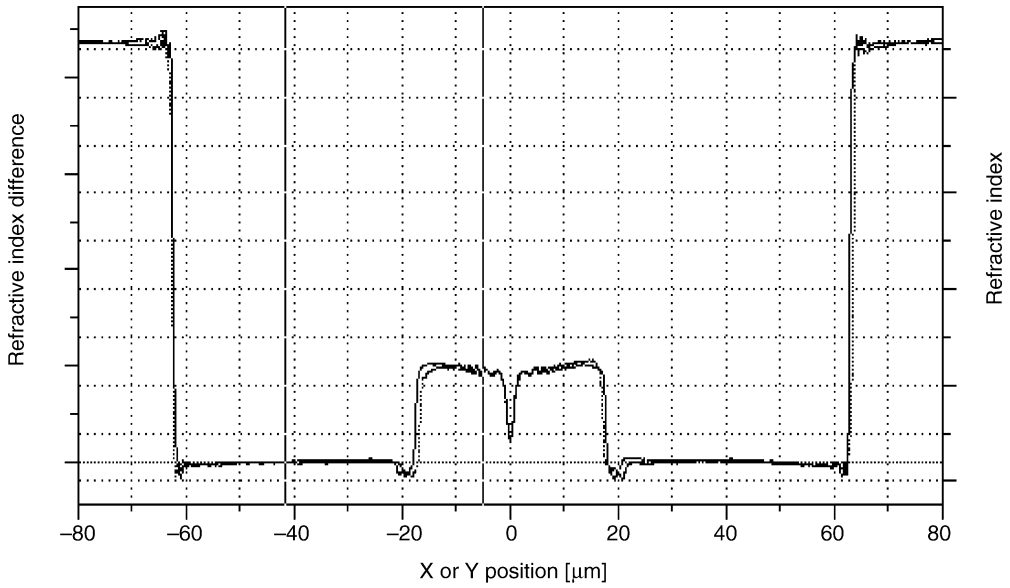

Figure 20 RIP from RNF measurement.

TNF image technique. The TNF image technique, also called near-field light distribution, is used for the measurement of the geometrical characteristics of singlemode fibers. The measurement is based on analysis of magnified images at the FUT output. Two subsets of the method are available:

- grey-scale technique which performs an x–y near-field scan using a video system; and
- Single near-field scanning technique performing a one-dimensional scan.

Mechanical diameter. This is a precision mechanical diameter measurement technique used to accurately determine the cladding diameter of silica fibers. The technique uses an electronic micrometer such as based on a double-pass Michelson interferometer. The technique is used for providing calibrated fibers to the industry as SRM.

Numerical Aperture

The NA is an important attribute for multimode fibers in order to predict their launching efficiency, joint loss at splices and micro/macrobending characteristics.

A method is available for the measurement of the angular radiant intensity distribution (far-field)

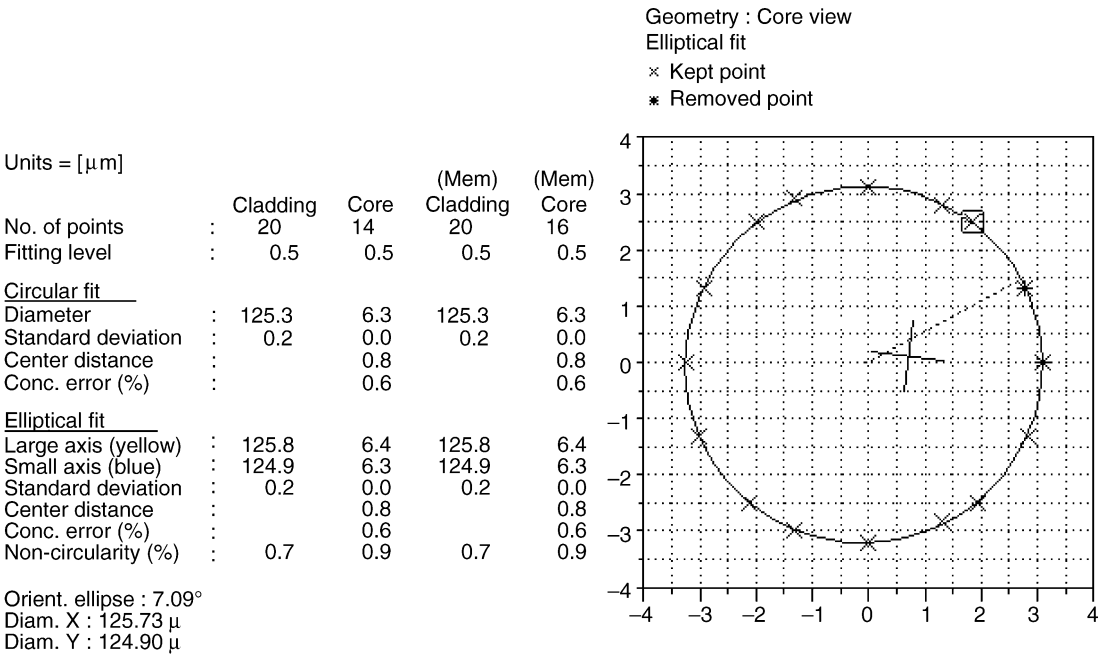

Figure 21 Core geometry by RNF measurement.

distribution or the RIP at the output of an FUT. NA can be determined from the analysis of the test results.

Mode Field Diameter

The definition of the MFD is given in the section describing the core center above. Four measurement methods are available:

- direct far-field scan determines MFD from the far-field intensity distribution;
- variable aperture in far field determines MFD from the complementary aperture transmission function $a(x)$, $x = d \tan \theta$ being the aperture radius and d the distance between the aperture and the FUT:

$$\mathrm{MFD} = \frac{\lambda}{\pi d}\left[\int_0^\infty a(x)\frac{x}{(x^2+d^2)^2}\,\mathrm{d}x\right]^{-1/2} \qquad [21]$$

Equation [21] is valid for small-θ approximation.

- near-field scan determines MFD from the near-field intensity distribution I_{NF}, r being the radial coordinate:

$$\mathrm{MFD} = 2\left[2\frac{\int_0^\infty rI_{\mathrm{NF}}(r)\,\mathrm{d}r}{\int_0^\infty r\left[\dfrac{\mathrm{d}I^{1/2}(r)}{\mathrm{d}r}\right]^2\mathrm{d}r}\right]^{1/2} \qquad [22]$$

Equation [22] is valid for small-θ approximation; and

- bidirectional backscattering uses an OTDR and bidirectional measurements to determine MFD by comparing the FUT results with a reference fiber.

Effective Area

A_{eff} is a critical nonlinearity parameter and is defined as follows:

$$A_{\mathrm{eff}} = \frac{2\pi[\int_0^\infty I(r)r\,\mathrm{d}r\,]^2}{\int_0^\infty I(r)^2 r\,\mathrm{d}r} \qquad [23]$$

$I(r)$ is the field intensity distribution of the fiber fundamental mode at radius r. The integration in the equation is carried out over the entire fiber cross-section. For a Gaussian approximation:

$$I(r) = \exp - 2\left(\frac{2r}{\mathrm{MFD}}\right)^2 \qquad [24]$$

which yields:

$$A_{\mathrm{eff}} = \frac{\pi}{4}\mathrm{MFD}^2 \qquad [25]$$

Three methods are available for the measurement of A_{eff}:

- direct far-field;
- variable aperture in far-field; and
- near-field.

Mechanical Measurement and Test Methods

Table 2 describes the various mechanical characteristics and their corresponding test methods.

Proof Stressing

The proof stress level is the value of tensile stress or strain applied to a full fiber length over a short period of time. The method for fiber proof stressing is the longitudinal tension which describes procedures for applying tensile loads to a length of fiber. The fiber stress is calculated from the applied tension. The tensile load is applied over short periods of time but not too short in order for the fiber to experience proof stress.

Residual Stress

Residual stress is the stress built up by the thermal expansion difference between core and cladding during the fiber drawing process or splicing. Methods are available for measuring residual stress based on polarization effects. A light beam produced by a rotating polarizer propagates to the x-axis direction while the beam polarization is in the $y-z$ plane and the fiber longitudinal axis in the z-axis. The light experiences different phase shift in the y- and z-axis due to the FUT birefringence. The photoelastic effect gives the relationship between this phase change and residual stresses.

Stress Corrosion Susceptibility

The stress corrosion susceptibility is related to the dependence of crack growth on applied stress. It depends on the environmental conditions and static and dynamic values may be observed.

Environmental Characteristics

Table 3 lists the fiber characteristics related to the effect of the environment.

Hydrogen Aging for Low-Water-Peak Single-Mode Fiber

Hydrogen aging on low-water peak fibers, such as G.652.C, is based on a test performed at 1.0 atmosphere of hydrogen pressure at room temperature over a period of one month. Other proportional combinations are possible.

Nuclear Gamma Irradiation

Nuclear radiation is considered on the basis of a steady state response of optical fibers and cables exposed to gamma radiation and to determine the level of related radiation-induced attenuation produced in singlemode or multimode cabled or uncabled fibers.

The fiber attenuation generally increases when exposed to gamma radiation. This is primarily due to the trapping of radiolytic electrons and holes at defect sites in the glass (i.e., the formation of 'color centers'). Two regimes are considered:

- the low dose rate suitable for estimating the effect of environmental background radiation; and
- the high dose rate suitable for estimating the effect of adverse nuclear environments.

The effects of environmental background radiation are measured by the attenuation (cut-back method). The effects of adverse nuclear environments are tested by power monitoring before, during and after FUT exposure.

Introduction

Many physical systems in various areas such as condensed matter or plasma physics, biological sciences, or optics, give rise to localized large-amplitude excitations having a relatively long lifetime. Such excitations lead to a host of phenomena referred to as nonlinear phenomena. Of the many disciplines of physics, the optics field is probably the one in which practical applications of nonlinear phenomena have been the most fruitful, in particular, since the discovery of the laser in 1960. This discovery has thus led to the advent of a new branch in optics, referred to as *nonlinear optics*. The applications of nonlinear phenomena in optics include the design of various kinds of laser sources, optical amplifiers, light converters, light-wave communication systems for data transmission purposes, to name a few.

In this article, we present an overview of some basic principles of nonlinear phenomena that result from the interaction of light waves with dielectric waveguides such as optical fibers. These nonlinear phenomena can be broadly divided into two main categories, namely, parametric effects and scattering phenomena. Parametric interactions arise whenever the state of the dielectric matter is left unchanged by the interaction, whereas scattering phenomena imply transitions between energy levels in the medium. More fundamentally, parametric interactions originate from the electron motion under the electric field of a light wave, whereas scattering phenomena originate from the motion of heavy ions (or molecules).

Linear and Nonlinear Signatures

The macroscopic properties of a physical system can be obtained by analyzing the response of the system under an external excitation. For example, consider at time t the response of a system, such as an amplifier, to an input signal $E_1 = A\sin(\omega t)$. In the low-amplitude limit of the output signal, the response R_1 of the system is proportional to the excitation:

$$R_1 = \alpha_1 E_1 \qquad [1]$$

where α_1 is a constant. This type of behavior corresponds to the so-called linear response. In general, a physical system executes a linear response when the superposition of two (or more) input signals E_1 and E_2 yields a response which is a superposition of the output signals, as schematically represented in Figure 1:

$$R = \alpha_1 R_1 + \alpha_2 R_2 \qquad [2]$$

Now, in almost all real physical systems, if the amplitude of an excitation E_1 becomes sufficiently large, distortions will occur in the output signals. In other words, the response of the system will no longer be proportional to the excitation, and consequently, the law of superposition of states will no longer be observed. In this case, the response of the system may take the following form:

$$R = \alpha_1 E_1 + \alpha_2 E_1^2 + \alpha_3 E_1^3 + \ldots \qquad [3]$$

which involves not only a signal at the input frequency ω, but also signals at frequencies 2ω, 3ω, and so on. Thus, harmonics of the input signal are generated. This behavior, called *nonlinear response*, is at the origin of a host of important phenomena in many

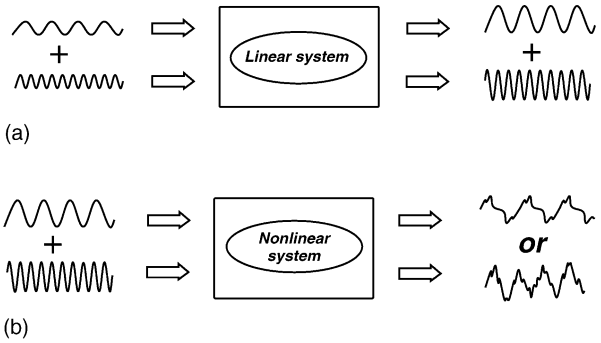

Figure 1 Schematic representation of linear and nonlinear responses of a system, to two input signals.

branches of sciences, such as in condensed matter physics, biological sciences, or in optics.

Physical Origin of Optical Nonlinearity

Optical nonlinearity originates fundamentally from the action of the electric field of a light wave on the charged particles of a dielectric waveguide. In contrast to conductors where charges can move throughout the material, dielectric media consist of *bound* charges (ions, electrons) that can execute only relatively limited displacements around their equilibrium positions. The electric field of an incoming light wave will cause the positive charges to move in the polarization direction of the electric field whereas negative charges will move in the opposite direction. In other words, the electric field will cause the charged particles to become dipoles, as schematically represented in Figure 2.

Then each dipole will vibrate under the influence of the incoming light, thus becoming a source of radiation. The global light radiated by all the dipoles represents the scattered light. When the charge displacements are proportional to the excitation (incoming light), i.e., in the low-amplitude limit of scattered radiation, the output light vibrates at the same frequency as that of the excitation. This process corresponds to Rayleigh scattering. On the other hand, if the intensity of the excitation is sufficiently large to induce displacements that are not negligible with respect to atomic distances, then the charge displacements will no longer be proportional to the excitation. In other words, the response of the medium, which is no longer proportional to the excitation, becomes nonlinear. In this case, the scattered waves will be generated not only at the excitation frequency (the Kerr effect), say ω, but also at frequencies that differ from ω (e.g., 2ω, 3ω). On the other hand, it is worth noting that when all induced dipoles vibrate coherently (that is, their relative phase does not vary randomly), their individual radiation may, under certain conditions, interfere constructively and lead to a global field of high intensity.

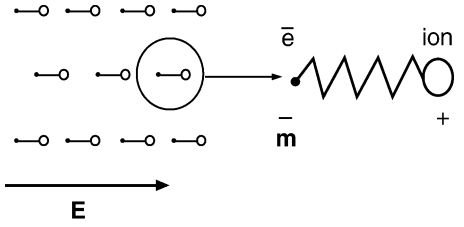

Figure 2 Electric dipoles in a dielectric medium under an external electric field.

The condition of constructive interference is the phase-matching condition.

In practice, the macroscopic response of a dielectric is given by the polarization, which corresponds to the total amount of dipole moment per unit volume of the dielectric. As the mass of an ion is much larger than that of an electron, the amplitude of the ion motion is generally negligible with respect to that of the electrons. As a consequence, the electron motion generally leads to the dominant contribution in the macroscopic properties of the medium. The behavior of an electron under an optical electric field is similar to that of a particle embedded in an anharmonic potential. A very simple model (called the Lorentz model) that provides a deep insight into the dielectric response consists of an electron of mass m and charge $-e$ connected to an ion by an elastic spring (see Figure 2). Under the electric field $E(t)$, the electron executes a displacement $x(t)$ with respect to its equilibrium position, which is governed by the following equation:

$$\frac{d^2x}{dt^2} + 2\lambda\frac{dx}{dt} + \omega_0^2 x + (a^{(2)}x^2 + a^{(3)}x^3 + \cdots) = -\frac{e}{m}E(t) \qquad [4]$$

where $a^{(2)}$, $a^{(3)}$, and so on, are constant parameters, ω_0 is the resonance angular frequency of the electron, and λ is the damping coefficient resulting from the dipolar radiation. When the amplitude of the electric field is sufficiently large, then the restoring force on the electrons becomes a nonlinear function of x; hence the presence of terms such as $a^{(2)}x^2$, $a^{(3)}x^3$, and so on, in eqn [4]. In this situation, the macroscopic response of the dielectric is the polarization

$$P = -\sum ex(\omega, 2\omega, 3\omega, \ldots) \qquad [5]$$

where $x(\omega, 2\omega, 3\omega, \ldots)$ is the solution of eqn [4] in the frequency domain, and the summation extends over all the dipole moments per unit volume. In terms of the electric field E the polarization may be written as

$$P = \varepsilon_0(\chi^{(1)}E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \cdots) \qquad [6]$$

where $\chi^{(1)}$, $\chi^{(2)}$, $\chi^{(3)}$, and so on, represent the susceptibility coefficients. Figure 3 (top left) illustrates schematically the polarization as a function of the electric field.

In particular, one can clearly observe that when the amplitude of the incoming electric field is sufficiently small (bottom left in Figure 3), the polarization (top right) is proportional to the electric field (bottom left), thus implying that the electric dipole radiates a wave having the same frequency as that of the incoming light (bottom right). On the other hand, Figure 4

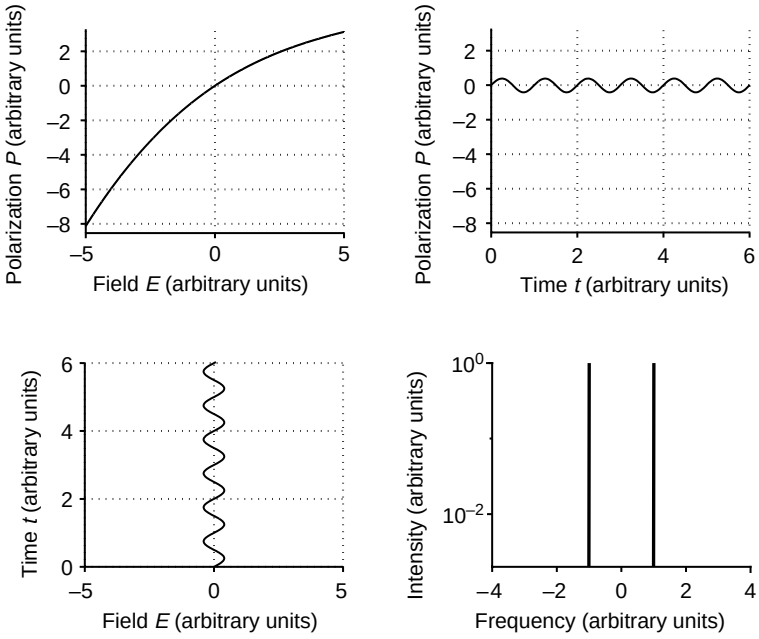

Figure 3 Polarization induced by an electric field of small amplitude. Nonlinear dependence of the polarization as a function of field amplitude (top left) and time dependence of the input electric field (bottom left). Time dependence of the induced polarization (top right) and corresponding intensity spectrum (bottom right).

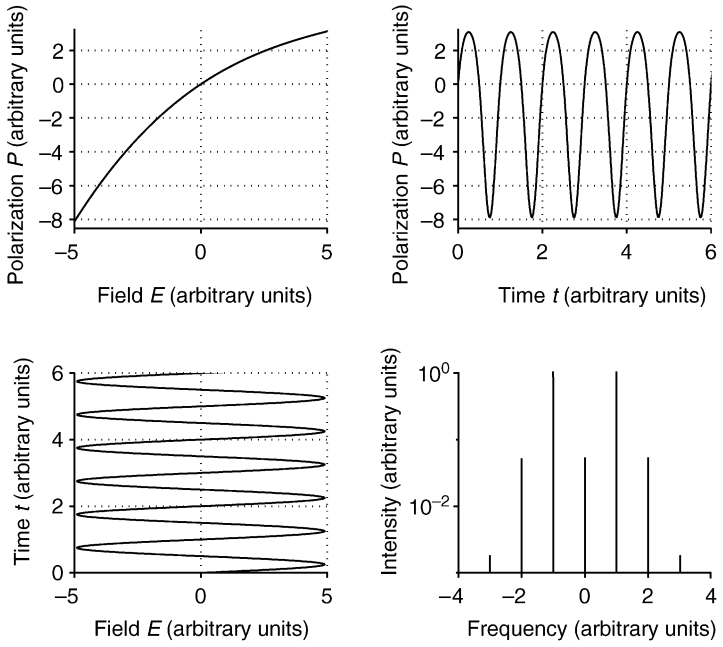

Figure 4 Polarization induced by an incoming electric field of large amplitude.

shows that for an electric field of large amplitude, the polarization is no longer proportional to the electric field, leading to radiation at harmonic frequencies (see Figure 4, bottom right).

This nonlinear behavior leads to a host of important phenomena in optical fibers, which are useful for many optical systems but detrimental for other systems.

Parametric Phenomena in Optical Fibers

In anisotropic materials, the leading nonlinear term in the polarization, i.e., the $\chi^{(2)}$ term, leads to phenomena such as the harmonic generation or optical rectification. This $\chi^{(2)}$ term vanishes in homogeneous isotropic materials such as cylindrical

optical fibers, and there the leading nonlinear term becomes the $\chi^{(3)}$ term. Thus, most of outstanding nonlinear phenomena in optical fibers originate from the third-order nonlinear susceptibility $\chi^{(3)}$. Some of those phenomena are described below.

Optical Kerr Effect

The optical Kerr effect is probably the most important nonlinear effect in optical fibers. This effect induces an intensity dependence of the refractive index, which leads to a vast wealth of fascinating phenomena such as self-phase modulation (SPM), cross-phase modulation (CPM), four-wave mixing (FWM), modulational instability (MI) or optical solitons. The Kerr effect can be conveniently described in the frequency domain through a direct analysis of the polarization, which takes the following form:

$$P_{\mathrm{NL}}(\omega) = \frac{3}{4}\varepsilon_0\chi^{(3)}(\omega)|E(\omega)|^2E(\omega) \qquad [7]$$

The constant 3/4 comes from the symmetry properties of the tensor $\chi^{(3)}$. Setting $P_{\mathrm{NL}}(\omega) = \varepsilon_0\varepsilon_{\mathrm{NL}}E(\omega)$, where $\varepsilon_{\mathrm{NL}} = \frac{3}{4}\chi^{(3)}|E|^2$ is the nonlinear contribution to the dielectric constant, the total polarization takes the form

$$P(\omega) = P_{\mathrm{L}} + P_{\mathrm{NL}} = \varepsilon_0[\chi^{(1)}(\omega) + \varepsilon_{\mathrm{NL}}]E(\omega) \qquad [8]$$

As eqn [8] shows, the refractive index n, at a given frequency ω, is given by

$$n^2 = 1 + \chi^{(1)} + \varepsilon_{\mathrm{NL}} = (n_0 + \Delta n_{\mathrm{NL}})^2 \qquad [9]$$

with $n_0^2 = 1 + \chi^{(1)}$. In practice $\Delta n_{\mathrm{NL}} \ll n_0$, and then, the refractive index is given by

$$n(\omega, |E|^2) = n_0(\omega) + n_2^e|E|^2 \qquad [10]$$

where n_2^e is the nonlinear refractive index defined by $n_2^e = 3\chi^{(3)}/(8n_0)$. The linear polarization P_{L} is responsible for the frequency dependence of the refractive index, whereas the nonlinear polarization P_{NL} causes an intensity dependence of the refractive index, which is referred to as the optical Kerr effect. Knowing that the wave intensity I is given by $I = \alpha|E|^2$, with $\alpha = \frac{1}{2}\varepsilon_0 c n_0$, the refractive index can be then rewritten as

$$n(\omega, I) = n_0(\omega) + n_2 I \qquad [11]$$

with $n_2 = n_2^e/\alpha = 2n_2^e/(\varepsilon_0 c n_0)$. For fused silica fibers one has typically: $n_2 = 2.66 \times 10^{-20}\ \mathrm{m^2\ W^{-1}}$. For example, an intensity of $I = 1\ \mathrm{GW\ cm^{-2}}$ leads to $\Delta n_{\mathrm{NL}} = 2.66 \times 10^{-7}$, which is much smaller than $n_0 \approx 1.45$.

Four-Wave Mixing

The four-wave mixing (FWM) process is a third-order nonlinear effect in which four waves interact through an energy exchange process. Let us consider two intense waves, $E_1(\omega_1)$ and $E_2(\omega_2)$, with $\omega_2 > \omega_1$, called pump waves, propagating in an optical fiber. Hereafter we consider the simplest case when waves propagate with the same polarization. In this situation the total electric field is given by

$$\begin{aligned} E_{\mathrm{tot}}(\mathbf{r}, t) &= E_1 + E_2 \\ &= A_1(\omega_1)\exp[\mathrm{i}(\mathbf{k}_1\cdot\mathbf{r} - \omega_1 t)] \\ &\quad + A_2(\omega_2)\exp[\mathrm{i}(\mathbf{k}_2\cdot\mathbf{r} - \omega_2 t)] \end{aligned} \qquad [12]$$

where $\mathbf{k}_1$ and $\mathbf{k}_2$ are the wavevectors of the fields E_1 and E_2, respectively. Equation [7], which gives the nonlinear polarization induced by a single monochromatic wave, remains valid provided that the frequency spacing between the two waves is relatively small, i.e., $|\Delta\omega| = |\omega_2 - \omega_1| \ll \omega_0 = (\omega_1 + \omega_2)/2$. In this context, eqn [7] leads to

$$P_{\mathrm{NL}} \approx \frac{3}{4}\varepsilon_0\chi^{(3)}(\omega_0)|E_{\mathrm{tot}}|^2E_{\mathrm{tot}} \qquad [13]$$

Substituting eqn [12] in eqn [13] yields

$$\begin{aligned} P_{\mathrm{NL}} = 2n_0n_2\varepsilon_0\Big[&\left(|E_1|^2 + 2|E_2|^2\right)E_1 \\ &+ \left(|E_2|^2 + 2|E_1|^2\right)E_2 + E_1^2E_2^* + E_1^*E_2^2\Big] \end{aligned} \qquad [14]$$

The term $|E_1|^2E_1$ in the right-hand side of eqn [14] represents the self-induced Kerr effect on the wave ω_1. The term $|E_2|^2E_1$, which corresponds to a modification of the refractive index seen by the wave ω_1, due to the presence of the wave ω_2, represents the cross-Kerr effect. Thus, the refractive index at frequency ω_1 depends simultaneously on the intensities of the two pumps, i.e., $n = n(\omega_1, |E_1|^2, |E_2|^2)$. Similarly the third and fourth terms in the right-hand side of eqn [14] illustrate the self-induced and cross-Kerr effects on the wave ω_2, respectively. Note that the self-induced Kerr effect is responsible for a self-phase modulation, which induces a spectral broadening of a pulse propagating through the optical fiber, whereas the cross-Kerr effect leads to a cross-phase modulation that induces a spectral broadening of one wave in the presence of a second wave. The two last terms in the right-hand side of eqn [14] correspond to the generation of new waves at frequencies $2\omega_1 - \omega_2$ and $2\omega_2 - \omega_1$, respectively. The wave with the smallest frequency $2\omega_1 - \omega_2 = \omega_{\mathrm{s}}$ is called the Stokes wave, whereas the wave with the highest frequency $2\omega_2 - \omega_1 = \omega_{\mathrm{as}}$ is called the anti-Stokes wave. These two newly generated waves interact

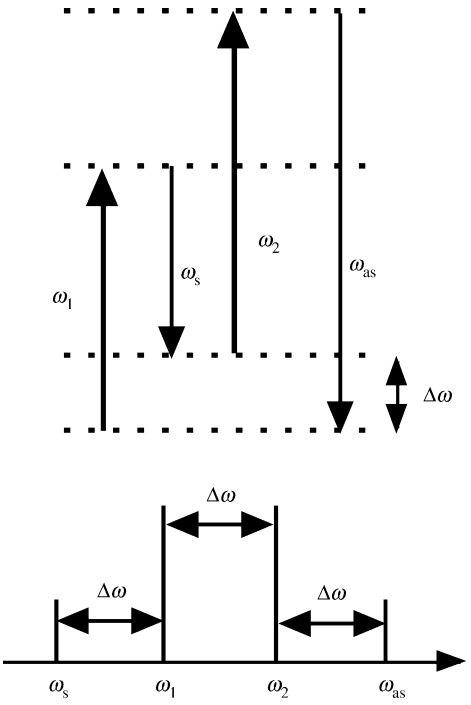

Figure 5 Schematic diagram representing a non-degenerate four-wave mixing process (top) and the corresponding frequency spectrum (bottom).

with the two pumps through an energy exchange process. This interaction is commonly referred to as a four-wave mixing process.

From a quantum mechanical point of view, four-wave mixing corresponds to a process in which two photons with frequencies ω_1 and ω_2 are annihilated with simultaneous creation of two photons at frequencies ω_s and ω_{as}, respectively. The new waves are generated at frequencies ω_s and ω_{as} such that

$$\omega_1 + \omega_2 = \omega_s + \omega_{as} \qquad [15]$$

which states that the total energy is conserved during the interaction. But the condition for this FWM process to occur is that the total momentum is conserved, that is,

$$\Delta\mathbf{k} = \mathbf{k}_s + \mathbf{k}_{as} - \mathbf{k}_1 - \mathbf{k}_2 = 0 \qquad [16]$$

or equivalently,

$$n(\omega_s)\omega_s + n(\omega_{as})\omega_{as} - n(\omega_1)\omega_1 - n(\omega_2)\omega_2 = 0 \quad [17]$$

Equation [16] is known as the phase-matching condition. Figure 5 displays a schematic diagram of a four-wave mixing process with the corresponding frequency spectrum.

FWM with different pump frequencies $\omega_1 \neq \omega_2$ is called 'nondegenerate FWM', whereas the case $\omega_1 = \omega_2$ is referred to as 'degenerate FWM', or more simply, as three-wave mixing.

Conclusion

Optical fibers constitute a key device for many areas of optical sciences, and in particular for ultrafast optical communications. The nonlinear phenomena that arise through the nonlinear refractive index change (induced mainly by the Kerr effect) have been largely investigated these last two decades for applications such as all-optical wavelength conversion, parametric amplification, generation of new optical frequencies or ultrahigh repetition rate pulse trains. However, in many other optical systems such as optical communication systems, these nonlinear phenomena become harmful effects, and in this case control processes are being developed in order to suppress or at least reduce their impact in the system.

List of Units and Nomenclature

Nonlinear refractive index n_2 [$m^2\ W^{-1}$]
Optical intensity I [$GW\ cm^{-2} = 10^9\ W\ cm^{-2}$]

CPM: cross phase modulation
FWM: four wave mixing
MI: modulational instability
SPM: self-phase modulation

Introduction

The invention of the laser provided us with a light source capable of generating extremely large optical power densities (several MW/m^2). At such large power densities, matter behaves in a nonlinear fashion and we come across new optical phenomena such as second-harmonic generation (SHG), sum and difference frequency generation, intensity dependent refractive index, mixing of various frequencies, etc. In SHG, an incident light beam at frequency ω interacts with the medium and generates a new light wave at frequency 2ω. In sum and difference frequency generation, two incident beams at frequencies ω_1 and ω_2 mix with each other producing sum $(\omega_1 + \omega_2)$ and difference $(\omega_1 - \omega_2)$ frequencies at the output. Higher-order nonlinear effects, such as self-phase modulation, four-wave mixing, etc. can also be routinely observed today. The field of nonlinear optics dealing with such nonlinear interactions is gaining importance due to numerous demonstrated applications in many diverse areas such as optical fiber communications, all-optical signal processing, realization of novel sources of optical radiation, etc.

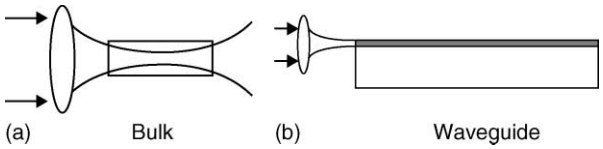

Figure 1 (a) In bulk media, tighter focusing produces larger intensities, but over shorter interaction lengths. (b) In optical waveguides diffraction effects are balanced by waveguiding and the interaction lengths are much larger.

Nonlinear optical interactions become prominent when the optical power densities are high and interaction takes place over long lengths. The usual method to increase optical intensity is to focus the light beam using a lens system. For a given optical power, the tighter the focusing, the larger will be the intensity for a given optical power; however, greater will be the divergence of the beam. Thus tighter focusing produces larger intensities, but over shorter interaction lengths (see Figure 1a). Optical waveguides, in which the light beam is confined to a small cross-sectional area, are currently being explored for realizing efficient nonlinear devices. In contrast to bulk media, in waveguides, diffraction effects are balanced by waveguiding and the beam can have small cross-sectional areas over much longer interaction lengths (see Figure 1b). A simple optical waveguide consists of a high index dielectric medium surrounded by a lower index dielectric medium so that light waves can be trapped in the high index region by the phenomenon of total internal reflection. Figure 2 shows a planar waveguide, a channel waveguide and an optical fiber. In the planar waveguide a film of refractive index n_f is deposited/diffused on a substrate of refractive index n_s and has a cover of refractive index n_c (with n_s, $n_c < n_f$). The waveguide has typical cross-sectional dimensions of a few micrometers. Unlike planar waveguides, in which guidance takes place only in one dimension, in channel waveguides the diffused region in a substrate is surrounded on all sides by lower index media. Optical fibers are structures with cylindrical symmetry and have a central cylindrical core of doped silica surrounded by a concentric cylindrical cladding of pure silica which has a slightly lower refractive index. Light guidance in all these waveguides takes place through the phenomenon of total internal reflection.

In contrast to bulk interactions requiring beam focusing, in the case of optical waveguides, the beam can be made to have extremely small cross-sectional

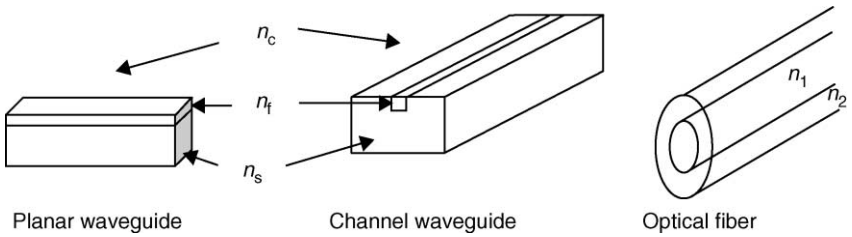

Figure 2 A planar waveguide, a channel waveguide and an optical fiber.

areas ($\sim$25 μm^2) over very long interaction lengths ($\sim$20 mm in integrated optical waveguides and tens of thousands of kilometers in the case of optical fibers). This leads to very much increased nonlinear interaction efficiencies even at moderate powers (approximately a few tens of mW).

In the following sections, we will discuss some of the important nonlinear interactions that are being studied with potential applications to various branches of science and engineering. Obviously it is impossible to cover all aspects of nonlinear optics – several books have been written in this area (see Further Reading section at the end of this article) – what we will do is to discuss the physics of some of the important nonlinear effects.

Apart from intensity and length of interaction, one of the most important requirements for many efficient nonlinear interactions is the requirement of phase matching. The concept of phase matching can be easily understood from the point of view of SHG. In SHG, the incident wave at frequency ω generates a nonlinear polarization at frequency 2ω and this nonlinear polarization is responsible for the generation of the wave at 2ω. Now, the phase velocity of the nonlinear polarization wave at 2ω is the same as the phase velocity of the electromagnetic wave at frequency ω, which is usually different from the phase velocity of the electromagnetic wave at frequency 2ω; this happens due to wavelength dispersion in the medium. When the two phase velocities are unequal, the polarization wave at 2ω (which is the source) and the electromagnetic wave at 2ω pass in and out of phase with each other as they propagate through the medium. Due to this, the energy flowing in from ω to 2ω cannot add constructively and the efficiency of second-harmonic generation is limited. If the phase velocities of the waves at ω and 2ω are matched then the polarization wave and the wave at 2ω remain in phase leading to drastically increased efficiencies. This condition is referred to as phase matching and plays a very important role in most nonlinear interactions.

Nonlinear Polarization

In a linear medium, the electric polarization P is assumed to be a linear function of the electric field E:

$$P = \varepsilon_0 \chi E \qquad [1]$$

where, for simplicity, a scalar relation has been written. The quantity χ is termed as linear dielectric susceptibility. At high optical intensities (which corresponds to high electric fields), all media behave in a nonlinear fashion. Thus eqn [1] is modified to

$$P = \varepsilon_0(\chi E + \chi^{(2)}E^2 + \chi^{(3)}E^3 + \ldots) \qquad [2]$$

where $\chi^{(2)}, \chi^{(3)}, \ldots$ are higher order susceptibilities giving rise to the nonlinear terms. The second term on the right-hand side is responsible for SHG, sum and difference frequency generation, parametric interactions, etc. while the third term is responsible for third-harmonic generation, intensity dependent refractive index, self-phase modulation, four-wave mixing, etc. For media possessing an inversion symmetry, $\chi^{(2)}$ is zero and there is no second-order nonlinear effect. Thus silica optical fibers, which form the heart of today's communication networks, do not possess the second-order nonlinearity.

We will first discuss second-harmonic generation and parametric amplification which arises due to the second-order nonlinear term and then go on to effects due to third-order nonlinear interaction.

Second-Harmonic Generation in Crystals

The first demonstration of SHG was made in 1961 by focusing a 3 kW ruby laser pulse ($\lambda_0 = 6943$ Å) on a quartz crystal. An incident beam from a ruby laser (red color) after passing through a crystal of KDP, gets partly converted into blue light which is the second harmonic. Ever since, SHG has been one of the most widely studied nonlinear interactions.

We consider a plane wave of frequency ω propagating along the z-direction through a medium and consider the generation of the second-harmonic frequency 2ω as the beam propagates through the medium. Now, the field at ω generates a polarization at 2ω, which acts as a source for the generation of an electromagnetic wave at 2ω. Corresponding to the frequencies ω and 2ω, the electric fields are assumed to be given by

$$E^{(\omega)} = \frac{1}{2}(E_1(z)e^{i(\omega t - k_1 z)} + \text{c.c.}) \qquad [3]$$

and

$$E^{(2\omega)} = \frac{1}{2}(E_2(z)e^{i(2\omega t - k_2 z)} + \text{c.c.}) \qquad [4]$$

respectively; c.c. stands for the complex conjugate of the preceding quantities. The quantities:

$$k_1 = \omega\sqrt{(\varepsilon_1 \mu_0)} = (\omega/c)n^{\omega} \qquad [5]$$

and

$$k_2 = 2\omega\sqrt{(\varepsilon_2 \mu_0)} = (2\omega/c)n^{2\omega} \qquad [6]$$

represent the propagation vectors at ω and 2ω, respectively; ε_1 and ε_2 represent the dielectric permittivities at ω and 2ω, and n^{ω} and $n^{2\omega}$ represent

the corresponding wave refractive indices. It should be noted that the amplitudes E_1 and E_2 are assumed to be z dependent – this is because at $z = 0$ (where the beam is incident on the medium) the amplitude E_2 is zero and this would develop as the beam propagates through the medium. We will now develop an approximate theory for the generation of the second harmonic.

We start with the wave equation:

$$\nabla^2 E - \varepsilon\mu_0 \frac{\partial^2 E}{\partial t^2} = \mu_0 \frac{\partial^2 P_{\mathrm{NL}}}{\partial t^2} \qquad [7]$$

where P_{NL} is the nonlinear polarization. An incident wave at frequency ω generates a polarization at 2ω, which acts as a source for the generation of an electromagnetic wave at 2ω.

In order to consider SHG, we write the wave equation corresponding to 2ω with the nonlinear polarization at 2ω given by

$$P_{\mathrm{NL}}^{(2\omega)} = \frac{1}{2}(\tilde{P}_{\mathrm{NL}}^{(2\omega)} \, \mathrm{e}^{2\mathrm{i}(\omega t - k_1 z)} + \mathrm{c.c.}) \qquad [8]$$

where

$$\tilde{P}_{\mathrm{NL}}^{(2\omega)} = dE_1 E_1 \qquad [9]$$

and

$$d = \frac{\varepsilon_0 \chi^{(2)}}{2} \qquad [10]$$

represents the effective nonlinear coefficient and depends on the nonlinear material, the polarization states of the fundamental and the second harmonic and also on the propagation direction. Simple manipulations give us, for the rate of change of amplitude of the second harmonic wave:

$$\frac{\mathrm{d}E_2}{\mathrm{d}z} = -\frac{i\mu_0 \, dc\omega}{n^{2\omega}} E_1^2(z) \mathrm{e}^{\mathrm{i}(\Delta k)z} \qquad [11]$$

where

$$\Delta k = k_2 - 2k_1 = (2\omega/c)(n^{2\omega} - n^{\omega}) \qquad [12]$$

and we have assumed:

$$\mathrm{d}^2 E_2/\mathrm{d}z^2 \ll k_2(\mathrm{d}E_2/\mathrm{d}z) \qquad [13]$$

In order to solve eqn [11] we neglect depletion of the fundamental field, i.e., $E_1(z)$ is almost a constant and the quantity E_1^2 on the right-hand side can be assumed to be independent of z. If we now integrate eqn [11], we obtain:

$$E_2(z) = -\frac{i\mu_0 \, \mathrm{d}c\omega}{n^{2\omega}} z E_1^2 \mathrm{e}^{\mathrm{i}\sigma} \frac{\sin\sigma}{\sigma} \qquad [14]$$

where

$$\sigma = \frac{1}{2}(\Delta k)z = (\omega/c)(n^{2\omega} - n^{\omega})z \qquad [15]$$

Now, the powers associated with the beams corresponding to ω and 2ω are given by:

$$P_1 = \frac{n^{\omega}}{2c\mu_0} S|E_1|^2, \qquad P_2 = \frac{n^{2\omega}}{2c\mu_0} S|E_2|^2 \qquad [16]$$

where S represents the cross-sectional area of the beams. Substituting for $|E_2|^2$ from eqn [16], we get after some elementary simplifications:

$$\eta = \frac{P_2}{P_1} = \frac{2c^3\mu_0^3 d^2 \omega^2}{(n^{\omega})^2 n^{2\omega}} z^2 \frac{P_1}{S} \left(\frac{\sin\sigma}{\sigma}\right)^2 \qquad [17]$$

when η represents the SHG efficiency. Note that the efficiency of SHG increases if P_1/S, the intensity of the fundamental wave increases. Also η increases if the nonlinear coefficient d increases (obviously) and if the frequency increases. However, for a given power P_1, the conversion efficiency increases if the area of the beam decreases – thus a focused beam will have a greater SHG efficiency. The most important factor is $(\sin\sigma/\sigma)^2$ which is a sharply peaked function around $\sigma = 0$, attaining a maximum value of unity at $\sigma = 0$. Thus for maximum SHG efficiency:

$$\sigma = 0 \Rightarrow n^{2\omega} = n^{\omega} \qquad [18]$$

i.e., the refractive index at 2ω must be equal to the refractive index at ω – this is known as the phase matching condition.

The phase matching condition can be pictorially represented by a vector diagram (see Figure 3). In Figure 3, $\mathbf{k}_1\omega$ and $\mathbf{k}_2\omega$ represent the wave vectors of the fundamental and the second harmonic respectively. To achieve reasonably effective SHG, it is very important to satisfy the phase-matching condition. Efficiencies under nonphase matched operation can be orders of magnitude lower than under phase-matched operation.

We see from eqn [17] that the smallest z for which η is maximum is:

$$z = L_{\mathrm{c}} = \frac{\pi}{\Delta k} = \frac{\pi c}{2\omega(n^{2\omega} - n^{\omega})} \qquad [19]$$

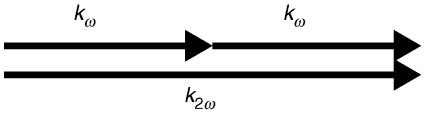

Figure 3 Vector diagram representing the phase matching condition for SHG.

where we have used eqn [15] for Δk. The length L_c is called the phase coherence length and represents the maximum crystal length up to which the second-harmonic power increases. Thus, if the length of the crystal is less than L_c, the second-harmonic power increases almost quadratically with z. For $z > L_c$, the second-harmonic power begins to reduce again.

In general, because of dispersion, it is very difficult to satisfy the phase-matching condition. However, in a birefringent medium, for example with $n_o > n_e$, it may be possible to find a direction along which the refractive index of the *o*-wave for ω equals the refractive index of the *e*-wave for 2ω (see Figure 4). For media with $n_e > n_o$, the direction would correspond to that along which the refractive index of the *e*-wave for ω equals the refractive index for the *o*-wave for 2ω. This can readily be understood by considering a specific example. We consider the SHG in KDP corresponding to the incident ruby laser wavelength ($\lambda_0 = 0.6943\ \mu m$, $\omega = 2.7150 \times 10^{15}$ Hz). For this frequency:

$$\left\{ \begin{array}{ll} n_o^{\omega} = 1.50502, & n_e^{\omega} = 1.46532 \\ n_o^{2\omega} = 1.53269, & n_e^{2\omega} = 1.48711 \end{array} \right\} \qquad [20]$$

The refractive index variation for the *e*-wave is given by:

$$n_e(\theta) = \left(\frac{\sin^2\theta}{n_e^2} + \frac{\cos^2\theta}{n_o^2} \right)^{-\frac{1}{2}} \qquad [21]$$

where θ is the angle that the wave propagation direction makes with the optic axis. Now, as can be seen from the above equations:

$$n_e < n_e(\theta) < n_o \qquad [22]$$

Since n_o at 0.6943 μm lies between n_e and n_o at 0.34715 μm, there will always exist an angle θ_m along which $n_e^{2\omega}(\theta_m) = n_o^{\omega}$. We can solve for θ_m and obtain:

$$\cos\theta_m = \left[\frac{(n_o^{\omega})^2 - (n_e^{2\omega})^2}{(n_o^{2\omega})^2 - (n_e^{2\omega})^2} \right]^{1/2} \frac{n_o^{2\omega}}{n_o^{\omega}} \qquad [23]$$

For the values given by eqn [20], we find $\theta_m = 50.5°$.

Quasi Phase Matching (QPM)

As mentioned earlier, phase matching is extremely important for any efficient nonlinear interaction. Recently the technique of quasi phase matching (QPM) has become a convenient way to achieve phase matching at any desired wavelength in any material. QPM relies on the fact that the phase mismatch in the two interacting beams can be compensated by periodically readjusting the phase of interaction through periodically modulating the nonlinear characteristics of the medium at a spatial frequency equal to the wavevector mismatch of the two interacting waves. Thus in SHG, when the nonlinear polarization at 2ω and the electromagnetic wave at 2ω have an accumulated phase difference of π, then the sign of the nonlinear coefficient is reversed so that the energy flowing from the polarization to the wave can add constructively with the existing energy (see Figure 5). Thus, by properly choosing the period of the spatial modulation of the nonlinear coefficient, one could achieve phase matching. This scheme, QPM, is being very widely studied for application to nonlinear interactions in bulk and in waveguides.

In a ferroelectric material such as lithium niobate, the signs of the nonlinear coefficients are linked to the direction of the spontaneous polarization. Thus a

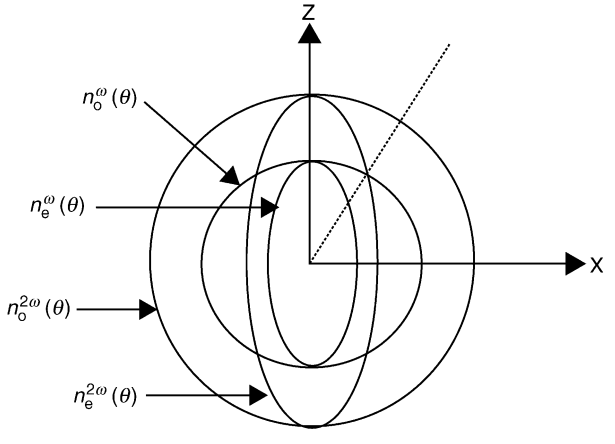

Figure 4 In a birefringent medium, for example with $n_o > n_e$, it may be possible to find a direction along which the refractive index of the *o*-wave for ω equals the refractive index of the *e*-wave for 2ω.

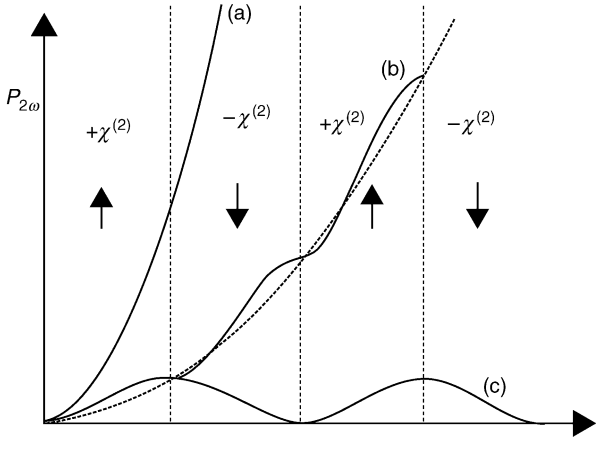

Figure 5 By reversing the sign of the nonlinear coefficient after every coherence length, the energy in the second harmonic can be made to grow. (a) Perfect phase matching; (b) Quasi phase matching; (c) Nonphase matched.

periodic reversal of the domains of the crystal can be used for achieving QPM (see Figure 6). This is the currently used technique to obtain high-efficiency SHG and other nonlinear interactions in $LiNbO_3$, $LiTaO_3$, and KTP. The most popular technique today, to achieve periodic domain reversal in $LiNbO_3$, is the technique of electric field poling. In this method, a high electric field pulse is applied to properly oriented lithium niobate crystal using lithographically defined electrode patterns to produce a permanent periodic domain reversed pattern. Such a periodically domain reversed $LiNbO_3$ crystal with the periodically reversed domains going through the entire depth of the crystal is also referred to as PPLN (periodically poled lithium niobate, pronounced 'piplin') and is now commercially available.

In order to analyze SHG in a periodically poled material, let us assume that the nonlinear coefficient d varies sinusoidally with a period Λ. In such a case we have:

$$d = d_0 \sin(Kz) \qquad [24]$$

where d_0 is the amplitude of modulation of the nonlinear coefficient and $K(= 2\pi/\Lambda)$ represents the spatial frequency of the periodic modulation. For easier understanding we are assuming the modulation to be sinusoidal; in general, the modulation will be periodic but not sinusoidal. Any periodic modulation can be written as a superposition of sinusoidal and cosinusoidal variations. Thus our discussion is valid for one of the Fourier components of the variation.

By using eqn [24], eqn [11] for the variation of the amplitude of the second harmonic becomes:

$$\frac{dE_2}{dz} = -\frac{i\mu_0 d_0 c\omega}{n^{2\omega}} E_1^2(z) e^{i(\Delta k)z} \sin(Kz) \qquad [25]$$

which can be written as:

$$\frac{dE_2}{dz} = -\frac{\mu_0 d_0 c\omega}{2n^{2\omega}} E_1^2(z) e^{i(\Delta k)z} [e^{iKz} - e^{-iKz}] \qquad [26]$$

Using similar arguments as earlier, it can be shown that if $\Delta k - K = 0$, then only the second term within the brackets in eqn [26] contributes to the growth of the second harmonic and similarly if $\Delta k + K = 0$, then only the first term within the brackets contributes to the growth of the second harmonic. The first condition implies that:

$$2\frac{2\pi}{\lambda_0}(n^{2\omega} - n^{\omega}) - \frac{2\pi}{\Lambda} = 0 \qquad [27]$$

where $\Lambda = 2\pi/K$ represents the spatial period of the modulation of the nonlinear coefficient, and λ_0 is the wavelength of the fundamental. Thus the modulation period Λ required for QPM SHG is:

$$\Lambda = \frac{\lambda_0}{2(n^{2\omega} - n^{\omega})} = 2L_c \qquad [28]$$

Figure 7 shows the vector diagram corresponding to QPM SHG. The phase mismatch between the fundamental and second harmonic is compensated by the spatial frequency vector of the periodic variation of d.

In the case of waveguides, n^{ω} and $n^{2\omega}$ would represent the effective indices of the modes at the fundamental and the second-harmonic frequency. It may be noted that the index difference between the fundamental and the second harmonic is typically 0.1 and thus the required spatial periods for a fundamental wavelength of 800 nm is ~ 4 μm.

The main advantage of QPM is that it can be used at any wavelength within the transparency window of the material; only the period needs to be correctly chosen for a specific fundamental wavelength. One can also choose appropriate polarization to make use of the largest nonlinear optical coefficients. Another advantage is the possibility of varying the domain reversal period (chirp) to achieve specific interaction characteristics such as increased bandwidth, etc.

In general, the spatial variation of the nonlinear grating is not sinusoidal. In this case the efficiency of interaction would be determined by the Fourier component of the spatial variation at the spatial frequency corresponding to the period given by eqn [28]. Also, since the required periods are very small, it is possible to use a higher spatial period of modulation and use one of the Fourier components for the nonlinear interaction process. Thus, in the case of periodic reversal of the nonlinear coefficient

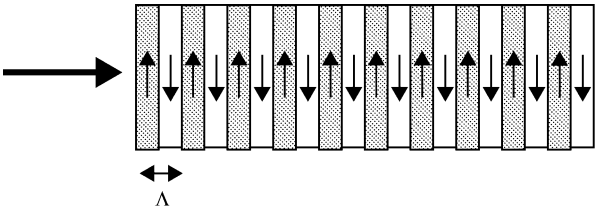

Figure 6 QPM can be achieved by a periodic reversal of the domains of a ferroelectric material. Arrows represent the direction of the spontaneous polarization of the crystal.

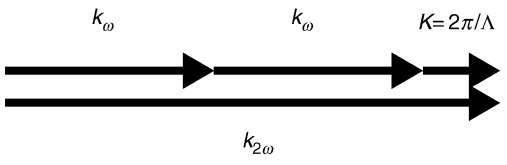

Figure 7 Vector diagram corresponding to QPM-SHG.

with a spatial period given by:

$$\Lambda_g = m\frac{\lambda_0}{2(n^{2\omega} - n^{\omega})}; \qquad m = 1, 3, 5, \ldots \qquad [29]$$

which happens to be the m^{th} harmonic of the fundamental spatial frequency required for QPM, the corresponding nonlinear coefficient that would be responsible for SHG would be the Fourier amplitude at that spatial frequency. This can be taken into account by defining an effective nonlinear coefficient:

$$d_{QPM} = \frac{2d_0}{m\pi} \qquad [30]$$

Of course the largest effective nonlinear coefficient is achieved by using the fundamental frequency with $m = 1$. Higher spatial periods are easier to fabricate but would lead to reduced nonlinear efficiencies.

As compared to bulk devices, in the case of waveguides, the interacting waves are propagating in the form of modes having specific intensity distributions in the transverse plane. Because of this, the nonlinear interaction also depends on the overlap between the periodically inverted nonlinear medium, the fields of the fundamental and second-harmonic waves. Thus if $E_\omega(x, y)$ and $E_{2\omega}(x, y)$ represent the electric field distributions of the waveguide modes at the fundamental and second-harmonic frequency, then the efficiency of SHG depends on the following overlap integral:

$$I_{ovl} = \int\int d_0(x, y)E_\omega^2(x, y)E_{2\omega}(x, y)\,dx\,dy \qquad [31]$$

where $d_0(x, y)$ represents the transverse variation of the nonlinear coefficient of the waveguide. Thus optimization of SHG efficiency in the case of waveguide interactions has to take account of the overlap integral.

Since QPM relies on periodic phase matching, it is highly wavelength dependent. Thus the required period Λ is different for different fundamental frequencies. Any deviation in the frequency of the fundamental would lead to a reduction in the efficiency due to deviation from QPM condition. Thus the pump laser needs to be highly stabilized at a frequency corresponding to the fabricated period.

Apart from SHG, QPM has been used for other three-wave interaction processes such as difference frequency generation, parametric amplification, etc. Among the many materials that have been studied for SHG using QPM, the important ones are lithium niobate, lithium tantalite, and potassium titanyl phosphate (KTP). Many techniques have been developed for periodic domain reversal to achieve a periodic variation in the nonlinear coefficient. This includes electric field poling, electron bombardment, thermal diffusion treatment, etc.

Third-Order Nonlinear Effects

In the earlier sections, we discussed effects arising out of second-order nonlinearity, i.e., the term proportional to E^2 in the nonlinear polarization. This nonlinear term is found only in media not possessing an inversion symmetry. Thus amorphous materials or crystals possessing inversion symmetry do not exhibit second-order effects. The lowest-order nonlinear effects in such a medium is of an order three wherein the nonlinear polarization is proportional to E^3.

Self-phase modulation (SPM), cross-phase modulation (XPM) and four-wave mixing (FWM) represent some of the very important consequences of third-order nonlinearity. These effects have become all the more important as they play a significant and important role in wavelength division multiplexed optical fiber communication systems.

Self-Phase Modulation (SPM)

Consider the propagation of a plane light wave at frequency ω through a medium having $\chi^{(3)}$ nonlinearity. The polarization generated in the medium is given by

$$P = \varepsilon_0\chi E + \varepsilon_0\chi^{(3)}E^3 \qquad [32]$$

If we consider a single frequency wave with an electric field given by

$$E = E_0\cos(\omega t - kz) \qquad [33]$$

then

$$P = \varepsilon_0\chi E_0\cos(\omega t - kz) + \varepsilon_0\chi^{(3)}E_0^3\cos^3(\omega t - kz) \qquad [34]$$

Expanding $\cos^3\theta$ in terms of $\cos\theta$ and $\cos 3\theta$, we obtain the following expression for the polarization at frequency ω:

$$P = \varepsilon_0\left(\chi + \frac{3}{4}\chi^{(3)}E_0^2\right)E_0\cos(\omega t - kz) \qquad [35]$$

For a plane wave given by eqn [33], the intensity is

$$I = \frac{1}{2}c\varepsilon_0 n_0 E_0^2 \qquad [36]$$

where n_0 is the refractive index of the medium at low intensity. Then

$$P = \varepsilon_0\left(\chi + \frac{3}{2}\frac{\chi^{(3)}}{c\varepsilon_0 n_0}I\right)E \qquad [37]$$

The polarization P and electric field are related through the following equation:

$$P = \varepsilon_0(n^2 - 1)E \qquad [38]$$

where n is the refractive index of the medium. Comparing eqns [37] and [38], we get

$$n^2 = n_0^2 + \frac{3}{2}\frac{\chi^{(3)}}{c\varepsilon_0 n_0} I \qquad [39]$$

where

$$n_0^2 = 1 + \chi \qquad [40]$$

Since the last term in the eqn [39] is usually very small, we get

$$n = n_0 + n_2 I \qquad [41]$$

where

$$n_2 = \frac{3}{4}\frac{\chi^{(3)}}{c\varepsilon_0 n_0^2} \qquad [42]$$

is the nonlinear coefficient.

For fused silica $n_0 \approx 1.47$, $n_2 \approx 3.2 \times 10^{-20}$ m^2/W and if we consider power of 100 mW having a cross-sectional area of 100 μm^2, the resultant intensity is 10^9 W/m^2 and the corresponding change in refractive index is

$$\Delta n \approx n_2 I \approx 3.2 \times 10^{-11} \qquad [43]$$

Although this is very small, when the beam propagates over an optical fiber over long distances (a few hundred to a few thousand kilometers), the accumulated nonlinear effects can be significant.

In the case of an optical fiber, the light beam propagates as a mode having a specific transverse electric field distribution and thus the intensity is not constant across the cross-section. In such a case, it is convenient to express the nonlinear effect in terms of the power carried by the mode (rather than in terms of intensity). If the linear propagation constant of the mode is represented by β, then in the presence of nonlinearity, the effective propagation constant is given by

$$\beta_{\mathrm{NL}} = \beta + \frac{k_0 n_2}{A_{\mathrm{eff}}} P \qquad [44]$$

where $k_0 = 2\pi/\lambda_0$, P is the power carried by the mode. The quantity A_{eff} represents the effective transverse cross-sectional area of the mode and is defined by

$$A_{\mathrm{eff}} = \frac{\left[\int_0^{\infty}\int_0^{2\pi} \psi^2(r) r \, \mathrm{d}r \, \mathrm{d}\phi\right]^2}{\int_0^{\infty}\int_0^{2\pi} \psi^4(r) r \, \mathrm{d}r \, \mathrm{d}\phi} \qquad [45]$$

where $\psi(r)$ represents the transverse mode field distribution of the mode. For example, under the Gaussian approximation:

$$\psi(r) = \psi_0 \, \mathrm{e}^{-r^2/w_0^2} \qquad [46]$$

where ψ_0 is a constant and $2w_0$ represents the mode field diameter (MFD), we get:

$$A_{\mathrm{eff}} = \pi w_0^2 \qquad [47]$$

It is usual to express the nonlinear characteristic of an optical fiber by the coefficient given by

$$\gamma = \frac{k_0 n_2}{A_{\mathrm{eff}}} \qquad [48]$$

Thus, for the same input power and same wavelength, smaller values of A_{eff} lead to greater nonlinear effects in the fiber. Typically:

$$A_{\mathrm{eff}} \sim 50\text{–}80 \ \mu\mathrm{m}^2 \quad \text{and} \quad \gamma \approx 2.4 \ \mathrm{W}^{-1}\,\mathrm{km}^{-1} \ \text{to} \ 1.5 \ \mathrm{W}^{-1}\,\mathrm{km}^{-1} \qquad [49]$$

When a light beam propagates through an optical fiber, the power decreases because of attenuation. Thus, the corresponding nonlinear effects also reduce. Indeed, the phase change suffered by a beam in propagating from 0 to L is given by

$$\phi = \int_0^L \beta_{\mathrm{NL}} \, \mathrm{d}z = \beta L + \gamma \int_0^L P \, \mathrm{d}z \qquad [50]$$

If α represents the attenuation coefficient, then

$$P(z) = P_0 \, \mathrm{e}^{-\alpha z} \qquad [51]$$

and we get

$$\phi = \beta L + \gamma P_0 L_{\mathrm{eff}} \qquad [52]$$

where

$$L_{\mathrm{eff}} = \frac{1 - \mathrm{e}^{-\alpha L}}{\alpha} \qquad [53]$$

is referred to as the effective length. For $\alpha L \gg 1$, $L_{\mathrm{eff}} \approx 1/\alpha$ and for $\alpha L \ll 1$, $L_{\mathrm{eff}} \approx L$.

The effective length represents the length of the fiber over which most of the nonlinear effects has accumulated. For a loss coefficient of 0.20 dB/km, $L_{\mathrm{eff}} \approx 21$ km.

If we consider a fiber length much longer than L_{eff}, then to have reduced impact of SPM, we must have

$$\gamma P_0 L_{\mathrm{eff}} \ll 1 \qquad [54]$$

or

$$P_0 \ll \frac{1}{\gamma L_{\mathrm{eff}}} \approx \frac{\alpha}{\gamma} \qquad [55]$$

For $\alpha = 4.6 \times 10^{-2}$ km^{-1} (which corresponds to an attenuation of 0.2 dB/km) and $\gamma = 2.4$ W^{-1} km^{-1}, we get

$$P_0 \ll 19 \ \mathrm{mW} \qquad [56]$$

Propagation of a Pulse

When an optical pulse propagates through a medium, it suffers from the following effects:

(i) attenuation;
(ii) dispersion; and
(iii) nonlinearity.

Attenuation refers to the reduction in the pulse energy due to various mechanisms, such as scattering, absorption, etc. Dispersion is caused by the fact that a light pulse consists of various frequency components and each frequency component travels at a different group velocity. Dispersion causes the temporal width of the pulse to change; in most cases it results in an increase in pulse width, however, in some cases the temporal width could also decrease. Dispersion is accompanied by chirping, the variation of the instantaneous frequency of the pulse within the pulse duration. Since both attenuation and dispersion cause a change in the temporal variation of the optical power, they closely interact with nonlinearity in deciding the pulse evolution as it propagates through the medium.

Let $E(x, y, z, t)$ represent the electric field variation of an optical pulse. It is usual to express E in the following way:

$$E(x, y, z, t) = \frac{1}{2}[A(z, t)\psi(x, y)\mathrm{e}^{\mathrm{i}(\omega_0 t - \beta_0 z)} + \text{c.c.}] \quad [57]$$

where $A(z, t)$ represents the slowly varying complex envelope of the pulse, $\psi(x, y)$ represents the transverse electric field distribution, ω_0 represents center frequency, and β_0 represents the propagation constant at ω_0.

In the presence of attenuation, second-order dispersion and third-order nonlinearity, the complex envelope $A(z, t)$ can be shown to satisfy the following equation:

$$\frac{\partial A}{\partial z} = -\frac{\alpha}{2}A - \beta_1\frac{\partial A}{\partial t} + i\frac{\beta_2}{2}\frac{\partial^2 A}{\partial t^2} - i\gamma|A|^2 A \quad [58]$$

Here

$$\beta_1 = \left|\frac{\mathrm{d}\beta}{\mathrm{d}\omega}\right|_{\omega=\omega_0} = \frac{1}{v_\mathrm{g}} \quad [59]$$

represents the inverse of the group velocity of the pulse, and

$$\beta_2 = \left|\frac{\mathrm{d}^2\beta}{\mathrm{d}\omega^2}\right|_{\omega=\omega_0} = -\frac{\lambda_0^2}{2\pi c}D \quad [60]$$

where D represents the group velocity dispersion (measured in ps/km nm).

The various terms on the RHS of the eqn [58] represent the following:

I term: attenuation
II term: group velocity term
III term: second-order dispersion
IV term: nonlinear term

If we change to a moving frame defined by coordinates $T = t - \beta_1 z$, eqn [58] becomes

$$\frac{\partial A}{\partial z} = -\frac{\alpha}{2}A + i\frac{\beta_2}{2}\frac{\partial^2 A}{\partial T^2} - i\gamma|A|^2 A \quad [61]$$

If we neglect the attenuation term, we obtain the following equation which is also referred to as the nonlinear Schrödinger equation:

$$\frac{\partial A}{\partial z} = i\frac{\beta_2}{2}\frac{\partial^2 A}{\partial T^2} - i\gamma|A|^2 A \quad [62]$$

The above equation has a solution given by

$$A(z, t) = A_0 \operatorname{sech} \sigma T\, \mathrm{e}^{-\mathrm{i}gz} \quad [63]$$

with

$$A_0^2 = -\frac{\beta_2}{\gamma}\sigma^2, \qquad g = -\frac{\sigma^2}{2}\beta_2 \quad [64]$$

Equation [63] represents an envelope soliton and has the property that it propagates undispersed through the medium. The full width at half maximum (FWHM) of the pulse envelope will be given by $\tau_\mathrm{f} = 2\tau_0$, where

$$\operatorname{sech}^2 \sigma\tau_0 = \frac{1}{2} \quad [65]$$

which gives the FWHM τ_f:

$$\tau_\mathrm{f} = 2\tau_0 = \frac{2}{\sigma}\ln(1 + \sqrt{2}) \approx \frac{1.7627}{\sigma} \quad [66]$$

The peak power of the pulse is:

$$P_0 = |A_0|^2 = \frac{|\beta_2|}{\gamma}\sigma^2 \quad [67]$$

Replacing σ by τ_f, we obtain

$$P_0\tau_\mathrm{f}^2 \approx \frac{\lambda_0^2}{2cy}D \quad [68]$$

where we have used eqn [60]. The above equation gives the required peak for a given τ_f for the formation of a soliton pulse.

As an example, we have $\tau_\mathrm{f} = 10$ ps, $\gamma = 2.4\ \mathrm{W}^{-1}\ \mathrm{km}^{-1}$, $\lambda_0 = 1.55\ \mu\mathrm{m}$, $D = 2$ ps/km nm and the required peak power will be $P_0 = 33$ mW.

Soliton pulses are being extensively studied for application to long distance optical fiber

communication. In actual systems, the pulses have to be optically amplified at regular intervals to compensate for the loss suffered by the pulses. The amplification could be carried out using erbium doped fiber amplifiers (EDFAs) or fiber Raman amplifiers.

Spectral Broadening due to SPM

In the presence of only nonlinearity, eqn [61] becomes

$$\frac{\mathrm{d}A}{\mathrm{d}z} = -i\gamma|A|^2A \qquad [69]$$

whose solution is given by

$$A(z,t) = A(z=0,t)\mathrm{e}^{-\mathrm{i}\gamma Pz} \qquad [70]$$

where $P = |A|^2$ is the power in the pulse. If P is a function of time, then time dependent phase term at $z = L$ becomes

$$\mathrm{e}^{\mathrm{i}\phi(t)} = \mathrm{e}^{\mathrm{i}[\omega_0 t - \gamma P(t)L]} \qquad [71]$$

We can define an instantaneous frequency as

$$\omega(t) = \frac{\mathrm{d}\phi}{\mathrm{d}t} = \omega_0 - \gamma L\frac{\mathrm{d}P}{\mathrm{d}t} \qquad [72]$$

for a Gaussian pulse:

$$P = P_0\,\mathrm{e}^{-2T^2/\tau_0^2} \qquad [73]$$

giving

$$\omega(t) = \omega_0 + \frac{4\gamma LTP_0\,\mathrm{e}^{-2T^2/\tau_0^2}}{\tau_0^2} \qquad [74]$$

Thus the instantaneous frequency within the pulse changes with time, leading to chirping of the pulse (see Figure 8). Note that since the pulsewidth has not changed, but the pulse is chirped, the frequency spectrum of the pulse has increased. Thus SPM leads to the generation of new frequencies. By Fourier transform theory, an increased spectral width implies that the pulse can now be compressed in the temporal domain by passing it through a medium with the proper sign of dispersion. This is indeed one of the standard techniques to realize ultrashort femtosecond optical pulses.

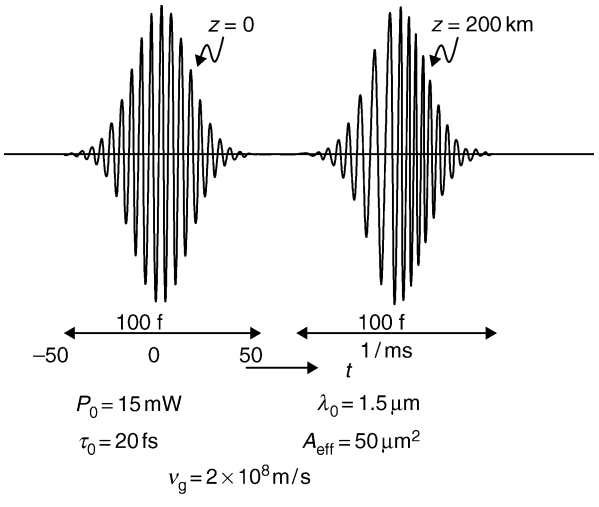

Figure 8 Due to self phase modulation, the instantaneous frequency within the pulse changes with time leading to chirping of the pulse.

Cross Phase Modulation (XPM)

Like SPM, cross-phase modulation also arises due to the intensity dependence of refractive index, leading to spectral broadening. Unlike SPM, in the case of XPM, intensity variations of a light beam at a particular frequency modulate the phase of light beam at another frequency. If the signals at both frequencies are pulses, then due to difference in group velocities of the pulses, there is a walk off between the two pulses, i.e., if they start together, they will separate as they propagate through the medium. Nonlinear interaction takes place as long as they physically overlap in the medium. Smaller the dispersion, smaller will be the difference in group velocities (assuming closely spaced wavelengths) and the longer they will overlap. This would lead to stronger XPM effects. At the same time, if two pulses pass through each other, then since one pulse will interact with both the leading and the trailing edge of the other pulse, XPM effects will be nil provided there is no attenuation. In the presence of attenuation in the medium, the pulse will still get modified due to XPM. A similar situation can occur when the two interacting pulses are passing through an optical amplifier.

To study XPM, we assume simultaneous propagation of two waves at two different frequencies through the medium. If ω_1 and ω_2 represent the two frequencies, then one obtains for the variation of the amplitude A_1 of the frequency ω_1:

$$\frac{\mathrm{d}A_1}{\mathrm{d}z} = -i\gamma(\tilde{P}_1 + 2\tilde{P}_2)A_1 \qquad [75]$$

where $\tilde{P}_1$ and $\tilde{P}_2$ represent the powers at frequencies ω_1 and ω_2, respectively. The first term in eqn [75] represents SPM while the second term corresponds to XPM. If the powers are assumed to attenuate at the same rate, i.e.:

$$\tilde{P}_1 = P_1\,\mathrm{e}^{-\alpha z}, \qquad \tilde{P}_2 = P_2\,\mathrm{e}^{-\alpha z} \qquad [76]$$

then the solution of eqn [75] is

$$A_1(L) = A_1(0)\,\mathrm{e}^{-\mathrm{i}\gamma(P_1+2P_2)L_{\mathrm{eff}}} \qquad [77]$$

where, as before, L_{eff} represents the effective length of the medium. When we are studying the effect of

power at ω_2 on the light beam at frequency ω_1, we will refer to the wave at frequency ω_2 as pump, and the wave at frequency ω_1 as probe or signal. From eqn [77] it is apparent that the phase of signal at frequency ω_1 is modified by the power at another frequency. This is referred to as XPM. Note also that XPM is twice as effective as SPM.

Similar to the case of SPM, we can now write for the instantaneous frequency in the presence of XPM as eqn [72]:

$$\omega(t) = \omega_0 - 2\gamma L_{\text{eff}} \frac{dP_2}{dt} \qquad [78]$$

Hence the part of the signal that is influenced by the leading edge of the pump will be down-shifted in frequency (since in the leading edge $dP_2/dt > 0$) and the part overlapping with the trailing edge will be up-shifted in frequency (since $dP_2/dt < 0$). This leads to a frequency chirping of the signal pulse just as in the case of SPM.

If the probe and pump beams are pulses, then XPM can lead to induced frequency shifts depending on whether the probe pulse interacts only with the leading edge or trailing edge or both, as they both propagate through the medium. Let us consider a case when the group velocity of pump pulse is greater than that of the probe pulse. Thus, if both pulses enter the medium together, then since the pump pulse travels faster, the probe pulse will interact only with the trailing edge of the pump. Since in this case dP_2/dt is negative, the probe pulse suffers a blue-induced frequency shift. Similarly if the pulses enter at different instants but completely overlap at the end of the medium, then $dP_2/dt > 0$ and the probe pulse would suffer a red-induced frequency shift. Indeed, if the two pulses start separately and walk through each other, then there is no induced shift due to cancellation of shifts induced by leading and trailing edges of the pump. Figure 9 shows measured induced frequency shift of 532 nm probe pulse as a function of the delay between this pulse and a pump pulse at 1064 nm, when they propagate through a 1 m long optical fiber.

When pulses of light at two different wavelengths propagate through an optical fiber, due to different group velocities of the pulses, they pass through each other, resulting in what could be termed as a collision. In the linear case, the pulses will pass through without affecting each other, but when intensity levels are high, XPM induces phase shifts in both pulses. We can define a parameter termed walk off length L_{wo} which is the length of the fiber required for the interacting pulses to walk off relative to each other. The walk off length is given by

$$L_{\text{wo}} = \frac{\Delta\tau}{D\Delta\lambda} \qquad [79]$$

where D represents the dispersion coefficient, and $\Delta\lambda$ represents the wavelength separation between the interacting pulses. For return to zero (RZ) pulses, $\Delta\tau$ represents the pulse duration while for nonreturn to zero (NRZ) pulses, $\Delta\tau$ represents the rise term or fall time of the pulse. Closely spaced channels will thus interact over longer fiber lengths, thus leading to greater XPM effects. Larger dispersion coefficients will reduce L_{wo} and thus the effects of XPM. Since the medium is attenuating, the power carried by the pulses decreases as they propagate and thus leading to reduced XPM effect. The characteristic length for attenuation is the effective length L_{eff}, defined by eqn [53]. If $L_{\text{wo}} \ll L_{\text{eff}}$, then over the length of interaction of the pulses, the intensity levels do not change appreciably and the magnitude of the XPM-induced effects will be proportional to the wavelength spacing $\Delta\lambda$. For small $\Delta\lambda$'s, $L_{\text{wo}} \gg L_{\text{eff}}$ and the interaction length is now determined by the fiber losses (rather than by walk off) and the XPM-induced effects become almost independent of $\Delta\lambda$. Indeed, if we consider XPM effects between a continuous wave (cw) probe beam and a sinusoidally industry modulated pump beam, then the amplitude of the XPM-induced

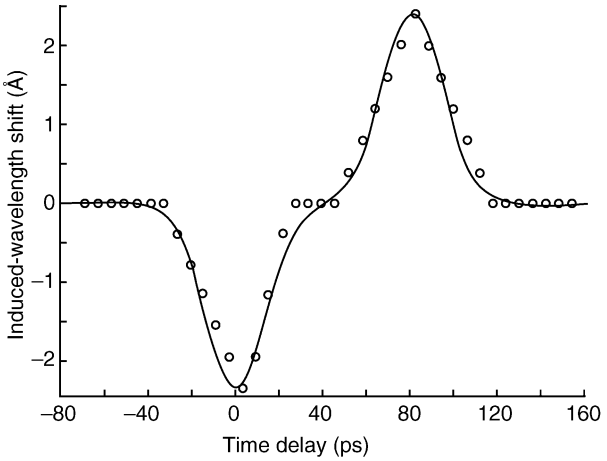

Figure 9 Measured induced frequency shift of 532 nm probe pulse as a function of the delay between this pulse and a pump pulse at 1064 nm, when they propagate through a 1 m long optical fiber. (Reproduced from Baldeck PL, Alfano RR and Agrawal GP (1998) Induced frequency shift of copropagating ultrafast optical pulses. *Applied Physics Letters* 52: 1939–1941 with permission from the American Institute of Physics.)

phase shift ($\Delta\Phi_{pr}$) in the probe beam is given by:

$$\begin{aligned} \Delta\Phi_{pr} &\approx 2\gamma P_{2m} L_{eff} \quad \text{for} \quad L_{wo} \gg L_{eff} \\ \Delta\Phi_{pr} &\approx 2\gamma P_{2m} L_{wo} \quad \text{for} \quad L_{wo} \ll L_{eff} \end{aligned} \qquad [80]$$

Here P_{2m} is the amplitude of the sinusoidal power modulation of the pump beam.

XPM-induced intensity interference can be studied by simultaneously propagating an intensity modulated pump signal and a cw probe signal at a different wavelength. The intensity modulated signal will induce phase modulation on the cw probe signal and the dispersion of the medium will convert the phase modulation to intensity modulation of the probe. Thus, the magnitude of the intensity fluctuation of the probe signal serves as an estimate of the XPM induced interference. Figure 10 shows the intensity fluctuations on a probe signal at 1550 nm, induced by a modulated pump for a channel separation of 0.6 nm. Figure 11 shows the variation of the RMS value of probe intensity modulation with the wavelength separation between the intensity modulated signal and the probe. The experiment has been performed over four amplified spans of 80 km of standard single mode fiber (SMF) and nonzero dispersion shifted fiber (NZDSF). The large dispersion in SMF has been compensated using dispersion compensating chirped gratings. The probe modulation, in the case of SMF, decreases approximately linearly with $1/\Delta\lambda$ for all $\Delta\lambda$s; the modulation is independent of $\Delta\lambda$. In contrast the NZDSF shows a constant modulation for $\Delta\lambda \leq 1$ nm.

This is consistent with the earlier discussion in terms of L_{wo} and L_{eff}.

Four-Wave Mixing (FWM)

Four-wave mixing (FWM) is a nonlinear interaction that occurs in the presence of multiple wavelengths in a medium, leading to the generation of new frequencies. Thus, if light waves at three different frequencies ω_2, ω_3, ω_4 are launched simultaneously into a medium, the same nonlinear polarization that led to intensity dependent refractive index, leads to nonlinear polarization component at a frequency:

$$\omega_1 = \omega_3 + \omega_4 - \omega_2 \qquad [81]$$

This nonlinear polarization, under certain conditions, leads to the generation of electromagnetic waves at ω_1. This process is referred to as four-wave mixing due to the interaction between four different frequencies. Degenerate four-wave mixing corresponds to the case when two of the input waves have the same frequency. Thus, if $\omega_3 = \omega_4$, then inputting waves at ω_2 and ω_3 leads to the generation of waves at the frequency

$$\omega_1 = 2\omega_3 - \omega_2 \qquad [82]$$

During FWM process, there are four different frequencies present at any point in the medium. If we write the electric field of the waves as

$$E_i = \frac{1}{2}[A_i(z)\psi_i(x,y)e^{i(\omega_i t - \beta_i z)} + \text{c.c.}], \quad i = 1,2,3,4 \qquad [83]$$

where, as before, $A_i(z)$ represents the amplitude of the wave, $\psi_i(x, y)$ the transverse field distribution, and β_i the propagation constant of the wave. The total electric field is given by

$$E = E_1 + E_2 + E_3 + E_4 \qquad [84]$$

Substituting for the total electric field in the equation for nonlinear polarization, the term with frequency ω_1 comes out as

$$P_{\mathrm{NL}}^{(\omega_1)} = \frac{1}{2}[P_{\mathrm{NL}}^{(\omega_1)}\, \mathrm{e}^{\mathrm{i}(\omega_1 t - \beta_1 z)} + \mathrm{c.c.}] \qquad [85]$$

where

$$P_{\mathrm{NL}}^{(\omega_1)} = \frac{3\varepsilon_0}{2}\chi^{(3)} A_2^* A_3 A_4 \psi_2 \psi_3 \psi_4\, \mathrm{e}^{-\mathrm{i}\Delta\beta z} \qquad [86]$$

and

$$\Delta\beta = \beta_3 + \beta_4 - \beta_2 - \beta_1 \qquad [87]$$

In writing eqn [86], we have only considered the FWM term, neglecting the SPM and XPM terms.

Substituting the expression for $P_{\mathrm{NL}}^{(\omega_1)}$ in the wave equation for ω_1 and making the slowly varying approximation (in a manner similar to that employed in the case of SPM and XPM), we obtain the following equation for $A_1(z)$:

$$\frac{\mathrm{d}A_1}{\mathrm{d}z} = -2i\gamma A_2^* A_3 A_4\, \mathrm{e}^{-\mathrm{i}\Delta\beta z} \qquad [88]$$

where γ is defined by eqn [48] with $k_0 = \omega/c$, ω representing the average frequency of the four interacting waves, and A_{eff} is the average effective area of the modes.

Assuming all waves to have the same attenuation coefficient α and neglecting depletion of waves at frequencies ω_2, ω_3 and ω_4, due to nonlinear conversion we obtain for the power in the frequency ω_1 as

$$P_1(L) = 4\gamma^2 P_2 P_3 P_4 L_{\mathrm{eff}}^2 \eta\, \mathrm{e}^{-\alpha L} \qquad [89]$$

where

$$\eta = \frac{\alpha^2}{\alpha^2 + \Delta\beta^2}\left[1 + \frac{4\mathrm{e}^{-\alpha L}\sin^2\dfrac{\Delta\beta L}{2}}{(1 - \mathrm{e}^{-\alpha L})^2}\right] \qquad [90]$$

and L_{eff} is the effective length (see eqn [53]). Maximum four-wave mixing takes place when $\Delta\beta = 0$, since in such a case $\eta = 1$. Now:

$$\Delta\beta = \beta(\omega_3) + \beta(\omega_4) - \beta(\omega_2) - \beta(\omega_1) \qquad [91]$$

Since the frequencies are usually close to each other, we can make a Taylor series expansion about any frequency, say ω_2. In such a case, we obtain

$$\Delta\beta = (\omega_3 - \omega_2)(\omega_3 - \omega_1)\left|\frac{\mathrm{d}^2\beta}{\mathrm{d}\omega^2}\right|_{\omega=\omega_2} \qquad [92]$$

In optical fiber communication systems, the channels are usually equally spaced. Thus, we assume the frequencies to be given by

$$\omega_4 = \omega_2 + \Delta\omega, \qquad \omega_3 = \omega_2 - 2\Delta\omega \text{ and} \qquad \omega_1 = \omega_2 - \Delta\omega \qquad [93]$$

Using these frequencies and eqn [60], eqn [92] gives us:

$$\Delta\beta = -\frac{4\pi D\lambda^2}{c}(\Delta\nu)^2 \qquad [94]$$

where $\Delta\omega = 2\pi\Delta\nu$. Thus maximum FWM takes place when $D = 0$. This is the main problem in using wavelength division multiplexing (WDM) in dispersion shifted fibers which are characterized by zero dispersion at the operating wavelength of 1550 nm, as FWM will then lead to crosstalk among various channels. FWM efficiency can be reduced by using fiber with nonzero dispersion. This has led to the development of nonzero dispersion shifted fiber (NZDSF) which have a finite nonzero dispersion of about ± 2 ps/km nm at the operating wavelength.

From eqn [94], we notice that for a given dispersion coefficient D, FWM efficiency will reduce as $\Delta\nu$ increases.

In order to get a numerical appreciation, we consider a case with $D = 0$, i.e., $\Delta\beta = 0$. For such a case $\eta = 1$. If all channels were launched with equal power P_{in} then:

$$P_1(L) = 4\gamma^2 P_{\mathrm{in}}^3 L_{\mathrm{eff}}^2\, \mathrm{e}^{-\alpha L} \qquad [95]$$

Thus the ratio of power generated at ω_1, due to FWM and that existing at the same frequency, is

$$\frac{P_{\mathrm{g}}}{P_{\mathrm{out}}} = \frac{P_1(L)}{P_{\mathrm{in}}\,\mathrm{e}^{-\alpha L}} = 4\gamma^2 P_{\mathrm{in}}^2 L_{\mathrm{eff}}^2 \qquad [96]$$

Typical values are $L_{\mathrm{eff}} = 20$ km, $\gamma = 2.4\ \mathrm{W}^{-1}\ \mathrm{km}^{-1}$. Thus:

$$\frac{P_{\mathrm{g}}}{P_{\mathrm{out}}} \approx 0.01 P_{\mathrm{in}}^2(\mathrm{mW}^2) \qquad [97]$$

Figure 12 shows the output spectrum measured at the output of a 25 km-long dispersion shifted fiber ($D = -0.2$ ps/km nm) when three 3 mW wavelengths are launched simultaneously. Notice the generation of many new frequencies by FWM. Figure 13 shows the

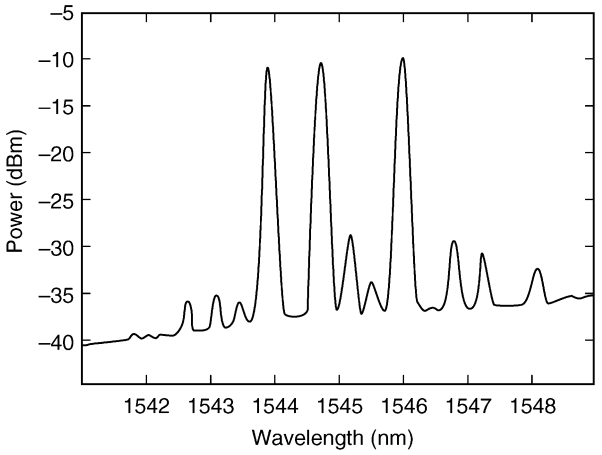

Figure 12 Generation of new frequencies because of FWM when waves at three frequencies are incident in the fiber. Figure 13 Ratio of generated power to the output as a function of channel spacing $\Delta\lambda$ for different dispersion coefficients. (Reproduced with permission from Tkach RW, Chraplyvy AR, Forghiari F, Gnanck AH and Derosier RM (1995) Four-photon mixing and high speed WDM systems. *Journal of lightwave Technology* 13: 841–849, © 2004 IEEE.)

ratio of generated power to the output as a function of channel spacing $\Delta\lambda$ for different dispersion coefficients. It can be seen that by choosing a nonzero value of dispersion, the four-wave mixing efficiency can be reduced. Larger the dispersion coefficient, smaller can be the channel spacing for the same crosstalk.

Since dispersion leads to increased bit error rates in fiber optic communication systems, it is important to have low dispersion. On the other hand, lower dispersion leads to crosstalk due to FWM. This problem can be resolved by noting that FWM depends on the local dispersion value in the fiber, while the pulse spreading at the end of a link depends on the overall dispersion in the fiber link. If one chooses a link made up of positive and negative dispersion coefficients, then by an appropriate choice of the lengths of the positive and negative dispersion fibers, it would be possible to achieve a zero total link dispersion while at the same time maintaining a large local dispersion. This is referred to as dispersion management in fiber optic systems.

Although FWM leads to crosstalk among different wavelength channels in an optical fiber communication system, it can be used for various optical processing functions such as wavelength conversion, high-speed time division multiplexing, pulse compression, etc. For such applications, there is a concerted worldwide effort to develop highly nonlinear fibers with much smaller mode areas and higher nonlinear coefficients. Some of the very novel fibers that have been developed recently include holey fibers, photonic bandgap fibers, or photonic crystal fibers which are very interesting since they possess extremely small mode effective areas ($\sim 2.5\ \mu m^2$ at 1550 nm) and can be designed to have zero dispersion even in the visible region of the spectrum. This is expected to revolutionize nonlinear fiber optics by providing new geometries to achieve highly efficient nonlinear optical processing at lower powers.

Supercontinuum Generation

Supercontinuum (SC) generation is the phenomenon in which a nearly continuous spectrally broadened output is produced through nonlinear effects on high peak power picosecond and subpicosecond pulses. Such broadened spectra find applications in spectroscopy, wavelength characterization of optical components such as a broadband source from which many wavelength channels can be obtained by slicing the spectrum.

Supercontinuum generation in an optical fiber is a very convenient technique since it provides a very broad bandwidth (>200 nm), the intensity levels can be maintained high over long interaction lengths by choosing small mode areas, and the dispersion profile of the fiber can be appropriately designed by varying the transverse refractive index profile of the fiber.

The spectral broadening that takes place in the fiber is attributed to a combination of various third-order effects such as SPM, XPM, FWM, and Raman scattering. Since dispersion plays a significant role in the temporal evolution of the pulse, different dispersion profiles have been used in the literature to achieve broadband SC.

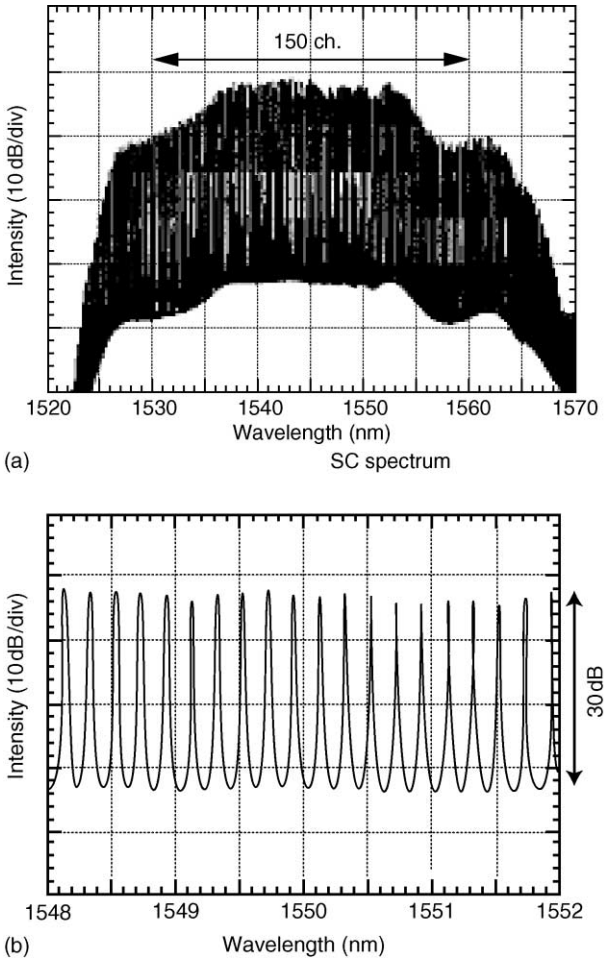

Figure 14 Super Continuum spectrum generated by passing 25 GHz optical pulse train at 1544 nm generated by a mode locked laser diode and amplified by an erbium doped fiber. (Reproduced from Yamada E, Takara H, Ohara T, Satc K, Morioka T, Jinguji K, Itoh M and Ishi M (2001) A high SNR, 150 Ch. Supercontinuum CW optical source with high SNR and precise 25 GHz spacing for 10 Gbit/s DWDM systems. *Electronics Letters* 37: 304–306 with permission from IEEE.)

Some studies have used dispersion decreasing fibers, dispersion flattened fibers, while others have used a constant anamolous dispersion fiber followed by a normal dispersion fiber.

Figure 14 shows the SC spectrum generated by passing 25 GHz optical pulse train at 1544 nm generated by a mode locked laser diode and amplified by an erbium doped fiber. The fiber used for SC generation is a polarization maintaining dispersion flattened fiber. The output is a broad spectrum containing more than 150 spectral components at a spacing of 25 GHz with a flat top spectrum over 18 nm. The output optical powers range from −9 dBm to +3 dBm. Such sources are being investigated as attractive solutions for dense WDM (DWDM) optical fiber communication systems.

Conclusions

The advent of lasers provided us with an intense source of light and led to the birth of nonlinear optics. Nonlinear optical phenomena exhibit a rich variety of effects and coupled with optical waveguides and fibers, such effects can be observed even at moderate optical powers. With the realization of compact femtosecond lasers, highly nonlinear holey optical fibers, quasi phase matching techniques, etc, the field of nonlinear optics is expected to grow further and lead to commercial exploitation such as in compact blue lasers, soliton laser sources and multiwavelength sources and for fiber optic communication.

List of Units and Nomenclature

Attenuation	The decrease in optical power of a propagating mode usually expressed in dB/km
Birefringent medium	A medium characterized by two different modes of propagation characterized by two different polarization states of a plane light wave along any direction
Cross-phase modulation (XPM)	The phase modulation of a propagating light wave due to the nonlinear change in refractive index of the medium brought about by another propagating light wave
Effective length (L_{eff})	The length over which most of the nonlinear effect is accumulated in a propagating light beam
Four-wave mixing (FWM)	The mixing of four propagating light waves due to intensity dependent refractive index of the medium. This mixing leads to the generation of new frequencies from a set of two or three input light beams
Mode effective area (A_{eff})	The cross sectional area of the mode which determines the nonlinear effects on the propagating mode. This is different from the core area
Nonlinear polarization (P_{NL})	When the response of the medium to an applied electric field is not proportional to the applied electric field, then this results in a nonlinear polarization
Optical waveguides	Devices which are capable of guiding optical beams by overcoming diffraction effects using

	the phenomenon of total internal reflection
Phase coherence length	The minimum crystal length upto which the second harmonic power generated by the nonlinear interaction increases
Phase matching	Condition under with the nonlinear polarization generating an electromagnetic wave propagates at the same phase velocity as the generated electromagnetic wave
Pulse dispersion	The broadening of a light pulse as it propagates in an optical fiber
Quasi-phase matching (QPM)	Periodic modulation of the nonlinear coefficient to achieve efficient nonlinear interaction
Second-harmonic generation (SHG)	The generation of a wave of frequency 2ω from an incident wave of frequency ω through nonlinear interaction in a medium
Self-phase modulation (SPM)	The modulation of the phase of a propagating light wave due to the nonlinear change in refractive index of the medium brought about by itself
Supercontinuum generation (SC)	The phenomenon in which a nearly contiunuous spectrally broadband output is produced through nonlinear effects on high peak power picosecond and sub-picosecond pulses
Walk off length (L_{wo})	Length of the fiber required for two interacting pulses at different wavelengths to walk off relative to each other

Optical Fiber Cables

Introduction

In order to be put to practical use in the telecommunication network, optical fibers must be protected from environmental and mechanical stresses which can change their transmission characteristics and reliability.

The fibers, during manufacturing, are individually protected with a thin plastic layer (extruded during the drawing) to preserve directly their characteristics from damage due to the environment and handling. This coating surrounding the fiber cladding (with an external diameter of 125 μm) is known as the primary coating, which is obtained with a double layer of UV resin for a maximum external diameter of about 250 μm.

Primary coated fiber, at the end of the manufacturing process, is subjected to a dynamic traction test (proof-test) to monitor its mechanical strength. This test, carried out on all fibers manufactured, consists of the application of a well-defined strain (from 0.5% to 1%) for a fixed time (normally 1 s) and thus permits the exclusion of, from successive cabling, those fibers with poor mechanical characteristics.

At the end of the manufacturing process the optical fibers are not directly usable. It is necessary to surround the single fiber (or groups of fibers) with a structure which provides protection from mechanical and chemical hazards and allows for stresses that may be applied during cable manufacture, installation, and service.

Suitable protection is provided using fiber conditioning within the cable (secondary coating or loose cabling), while entire protection is obtained with some cable elements, such as strength members, core assembling, filling, and outer protections. Moreover, the cable structure and its design is heavily influenced by the application (e.g., number of fibers), installation (laying and splicing), and environmental conditions of service (underground, aerial, or submarine).

In this article, the main characteristics of optical cables (with both multimode or single mode fibers) are described and analyzed, together with suitable solutions.

Secondary Fiber Coating

The fiber, before cabling, can be protected with a secondary coating (a tight jacketing) to preserve it during cable stranding. However, fiber with only a primary coating may be cabled with a suitable cable protection.

In the first case the fiber can be directly stranded to form a cable core; in the second case, a single group of fibers must be inserted into a loose structure (tubes or grooves) with a proper extra-length. These two solutions are not always distinguishable; in fact, tight fibers inserted into loose tubes or grooves are often used.

The implementation of the secondary coating and the choice of proper materials requires particular attention, in order to avoid microbending effects on the fiber, which can cause degradation of the transmission characteristics. Microbending is caused by the pressure of the fiber on a microrough surface, or by the fiber buckling, due to the contraction of the structure (e.g., secondary coating) containing it. Microbending causes an increase in fiber attenuation at long wavelengths (1300 and 1550 nm) for both single and multimode fibers, but is particularly emphasized in multimode fibers.

Tight Jacket

In a tight protection, the primary coating fiber is surrounded by a second plastic jacket in contact with the fiber. This jacket mainly protects the fiber from lateral stresses that can cause the microbending.

The fiber can be individually protected with a single or double layer of plastic material or in a ribbon structure. In Figure 1 four different types of tight jacket are shown. In Figure 1a and b the fibers are singularly protected with a single or double layer up to an external diameter of 0.9 mm. The second type is normally preferred because the external hard plastic gives a good fiber protection and the inner soft plastic avoids microbending effects on the fiber.

In a ribbon structure, from 4 to 16 primary coated fibers are laid close and parallel and covered with plastic. Two types of ribbon are normally classified 'encapsulated' (Figure 1c) or 'edge bonded' (Figure 1d). In the first case, the fibers are assembled with a common secondary coating (one or two layers), in the second case, an adhesive is used to stick together the fibers with only the primary coating.

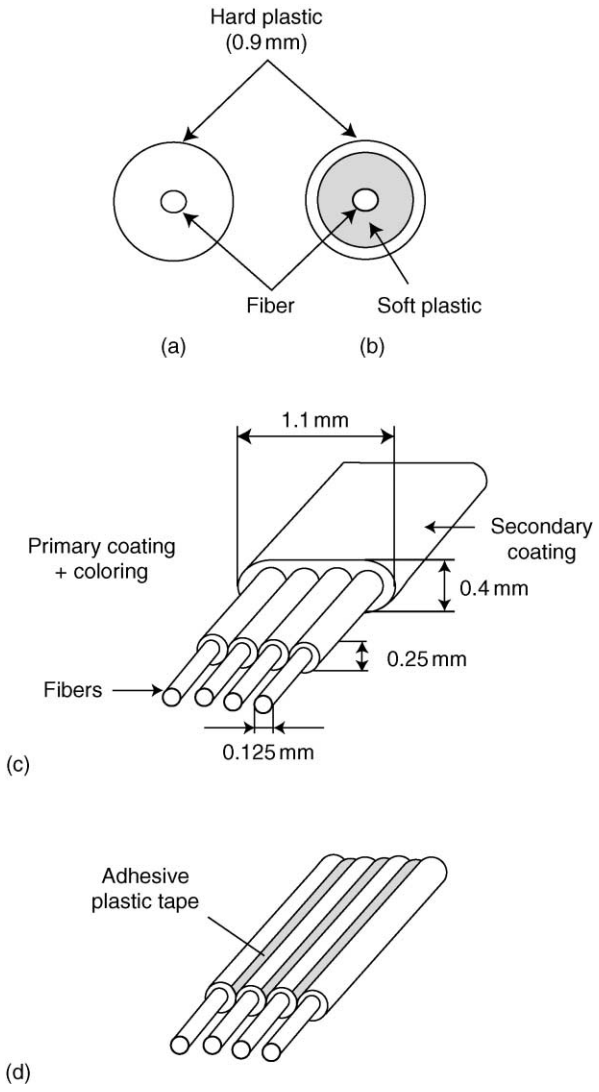

Figure 1 Different types of tight coatings.

Care should be taken in applying tight protection, in particular for a ribbon structure, to avoid an attenuation increase due to the action of the jacket on the fiber (in particular for the thermal contraction of the coating materials). The ribbon structure is designed to permit the simultaneous junction of multiple fibers; for this reason the ribbon geometry must be precision controlled.

Loose Jacket

In a loose protection the fiber can be inserted into a cable with only the primary coating. A thin layer of colored plastic may be added onto the primary coating to identify the fiber in the cable. The fibers are arranged in a tube or in a groove on a plastic core (slotted core). The diameter of the tube or the dimension of the core must be far larger than the diameter of the fiber so that the fiber is completely free inside the structure. The fibers can be inserted into a tube or into a slotted core, singularly or in groups. The space inside the tube around the fibers can be empty or filled with a suitable jelly. Some examples of loose structures are shown in Figure 2. In the tube structure, the external diameter of the jacket depends on the number of the fibers: for a single fiber up to 2 mm (Figure 2a), and for a multifiber tube (Figure 2b) up to 3 mm (for 10 fibers).

Examples of slotted core structures are shown in Figure 2c and d, respectively, for one fiber and for a group of fibers, the dimensions of grooves depending on the number of fibers.

Plastic materials with a high Young modulus are normally used for the tube that is extruded on the single or on the group of fibers. Instead, for the slotted core, plastic materials with good extrusion are used to obtain a precise profile of the grooves.

The loose structure guarantees freedom to the fibers in a defined interval of elongation and compression. Out of this interval, microbending effects can arise which increase fiber attenuation. Axial compression generally occurs when the cable is subjected to low temperatures and is generated from the thermal contraction of the cable materials that is different from that of the fibers. Axial elongation normally occurs when the cable is pulled or by the effects of high temperature.

For a correct design of a cable with a loose structure, the extra length of the fiber with respect to the tube or groove dimension and the stranding pitch must be evaluated, starting from the range of axial compression and elongation. In fact, care must be taken to prevent the fiber from being strained or forced against the tube or groove walls in the designed range.

For the tube solution, the extra length of the fibers is controlled during the tube extrusion; for the slotted core solution, the length is controlled during cabling, giving a controlled tension to the slotted core. The loose structure is often used for the cabling of fibers with tight jacketing, joining the advantages of the tight protection and loose cable. This solution is typical for ribbon cables.

Fiber Identification

To identify the fibers in a cable, a proper coloration with defined color codes must be given to the single fibers. In the tight protection, the tight buffer is directly colored during extrusion. In the loose protection, a thin colored layer is added on the primary coating of the fiber; tubes or slotted core may

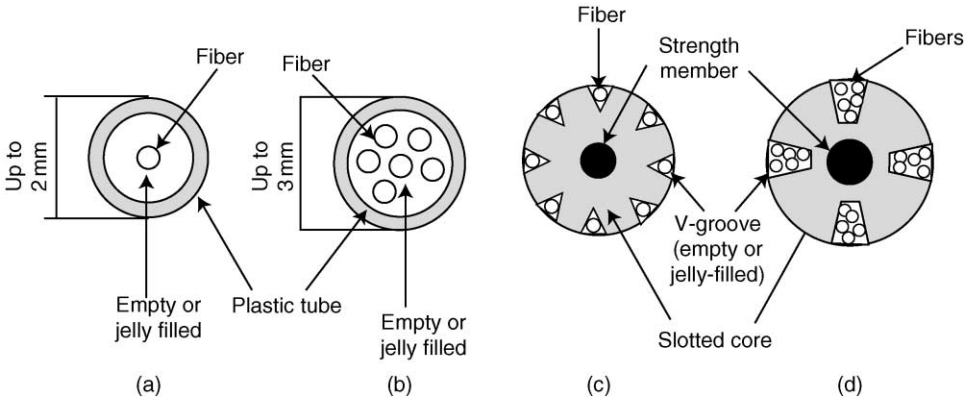

Figure 2 Different types of loose coatings.

be also colored to identify groups of fibers in high potentiality cables.

Cable Components

The fundamental components of an optical cable are: the cable core with the optical fibers, the strength member (one or more) which provide the mechanical strength of the cable, sheaths which provide the external protection, and filling materials.

Cable Core

The optical fibers with the secondary coating (tight or loose) are rejoined together in a cable core. For tight fibers or loose tubes, the cable core is obtained by stranding the fibers or the tubes around central elements that normally act as strength members too (see below).

The stranding pitch must be long enough to avoid excessive bending of the fibers and short enough to guarantee stress apportionment among the fibers in cable bends and maximum elongation of the cable without fiber strain. Normally, a helical stranding is used, but often SO stranding, that consists in an inversion of stranding direction every three of more turns, is employed. The second stranding type makes the cabling easier but may reduce its performance.

The unit core or the slotted core are made of plastic and normally incorporate a central strength member.

Strength Member

The strength member may be defined as an element that provides the mechanical strength of the cable, to withstand elongation and contraction during the installation and to ensure thermal stability. Fiber elongation, when the cable is pulled or the fiber compressed due to low temperatures, depends greatly

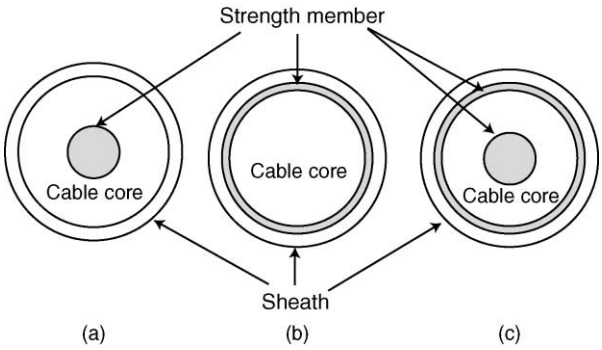

Figure 3 Different locations of the strength member in an optical cable.

on the characteristics of the strength member inserted in the cable.

As the maximum elongation values suggested for the fibers are in the range from 20 to 30% of the proof-test value, the maximum elongation allowed for a tight cable is ~0.1% instead of ~0.3% for a loose cable. To warrant these performances, a material with a high Young modulus is normally used as a strength member. Also, the strength member must be light (to avoid excessive cable weight) and flexible: these properties make it easier when laying the cable in ducts.

The strength member may be metallic or non-metallic and may be inserted in the core (Figure 3a) or in the outer part of the cable (Figure 3b), normally under the external sheath. Often two strength members are placed in an optical cable: the first one in the core and the second one under the sheath (Figure 3c).

Metallic strength members, generally one or more wires of steel, are inserted in the center or in the outer part of the cable. The steel, for its low thermal expansion coefficient and high Young modulus, behaves as a good strength member, particularly

when it is arranged in the central core. Steel is a nonexpensive material, but needs protection against corrosion and electrical-induced voltages, such as by lightning or current flow in the ground.

If cables with high flexibility are requested, steel is not suitable and aramid fiber yarn or glass-fiber reinforced plastic (G-FRP) are used, particularly when the strength member is placed in the outer part of the cable. Glass fiber elements are generally used as a compressive strength member in the central cable core to avoid contraction at low temperatures, but they may be used as strength elements when the traction strength is low.

Aramid yarns are not active as resisting compression elements but are normally arranged in the outer part of the optical cable. Aramid yarns have a high Young modulus (as with steel) and low specific weight: in commercial form they consist of a large number of filaments gathered into a layer. Normally two layers stranded in opposite directions are used to avoid cable torsion during the installation.

Metal-free cables are protected by G-FRP and aramid yarns. This solution results in optical cables which are insensitive to electrical interferences.

Sheaths

The functions of the sheaths are to protect an optical cable during its life, in particular from mechanical and environmental stresses. During the installation or when the cable is in service, it may be subjected to mechanical stresses, for example, presence of humidity or water and chemical agents. The sheaths act as a barrier to avoid degradations of the fibers in the internal cable core.

The plastic sheaths (one or more, depending on the cable type and structure) are extruded over the core. This extrusion is a delicate operation in cable manufacturing because the cable core may be subjected to tension, while during the cooling the thermal compression of the plastic produces a stress on all the cable elements. Examples of cable sheaths are shown in Figure 4.

Different plastic materials, such as polyvinylchloride (PVC), polyethylene, and polyurethane are normally used. PVC has excellent mechanical properties, flexibility, and is flame retardant but is permeable to humidity. On the other hand, high-density polyethylene has a permeability lower than PVC, with good mechanical properties and low coefficient of friction, but it is more flammable than PVC and less flexible. Finally, polyurethane, for its softness and high flexibility, is often used for inner sheaths. When low toxicity is requested (e.g., in indoor cables), halogen-free materials are employed.

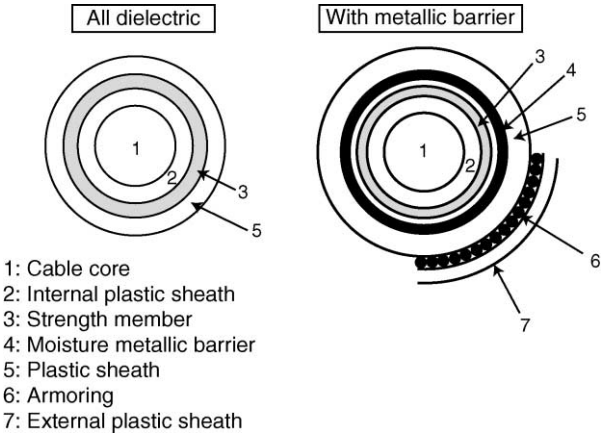

Figure 4 Examples of optical cable sheaths.

Often a metallic barrier is used under the external sheath to prevent moisture entering the cable core. The type most widely used is an aluminum ribbon (of a few tenths of a millimeter) bonded into the external polyethylene sheath, during the sheath extrusion. This structure is normally indicated as a LAP (laminated aluminum polyethylene) sheath.

When the cable is directly buried, a metallic armor (corrugated steel tape or armoring wires) is generally inserted. The metallic armor protects the cable core against radial stresses but it is also used as protection against rodents and insects.

Filling Compounds and Other Components

Fillings are used in optical cables to avoid the presence of moisture and water propagation in the cable core should a failure occur in the cable sheath. Suitable jelly compounds, with constant viscosity at a wide range of temperatures and chemical stabilities, are generally inserted in the cable core and, sometimes, in the outer protection layer. In loose structures, the jelly is in direct contact with the fibers: the compound must be compatible with them and guarantee the fiber freedom. Special compounds may be used to adsorb and permanently fix any hydrogen present in the cable core. The presence of hydrogen gas, that may be generated from the internal materials of the cable (mainly metals), is harmful to the fibers because it causes permanent attenuation increases and thus damage to them.

With the generic terminology 'other components', some other components used in the optical cables are included. They are often similar to those used in conventional cables. The most important are: insulated conductors, plastic fillers, and cushion layers and tapes around the fiber core.

Insulated copper conductors may be incorporated in the cable core, for example, to carry power supply

or as service channels, or to detect the presence of moisture in the cable (in this case, the insulation is missing or partial). The conductors may cause problems due to the voltages induced by power lines or lighting.

Plastic fillers are often used to complete the cable core geometry. Cushion layers are used to protect the cable core against radial compression. Normally, they are based on plastic materials wound around the core. Tapes are wound around the cable core to hold the assemblies together and secondly to provide a heat barrier during the sheath extrusion. Mylar tapes are usually employed.

Optical Cable Structures, Types, and Applications

Cable Structures

The structure of an optical cable is strictly dependent on the construction method and the application type that determines the design and the grade of external protection. The main core (or inner) structures of an optical cable can be classified as: stranded structures (tight and loose); slotted core cable; or ribbon cable. In this section, a few examples of cable structures are presented. Below, separate sections are devoted to submarine cables and to special application cables, for their particular structures and features.

In the stranded tight structure, a low number of tight or loose fibers is stranded around a strength member to form a cable unit. Some of this cable unit may be joined to constitute a cable with a medium/high number of fibers (Figure 5a). Alternatively the fibers may be arranged in a multilayer structure (Figure 5b).

The main advantages of a tight stranded structure are the small dimensions of the cable core, even when a large number of fibers are involved, and also the facility of handling. Care must be taken in the design of the strength member: in fact, the fibers are immediately subjected to tension when the cable is pulled into the ducts or compressed when subjected to low temperatures.

In the stranded loose structures, two categories of cables are defined, one fiber per tube and a group of fibers (up to 20) per tube (Figure 5c). As already mentioned, in the loose structures, the fibers are free inside the tube and for this reason the cable is less critical than the tight cable. The external dimensions of loose cables are larger than tight cables, but the solution with multiform tubes allows for cables with a high number of fibers in relatively small dimensions.

Slotted core cables (Figure 2c,d) contain fibers with only the primary coating and may be divided, as in the stranded loose structure, into one fiber per groove or into a group of fibers per groove. The cable design and the choice of a suitable plastic material for the slotted core joined to a proper strength member, make it possible to obtain cables with fiber stability at a wide range of temperature. As in the loose stranded solutions, the slotted core solution is adopted to obtain cables with a high number of fibers in small dimensions.

In the ribbon solution, the fibers (from 4 to 16) are placed in a linear ribbon array. Many ribbons are stacked together to constitute the optical unit. The ribbon cable normally has a loose structure (loose tube or slotted core). Three structures are shown in Figure 6. In the first example (classical AT & T cable), 12 ribbons of 12 fibers are directly stacked and stranded in a tube (Figure 6a). In the second and third examples, ribbons are inserted into tubes or grooves (Figure 6b,c). Several tubes or slotted cores can be assembled together to give a cable with very high fiber density. The ribbon approach may be efficient when a large number of fibers must be

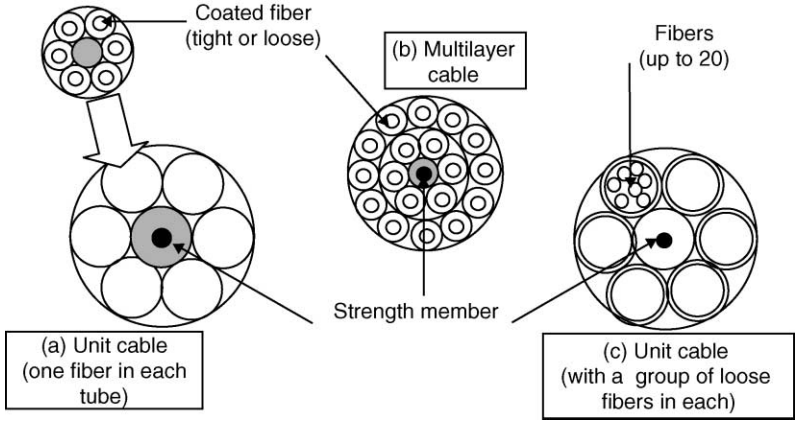

Figure 5 Structures of stranded core cables.

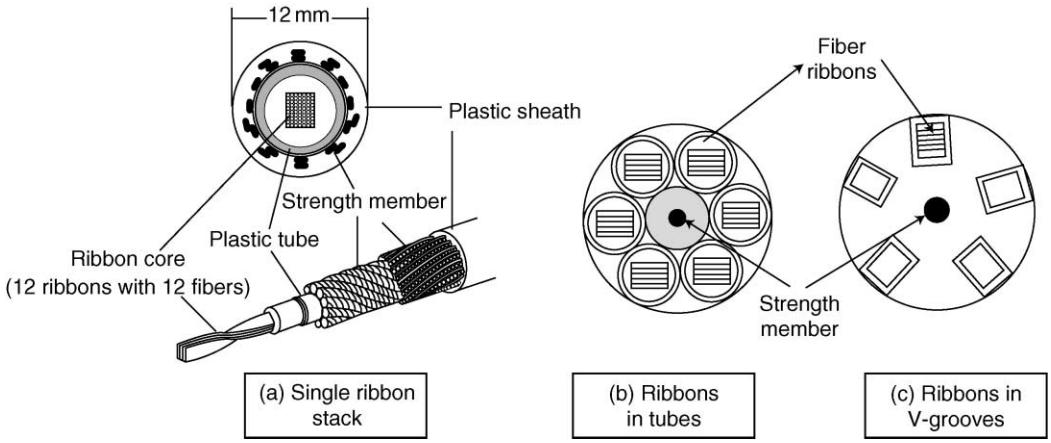

Figure 6 Structures of ribbon cables.

simultaneously handled, spliced, and terminated at connectors.

Types and Applications

The choice of an optical cable is heavily established by many factors, but mainly on the type of installation. On this basis, some different typology of cables may be identified: aerial cables, duct cables, direct buried cables, indoor cables, underwater cables, etc.

Aerial cables can be clasped onto a metal strand or can be self supporting. In the first case, the cable is not subjected to a particular tension but requires good thermal and mechanical performances. This solution is chosen when the cable must withstand strong ice and wind and when long distances between the poles are required. All the structures mentioned above may be adopted. In the second case, the cable is normally exposed to high mechanical stresses during its life and high tensile strength must be guaranted to maintain the fiber elongation at a safety level. Generally, loose structures are preferred for their greater fiber freedom. Often, in self-supporting cables, the strength member is external to the cable core. An example is shown in Figure 7.

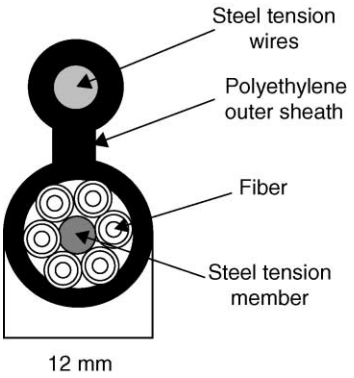

Figure 7 Self-supporting aerial cable.

Cables pulled in ducts must be resistant to pulling and torsion forces, and light and flexible to permit the installation of long sections. The cable must also protect the fibers against water and moisture that may be present in ducts or manholes. Usually the cable is filled with a jelly compound, a metallic barrier is normally used and, often, an armoring is added when protection against rodents is necessary. All the structures described above may be employed in duct cables.

The characteristics of direct buried cables are very similar to those of duct cables, but additional protections, such as metallic armoring, are required to avoid the risk of damages from digging and other earthmoving work.

Cables for indoor applications normally require a smaller number of fibers. Their main characteristics are: small dimensions, flexibility, small curvature radius, and ease in handling and jointing. For indoor applications, the sheath must not permit flame propagation and must have a low emission of toxic gases and dark smoke. Tight cables are preferably used for indoor applications due to their compactness and small dimensions.

Underwater cables are employed in the crossing of rivers, in lakes and lagoons, and for shallow water applications in general. Such cables must have stringent requirements such as resistance to moisture and water penetration and propagation, pulling resistance (during the installation, and recovery in event of failure), and high resistance to static pressure and core structure compatible with land cables (when it is part of a ground link). In addition, due to the presence of metallic structures, attention should be paid to hydrogen effects.

Submarine Cables

Submarine cable is manufactured for laying in deep-sea conditions. In designing a submarine cable, it is necessary to provide high reliability that the mechanical and transmission characteristics of the optical fibers will be stable over a long period of time. Different cables are used for submarine applications, but generally follow the basic scheme of Figure 8.

The central core (with a few fibers – up to 12 – in a slotted core or in a tight structure) is surrounded by a double layer of steel wires that act as strength members against tensile action and water pressure. Metal pipes at the inner or outer sides of the strength member, act as a water barrier and as power supply conductors (for the supply of the undersea regenerators).

The outer polyethylene insulating sheath is the ultimate protection for the ordinary deep-sea cable. For cables requiring special protection, steel wire armoring (anti-attack from fishes), and further polyethylene are added.

The cable must have stringent mechanical requirements, such as resistance to traction, torsion, crushing, impact, and to shark attack. The cable must be suitable for installation using standard cable-laying ships. Furthermore the cable materials must have low content of hydrogen and emissions. If necessary, a hydrogen absorber may be included in the cable core.

Special Cables

This category comprises cables not specifically used in ordinary telecommunication networks, but cables used for specific applications and according to specified requirements. Cables for military use are normally employed for temporary plant restoration. They must be light but crush resistant and with good mechanical characteristics. Cables for mobile applications (robots, elevators, aircrafts, submarines, etc.) generally require high flexibility and tensile strength. Special cables may be installed in particular environments, where they must be insensitive, for instance, to nuclear radiation, chemical agents, and high temperatures.

Optical cables can be installed in power lines, together with the power conductors, or into the ground wires of high-voltage overhead power lines. In this last type of cable, the central stranded steel wire, making up the ground wire, is replaced with a metal tube containing the optical unit (normally a small groups of optical fibers inserted in a tube or in a slotted core).

Blown Fiber

This technology consists of the installation of a single fiber or of small fiber bundles (or cables) into pre-installed tubes or ducts using a flux of compressed air. Initially, cables with empty tubes are installed and successively, at the time of need, the tubes can be filled by blowing fibers (singly, or in bundles) or cables. The installation time is normally fast; some compressors can blow tens of meters in a minute. The typical maximum blowing distance is about 1 km for horizontal planes, but it is reduced

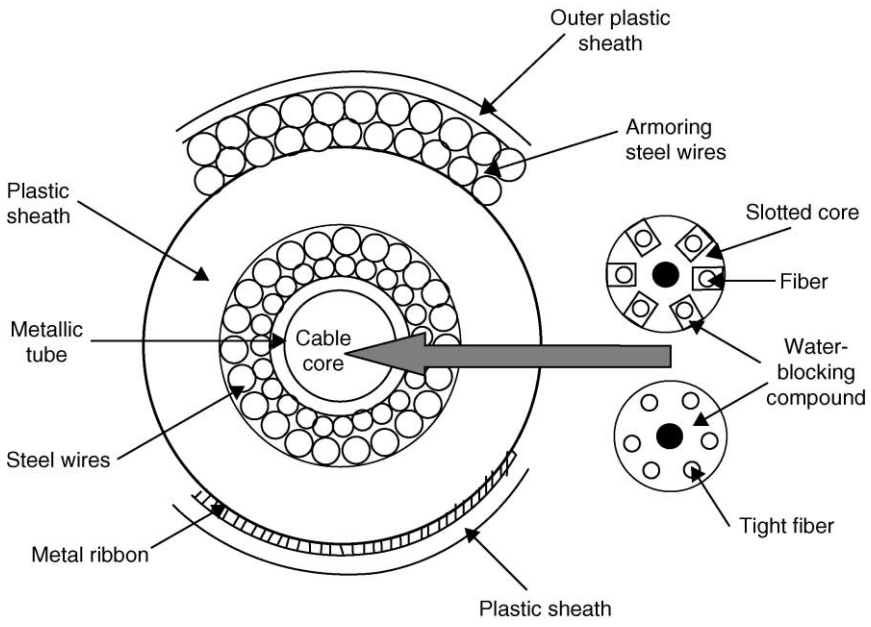

Figure 8 Basic structure of a submarine cable.

along winding roads. The advantage of this technique is to produce variable and flexible structures, increasing the number of fibers to fit the network need. Besides, substitutions or change of fibers can be quickly carried out without substitution of the cable.

Passive Optical Components

D Suino, Telecom Italia Lab, Torino, Italy

© 2005, Elsevier Ltd. All Rights Reserved.

Introduction

Modern telecommunications networks are based on fiber optics as signal transporters. In these networks the signals travel in the form of light confined within the fibers. As light power travels through the fibers from the source apparatus to the receiver, a number of components are employed to manage the optical signal. All other components that are not used to manage the signal are called 'passive optical components'. They serve several functions, such as to join two different fibers to distribute the signal onto more optical branches to limit the optical power to select particular wavelengths, and so on.

These components can be located anywhere in the network, depending on their function and on the network architecture. However, their main location is near the apparatus in which it is necessary to manage the signal before it is sent through the network or at the junction in the network where it is sent on to the receiver.

The main types of passive components that are found in a network can be grouped as follows:

- Joint devices:
  - Optical connectors;
  - Mechanical splices.
- Branching devices:
  - Nonwavelength-selective branching devices;
  - WDM.
- Attenuators;
- Filters;
- Isolators;
- Circulators.

Optical fibers are also divided into several groups (multimode 50/125, multimode 62.5/125, singlemode, dispersion shifted, NZD, and so on). There are also components of different typology that match up with each particular fiber. However, the general concept in terms of functionality, technology, and characteristic parameters, are the same among passive optical components of the same type (connectors, branching devices, or attenuators) but of different groups (single-mode, multimode, etc.).

Optical Joint Devices

The function of an optical joint is to perform a junction between two fibers, giving optical continuity to the line. Two different classes of joint can be considered: the connectors and the splices. The joints made by using connectors, are flexible points in the network, which means they can be opened and reconnected several times in order, for example, to reconfigure the network plan. However, a splice is a fixed joint and usually cannot be opened and re-mated. There are two type of splice: mechanical splices, holding joints to fibers by glue or mechanical crimp, and fusion splices fusing the two fiber heads with a suitable fusion splicer.

General Considerations

Considering that fibers can be described as pipes, in the core of which flows light, continuity between two fibers means that the two cores must be aligned in a stable and accurate way. Obviously this alignment must be carried out with minimum power loss in the junction. The main factors that

affect the power loss in a joint point between two fibers are:

- x = Lateral offset;
- z = Longitudinal offset;
- θ = Angular misalignment; and
- w_T/w_R = Mode field diameter ratio (in the single mode fiber) or numerical aperture ratio (in the multimode fiber).

These geometrical mismatching between the two fibers is represented in Figure 1.

The function that describes the joint attenuation is different for single-mode and multimode connectors, but the parameters that contribute to it are the same. The general formulation for these functions are complicated and, in particular, for the multimode connector it involves an integral on the shape distribution of the light in the fiber core. These functions become simpler in particular conditions: for example, if we consider a single-mode joint without a gap between the two fibers (that is the more usual condition in the modern connectors) the z parameter is nil, and in this case the function that describes the attenuation of the connector is

$$A(\mathrm{dB}) = -10\log\left\{\left(\frac{2w_T w_R}{w_T^2 + w_R^2}\right)^2 \times \exp\left[-2\frac{(x\lambda)^2 + (\pi n w_T w_R \sin(\vartheta))^2}{\lambda^2(w_T^2 + w_R^2)}\right]\right\} \quad [1]$$

where n is the fiber core refractive index and λ is the wavelength of the light.

Figure 2 shows the trend of eqn [1], where the parameter ranges in the graphs are typical for the most common products on the market. It is evident that the main contribution to attenuation arises from the lateral offset.

For connectors of good quality, both for single-mode and multimode fibers, the attenuation values are in the range of a few tenths of dB (typically less than 0.3 dB). Another important factor for a joint, in particular for connectors used in networks for high speed or analog signals, is the return loss (RL). This is a parameter that gives a measure of the quantity of light back-reflected onto the optical discontinuity of the connector, due to the Fresnel effect. The RL is defined as the ratio in dB between the incident light power (P_{inc}) and the reflected light power (P_{ref}):

$$\mathrm{RL} = -10\log\left(\frac{P_{ref}}{P_{inc}}\right) \quad [2]$$

Fresnel reflection arises when the light passes between two media with different refractive indices. In the case of connectors in which the two fibers are not in contact, the light passes from the silica of the fiber

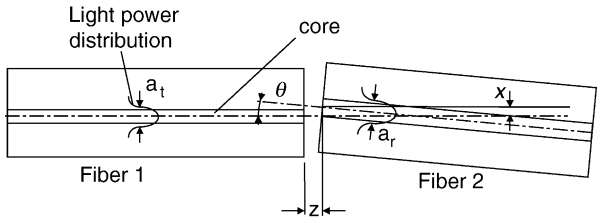

Figure 1 Main parameter that affects the joint power loss.

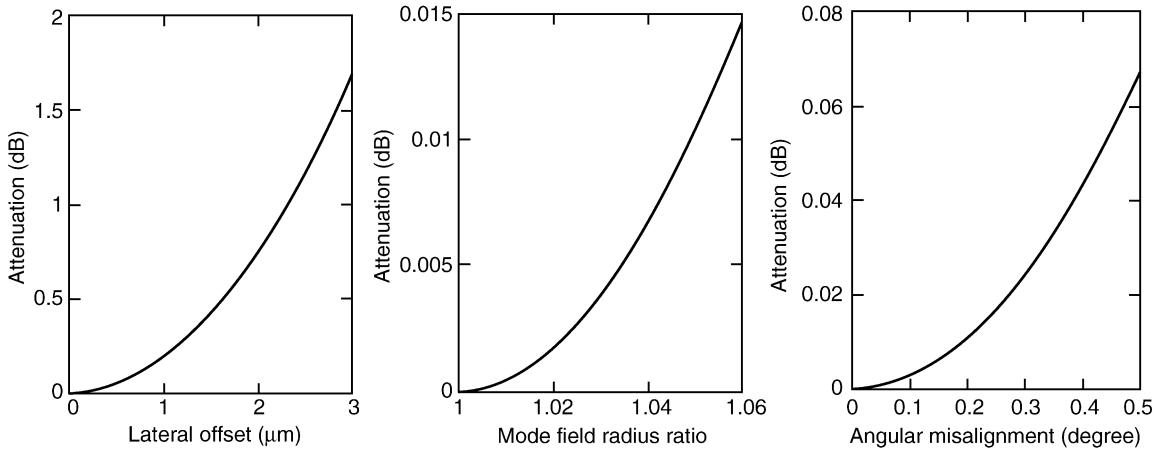

Figure 2 Single mode connector attenuation as a function of the geometrical parameters. Each curve is plotted keeping the other parameter constant.

core to the air in the gap. This causes the reflection of 4% of the incident light that, as RL, is about 14 dB.

To improve the RL performances of an optical joint, it is necessary to reduce the refractive index difference. This can be achieved either by index matching material between the two fibers that reduces the differences between the refractive index of the fiber and the gap, or by performing a physical contact between the fiber heads. The first technique is typically used in mechanical splices but, due to the problem related with the pollution contamination of the index matching, it is not a good solution for connectors that are to be opened and reconnected several times.

The physical contact solution is the most frequently adopted for these connectors. Physical contact is obtained by polishing the ferrule and the fiber end-faces in a convex shape, with the fiber core positioned in the apex (Figure 3). With this technique, the typical values of return loss for a single mode connector are in the range from 35 dB to 55 dB, depending on the polishing grade. The residual back-reflected light is generated in the thin layer of the fiber end surface, because of slight changes in the refractive index due to the polishing process.

Higher return loss values (small quantity of reflected light) are achieved with the angled physical contact (APC) technique. This is obtained by polishing the convex ferrule end face angled with respect to the fiber axis. In this way, the light is not back reflected into the fiber core, but into the cladding, and is thus eliminated (Figure 4). In APC connectors, typical return loss values are greater than 60 dB.

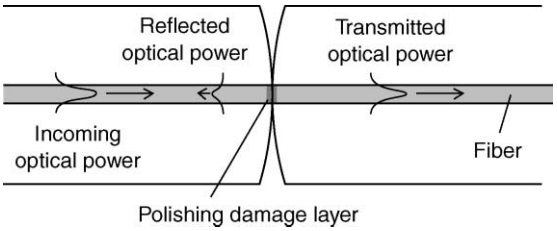

Figure 3 Back reflection effects in PC connectors.

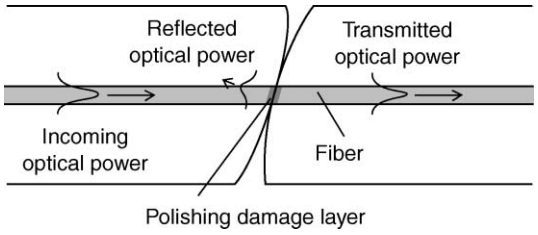

Figure 4 Back reflection effects in APC connectors.

Optical Connectors

On the market are several types of optical connectors. It is possible to divide them into three main groups:

- Connectors with direct alignment of bare fiber;
- Connectors with alignment by means of a ferrule; and
- Multifiber connectors.

Connectors with direct alignment of bare fiber

In this type of connector the bare fibers are aligned on an external structure that is usually a V-groove (Figure 5). Two configurations can be performed: plug and socket or plug–adapter–plug. In the first case, the fiber in the socket is fixed and the one in the plug aligns to it. In the plug–adapter–plug configuration, two identical plugs containing the bare fibers are locked onto an adapter in which the fibers are placed on the aligned structure. These connectors are cheaper than the connectors with a ferrule, (described below), but this is unreliable. In fact, the bare fibers are delicate and brittle and they can be affected by the external mechanical or environmental stresses.

Connectors with alignment by means ferrule

In this type of connector, the fibers are fixed in a secondary alignment structure, usually of cylindrical shape, called a ferrule. The fiber alignment is obtained by inserting the two ferrules containing the fibers into a sleeve. Usually this type of connector is in the plug–adapter–plug configuration (Figure 6). With this technique, the precision of the alignment is moved from the V-groove precision to the dimensional tolerance of the ferrule. Typical tolerance values on the parameters for a cylindrical ferrule with a diameter of 2.5 mm, are in the range of a tenth of a micrometer, and must be verified on the diameter, eccentricity between the hole (through which the fiber is fixed) and cylindricity of the external surface.

Multifiber connectors

In some types of optical cable, the fibers are organized in multiple structures, in which many fibers are glued together to form a ribbon. The ribbon can have

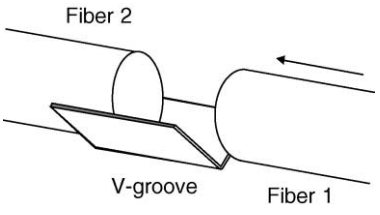

Figure 5 Scheme of the bare fibers alignment on a V-groove.

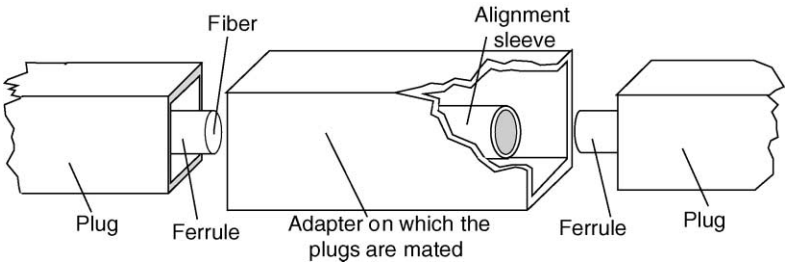

Figure 6 Scheme of a plug–adapter–plug connector with alignment by ferrules and sleeve.

2, 4, 8, 12, or 16 fibers, for example. When these cables are used, it is convenient to maintain the ribbon fiber structure in the connectors (until the point in which it is necessary to use the fibers singularly). Multifiber connectors are typically based on a secondary alignment on a plastic ferrule of rectangular shape in which the fibers maintain the same geometry that they have in the ribbon. The rectangular ferrules of the two plugs are normally aligned by means of two metallic pins placed in two hole in line with the fiber. In Figure 7, a scheme of a multifiber connector is shown.

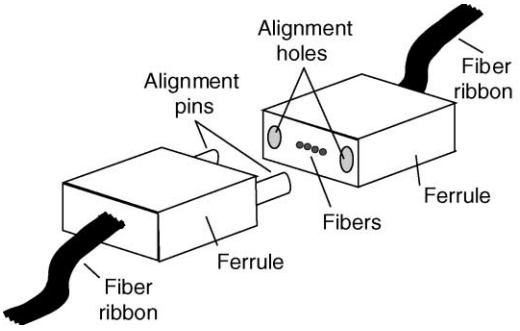

Figure 7 Multifiber connector.

Mechanical Splices

Mechanical splices are yet another way to join together two fibers. All the main considerations for the connectors are true for the mechanical splices. The difference is that the mechanical splice is a fixed joint and, normally, it cannot be opened and re-mated. Mechanical splices, both for single fiber and for multifiber structures, are the most usually manufactured. In a mechanical splice, the fibers are aligned directly in a V-groove and fixed by glue or a mechanical holder.

These components are cheaper than fusion splices but their optical, mechanical, and environmental functions are lower than the fusion splices. Figure 8, shows a mechanical splice for multifibers in which the fibers are crimped on a V-groove array. Usually, to avoid high optical reflection in the junction point, this type of joint is filled with index matching material.

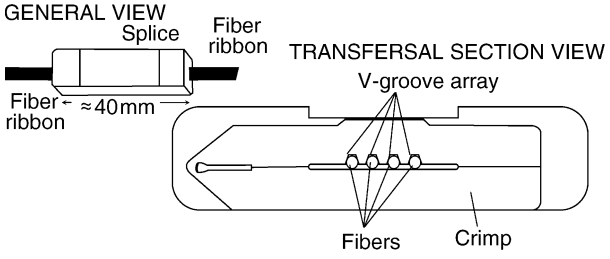

Figure 8 Example of a multifiber mechanical splice.

Branching Devices

Branching devices are passive components devoted to distributing the optical power from an input fiber to two or more fibers. These components can be classified in two broad classes, on the basis of the wavelength dependence. The nonwavelength-selective branching devices, called also couplers or splitters, share the input power to two or more fibers independently from the light wavelength. The components that perform the light distribution on more fibers on the basis of the different wavelengths of the input light are called a WDM (wavelength division (de)multiplexer).

Branching devices have three or more ports, bare fiber or connectors, for the input and/or output of optical power, and share optical power among these ports. A generic branching device can be represented as a multiport device having N input ports and M output ports, as shown in the Figure 9.

The optical characteristics of a branching device can be represented by a square transfer matrix of $n \times n$ coefficients, where n is the total number of the component ports. Each coefficient t_{ij} in the matrix is the fractional optical power transferred among designated ports, that is the ratio of the optical power P_{ij} transferred out of port j with respect to input

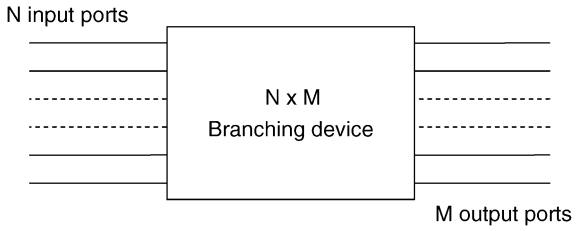

Figure 9 Scheme of a generic N × M branching device.

power P_i into port i:

$$T = \begin{bmatrix} t_{11} & t_{12} & \cdots & t_{1n} \\ t_{21} & & & \\ \vdots & & t_{ij} & \vdots \\ & & \ddots & \\ t_{n1} & & & t_{nn} \end{bmatrix} \quad [3]$$

where:

$$t_{ij} = \frac{P_{ij}}{P_i} \quad [4]$$

So, according to the relationship between two ports, the coefficients represent several parameters. For example, if the port i is an input port and j is an output port, t_{ij} is the transferred power signal through the component, while if they exist as two isolated ports the coefficients represent the crosstalk between the two ports.

The three main techniques to obtain this type of component are:

(i) All fiber components;
(ii) Micro-optics; and
(iii) Integrated optics.

Nonwavelength-Selective Branching Devices

A nonwavelength-selective branching device is a component having three or more ports, which shares an input signal among the output ports in a predetermined fashion. Usually these components are completely reversible and so they also work as a combiner of signals from more input ports onto a single output port.

There are several types of couplers for different applications:

- Y-coupler with one input port and two output ports;
- X-coupler with two input ports and two output ports; and

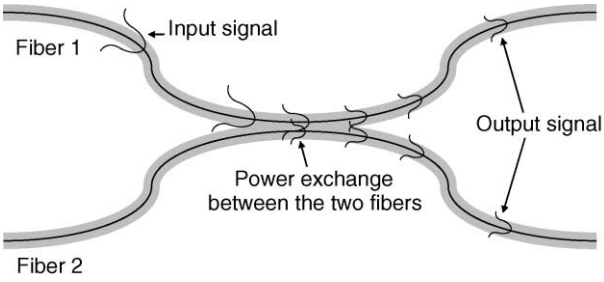

Figure 10 Scheme of a fusion 2 × 2 coupler.

- Star coupler with more than two ports in input and/or in output.

Moreover the couplers can be symmetrical, and in this case they divide the input power light onto n equal output flows, or asymmetrical devices in which the quantity of power light in the output ports is shared in a predefined nonuniform way.

The techniques used to carry out this type of device are mainly the fusion technique or planar technique. The first one is based on the phenomenon of evanescent wave coupling: when the core of two optical guides (as fibers) are located in close proximity, a power exchange from a guide to another is possible. This configuration can be obtained by stretching the fibers under controlled fusion (see Figure 10).

The planar technique, that is the simpler integrated optic application, is based on the optical guides with appropriate shapes being placed directly onto a silicon wafer by means of lithographic processes (Figure 11).

The fusion technique has the advantage of being 'all in fiber' so the component is ready to be inserted into the optical networks by means of usual joint techniques. But for a high number of ports, the coupling ratio among the branches cannot be controlled in a precise way and the cost of the fusion device is proportional to the number of the branches. On the contrary, a device obtained with the planar technology must be coupled with fibers normally used and this operation may be difficult due to the different geometry of the planar guide (rectangular) and the fiber (circular). On the other hand, this technology allows a high precision in the optical characteristics of the component and the cost of the device is independent of the branch number.

WDM

A wavelength-selective branching device, usually called WDM (Wavelength Depending Multiplexer),

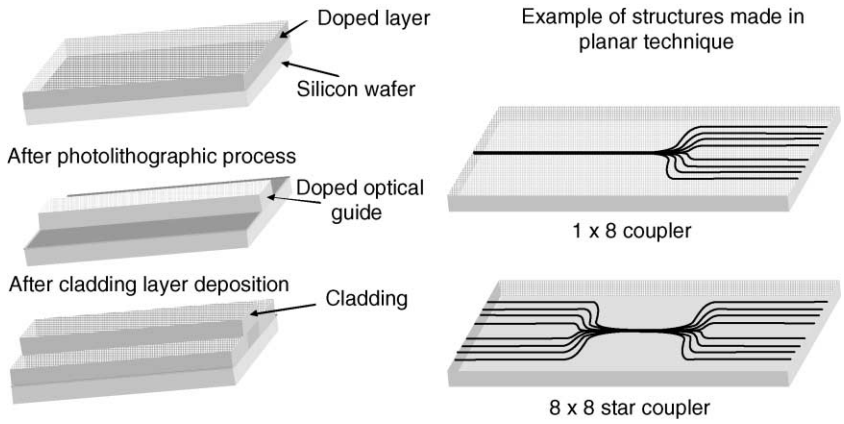

Figure 11 Scheme of the process to obtain a planar coupler and an example of a device.

is a component having three or more ports which shares an input signal among the output ports in a predetermined fashion, depending on the wavelength, so that at least two different wavelength ranges are nominally transferred between two different couples of ports.

WDM devices may be divided in three categories on the basis of the bandwidth of the channels (the spacing between two adjacent wavelength discriminated by the device):

(i) DWDM (Dense WDM) device operates for channel spacing equal or less than 1000 GHz (about 6–8 nm in the range of typical optical wavelength used in telecommunications systems, 1310 or 1550 nm);
(ii) CWDM (Coarse WDM) device operates for channel spacing less than 50 nm and greater than 1000 GHz; and
(iii) WWDM (Wide WDM) device operates for channel spacing equal or greater than 50 nm.

These components are used to combine, at the input side of an optical link in only one fiber, more optical signals with different wavelengths and separate them at the receiving end. This technology allows to send along a fiber, more communication channels, thus increasing the total bit rate transmitted. These types of components can be obtained using filters to select single a wavelength (as a diffractive grating that resolves the light into its monochromatic components) or using the phenomena of evanescent field coupling occurring between two adjacent fiber cores (as described for coupler devices), controlling in a precise way the coupling zone; this is, in fact, dependent on the wavelength (Figure 12).

Using wavelength filters, as they select a singular wavelength, it is necessary to perform a cascade filter structure for separating more than two wavelengths.

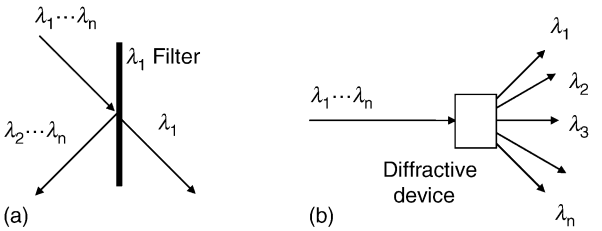

Figure 12 (a) Scheme of the filter technique and (b) diffractive device technique.

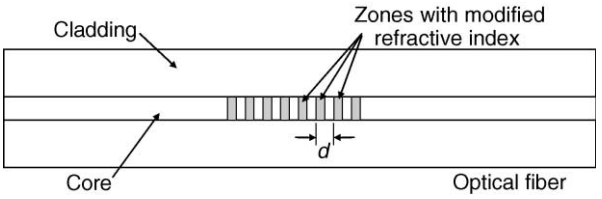

Figure 13 Scheme of FBG.

Micro-optic technologies are generally used for multimode fiber due to the critical collimation problem. For the single-mode fiber the evanescent field coupling technique is applied directly to fiber or to planar optical guides.

Another efficient technique to create WDM devices is with a fiber Bragg grating (FBG) wavelength filter directly applied to the fiber. FBGs consist in periodic modulation (see Figure 13) of the refractive index along the core of the fiber, and they act as reflection filters.

During the fabrication process (see Figure 14) the core of the optical fiber is exposed to UV radiation, and this exposure increases the refractive index of the core in defined zones, with a periodic shape obtained by the interference fringe created by crossing two coherent beams.

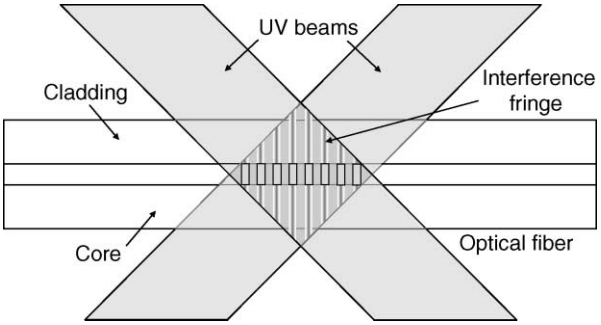

Figure 14 Scheme of FBG production.

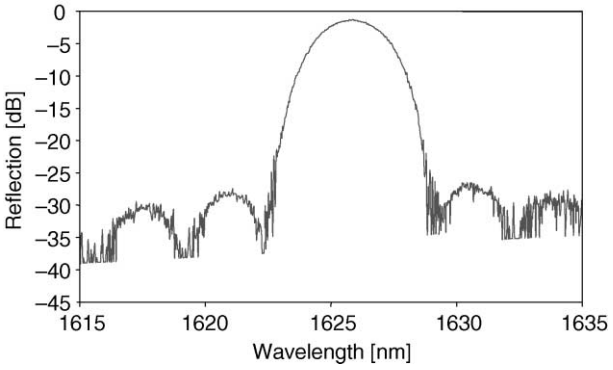

Figure 15 Transmission characteristic of FBG.

Figure 15 shows a representative spectral curve of a FBG filter centered at 1625 nm. The central wavelength, the width, and the value of reflection depend on the grating period (d) and on the deposited UV energy in the fiber core.

Other Passive Optical Components

In an optical network, besides the devices described above, there are a number of other passive optical components that perform particular functions on the optical signal; the main ones are:
